Abstract

In this article, we present simple and robust numerical methods for two-dimensional geometrical shape optimization problems, in the context of viscous flows driven by the stationary Navier-Stokes equations at low Reynolds number. The salient features of our algorithm are exposed with an educational purpose; in particular, the numerical resolution of the nonlinear stationary Navier-Stokes system, the Hadamard boundary variation method for calculating the sensitivity of the minimized function of the domain, and the mesh update strategy are carefully described. Several pedagogical examples are discussed. The corresponding program is written in the FreeFem++ environment, and it is freely available. Its chief features—and notably the implementation details of the main steps of our algorithm—are carefully presented, so that it can easily be handled and elaborated upon to deal with different, or more complex physical situations.

Keywords Shape optimization · Shape sensitivity · Fluid mechanics · Educational article · Numerical algorithm

1 Introduction

The first industrial developments of shape optimization in contexts involving fluid mechanics arose in the fields of aeronautic and aerospace engineering. These developments were motivated by the tremendous production and running costs of aircraft: even small improvements on the

performance of a design entail very large savings. Perhaps the most famous issue in this field is the design optimization of an airfoil, which dates back to at least 1964 (Carlson and Middleton 1964); see also Hicks and Henne (1978), Hicks et al. (1974), and Pironneau (1974) where optimal profiles for minimum drag problems are calculated thanks to shape sensitivity analyzes. We generally refer to Gunzburger (2003), Chap. 1 for a historical perspective about the emergence of optimal design techniques in the context of fluid mechanics. Since the aforementioned pioneering works, applications of shape optimization in fluid mechanics have raised a great interest in various areas such as the automotive industry—see Choi et al. (1997) about the numerical optimization of a cooling fan—or in computational biology: for instance, in Abraham et al. (2005), Agoshkov et al. (2006), the design optimization of an artery graft for preventing the formation of a stenosis is investigated from a numerical point of view.

Let us briefly outline the main features of the most popular shape optimization strategies in the literature, without looking for exhaustivity. For more in-depth discussions in the context of fluid mechanics, we refer to Gunzburger (2003), Mohammadi and Pironneau (2010), or to the review article (Mohammadi and Pironneau 2004). Any shape optimization method relies on a parametrization of shapes, that is, on the definition of a set of design variables. Depending on the situation, these design variables may be physical parameters of shapes (the length of some

pipe, or thickness of a region), control points of a CAD description, or the vertices of a meshed representation. In all cases, the sensitivity (i.e. derivative) of the objective and constraint functionals of the optimization problem with respect to the design variables—which is a key ingredient in most numerical optimization algorithms—can be evaluated either by approximate methods (for instance by finite differences featuring small perturbations of the parameters), or analytically, by relying on adjoint techniques from optimal control theory (Jameson 1988; Lions 1971; Pironneau 2012). In this last class of methods, which is by now quite popular, these sensitivities may be calculated at the discrete level (i.e. the derivative of the finite-dimensional functional resulting from the discretization of the shape and the physical equations is considered), which requires a perfect knowledge of the discretization and numerical methods involved in the resolution of the flow equations (but allows for the use of automatic differentiation methods). The opposite view consists in calculating first the derivative of the optimized criterion at the continuous level, then in discretizing it when it comes to the numerical implementation. This ‘continuous’ approach relies on advanced mathematical tools, but the stages of the optimization process associated with the calculation of the derivatives and the numerical resolution of the mechanical problem are more independent.

In any event, a great numerical challenge faced by all these methods is that of updating the design of the shape from one iteration of the process to the next, while avoiding that the numerical representation becomes invalid. For instance, if the shape is consistently described by means of a computational mesh, the latter is likely to develop self-intersecting elements in the course of the optimization process, causing it to abort prematurely; see the discussion in Section 3.4. Recently, several strategies have been devised to circumvent this difficulty, and more generally to allow for more freedom in terms of the variety of designs that can be represented, to the point that they make it possible to account for changes in their topology.

In this direction, quite popular density-based methods in structural mechanics—and notably the famous SIMP method (see Bendsoe and Sigmund 2013 and references therein)—have been introduced in the context of fluid mechanics in Borrvall and Petersson (2003); see also Pingen et al. (2007) and Aage et al. (2008), where a large-scale example is discussed. These relaxation methods rely on an extension of the set of admissible designs: ‘black-and-white’ shapes Ω contained in a fixed computational domain D , or equivalently their characteristic function $\chi : D \rightarrow \{0, 1\}$, taking values 1 inside Ω , and 0 in the ‘void’ region $D \setminus \overline{\Omega}$, are replaced with density functions $\rho : D \rightarrow$

$[0, 1]$, which may assume intermediate, ‘grayscale’ values in $(0, 1)$. The flow equations have then to be given an appropriate meaning to account for the presence of ‘void’ and ‘grayscale’ regions. This is typically achieved by adding a ρ -dependent damping term (or Brinkman’s law) to the flow equations (Borrvall and Petersson 2003), a heuristic inspired from the theory of porous media whereby the void is filled with a fluid with very low permeability, thus mimicking no slip boundary conditions at the interface between the fluid and void domains (see Guest and Prévost 2006 and Evgrafov 2006, then Gersborg-Hansen et al. 2005 for a generalization to the case of Navier-Stokes flows). Let us eventually mention the contribution (Kreissl et al. 2011b) where topology optimization problems are tackled in the context of the unsteady Navier-Stokes equations, and reveal the limitations of this penalization approach as far as the accuracy of the resolution of the flow equations is concerned.

Another class of shape and topology optimization strategies relies on the level set method, pioneered in Osher and Sethian (1988), then introduced in structural optimization in Sethian and Wiegmann (2000), Allaire et al. (2004), Wang et al. (2003). Such methods describe a shape Ω via the use of a scalar function ϕ defined on the whole computational domain D : the negative subdomain of ϕ coincides with Ω , while its positive subdomain accounts for void (or, in practice, another fluid with low permeability, according to the aforementioned ‘Brinkman’ penalization approximation). In the two-dimensional work (Duan et al. 2008), the level set method is used to deal with Navier-Stokes flows, in a variational framework which alleviates the need for the redistancing stage inherent to many level set based algorithms; this idea is continued in Zhou and Li (2008) in the three-dimensional setting. See also Bruneau et al. (2013) for another use of the Level Set method in the context of Navier-Stokes flows. Recent contributions have proposed alternative efficient level set methods where the flow equations are solved by the Lattice Boltzmann method (Ping et al. 2007; Kreissl et al. 2011a) or the Extended Finite Element method (Kreissl and Maute 2012), alleviating the need for the ‘Brinkman’ penalization method. On a different note, in Challis and Guest (2009a), the Level Set method is used to combine the information supplied by shape and topological derivatives, in the context of Stokes flows, in two and three space dimensions.

Eventually, let us also mention phase-field methods, which share a lot of features with level set methods, except for the fact that they bring into play shapes, or phases, with ‘thickened boundaries’ (Garcke et al. 2015).

Following the lead of Sigmund (2001) and Allaire and Pantz (2006), which take place in the context of structural

mechanics, this article is a pedagogical introduction to several basic shape optimization techniques in fluid mechanics. The discussion is didactic: we deliberately keep technicalities to a minimum, and provide adequate references when needed. We present a simple numerical framework, yet robust enough to deal with physically relevant situations, which is dedicated to solving shape optimization problems in the context of fluid mechanics. The proposed examples can be easily reproduced and elaborated upon to deal with more advanced models.

In the setting of the stationary Navier-Stokes equations at low Reynolds number, we optimize shapes in terms e.g. of the dissipated viscous energy, under volume or perimeter constraints. To this end, we rely on an augmented Lagrangian algorithm based on the first order information supplied by shape derivatives, in the sense of the Hadamard boundary variation method. From the numerical point of view, shapes are represented by a computational mesh, on which the flow equations are solved owing to the Finite Element method. The update of the shape between each iteration of the optimization process is achieved by moving the vertices of this mesh according to the calculated descent direction.

The numerical developments proposed in this article rely on the FreeFem++ (Hecht et al. 2005) software, a free environment allowing to solve a wide variety of Partial Differential Equations (PDE for short) using the Finite Element method within a few command lines.

A particular attention has been paid to the development of a user-friendly source code, which is available online at

<https://github.com/floennes/optiflow>

with the hope that it serve as a useful basis for further investigations.

The remainder of this article is organized as follows. In Section 2, we introduce the model physical problem at stake, as well as the shape optimization problem considered in this context. In passing, we recall in an elementary way some basic facts about shape derivatives. In Section 3, we describe in more details the main ingredients of the proposed numerical method: after a short motivating outline in Section 3.1, we discuss the salient features of our shape optimization algorithm in Sections 3.2, 3.3, 3.4, 3.5 and 3.6; a sketch of this algorithm is then provided in Section 3.7. Section 4 is then a short guide of our practical implementation; it is expected that, together with the thorough comments left throughout our code, this will allow the user to define and solve his own shape optimization test cases in a user-friendly way. In Section 5, we introduce and comment five test cases which are dealt with by our algorithm. Finally, Section 6 concludes by evoking limitations of our approach

as well as perspectives for possible improvements and extensions.

Readers primarily interested in the practical use of our optimization algorithm may go directly to Sections 3.7 and 4 where it is precisely described, returning to Sections 2 and 3 when theoretical highlights are needed.

2 Shape optimization for flows governed by the Navier-Stokes equations

In this section, we present the model physical situation and the shape optimization problem at stake, together with the necessary theoretical background. Notice that, while the concrete applications discussed in this article arise in two space dimensions (see Section 5), most of the presented techniques are available in the general, d -dimensional setting. For this reason, the discussion takes place in d dimensions inasmuch as it is possible without giving up simplicity and clarity.

2.1 The Navier-Stokes equations

In our applications, shapes are smooth bounded domains $\Omega \subset \mathbb{R}^d$ ($d = 2, 3$ in practice), occupied by a homogeneous Newtonian fluid with kinematic viscosity $\nu > 0$. The boundary $\partial\Omega$ is made of three disjoint regions: $\partial\Omega = \Gamma_{\text{in}} \cup \Gamma_{\text{out}} \cup \Gamma$, where

- Γ_{in} is the ‘inlet’, on which a known velocity profile \mathbf{u}_{in} is imposed;
- Γ_{out} is the ‘outlet’, which is free from of surface forces;
- Γ is the ‘free’ boundary; no slip boundary conditions are imposed on Γ , accounting for the fact that the fluid particles are stuck on it;

see Fig. 1 for an illustration. In the applications ahead, Γ is the only region of $\partial\Omega$ which is subject to optimization, i.e. Γ_{in} and Γ_{out} are fixed. From the physical point of view, Ω may represent a mammal’s lung, a duct in a ventilation system or a water radiator, etc.

The equilibrium behavior of the fluid inside Ω is classically described in terms of its (vector) velocity field

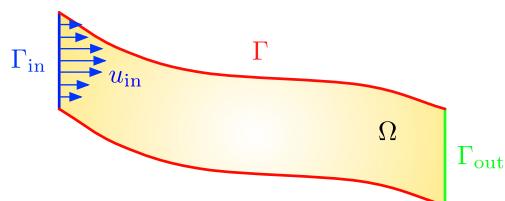

Fig. 1 Illustration of the model setting introduced in Section 2

$\mathbf{u} = (u_1, \dots, u_d) : \Omega \rightarrow \mathbb{R}^d$ and (scalar) pressure $p : \Omega \rightarrow \mathbb{R}$, which solve the stationary *incompressible Navier-Stokes equations*:

$$\left\{ \begin{array}{ll} -\nu \Delta \mathbf{u} + (\mathbf{u} \cdot \nabla) \mathbf{u} + \nabla p = 0 & \text{in } \Omega, \\ \operatorname{div}(\mathbf{u}) = 0 & \text{in } \Omega, \\ \mathbf{u} = \mathbf{u}_{\text{in}} & \text{on } \Gamma_{\text{in}}, \\ \mathbf{u} = 0 & \text{on } \Gamma, \\ \sigma(\mathbf{u}, p) \mathbf{n} = 0 & \text{on } \Gamma_{\text{out}}. \end{array} \right. \quad (1)$$

In the above system, the stress tensor $\sigma(\mathbf{u}, p)$ is defined by

$$\sigma(\mathbf{u}, p) = 2\nu e(\mathbf{u}) - p\mathbf{I}, \text{ where } e(\mathbf{u}) = \frac{1}{2}(\nabla \mathbf{u}^T + \nabla \mathbf{u}).$$

From the physical point of view, the first equation in (1) is the law of balance of momentum between viscous forces $-\nu \Delta \mathbf{u}$, acceleration forces $(\mathbf{u} \cdot \nabla) \mathbf{u}$ and pressure forces ∇p . The second equation $\operatorname{div}(\mathbf{u}) = 0$ accounts for the incompressibility of the fluid. Because of this incompressibility feature, a simple calculation allows to rewrite the law of balance of momentum under the equivalent form:

$$-\operatorname{div}(\sigma(\mathbf{u}, p)) + (\mathbf{u} \cdot \nabla) \mathbf{u} = 0.$$

For further reference, let us recall that this nonlinear system is often considered from the variational viewpoint, in particular when it comes to its numerical resolution using FreeFem++; the pair (\mathbf{u}, p) satisfies:

$$\left\{ \begin{array}{l} \text{For all } (\mathbf{v}, q) \text{ s.t. } \mathbf{v} = 0 \text{ on } \Gamma_{\text{in}}, \\ a(\mathbf{u}, \mathbf{v}) + c(\mathbf{u}, \mathbf{u}, \mathbf{v}) + b(\mathbf{v}, p) = 0 \\ b(\mathbf{u}, q) = 0 \end{array} \right. \quad (2)$$

where we have defined

$$\begin{aligned} a(\mathbf{u}, \mathbf{v}) &= 2\nu \int_{\Omega} e(\mathbf{u}) : e(\mathbf{v}) dx, \\ b(\mathbf{u}, p) &= - \int_{\Omega} p \operatorname{div}(\mathbf{u}) dx, \\ c(\mathbf{u}, \mathbf{v}, \mathbf{w}) &= \int_{\Omega} (\mathbf{u} \cdot \nabla) \mathbf{v} \cdot \mathbf{w} dx, \end{aligned}$$

and the notation $A : B$ stands for the usual Frobenius inner product of two $d \times d$ matrices A, B , that is $A : B = \sum_{i,j=1}^d A_{ij} B_{ij}$. In the following, we also denote by $\|A\| = (A : A)^{1/2}$ the associated Frobenius norm.

In the dimensionless version (1), (2) of the Navier-Stokes equations, the Reynolds number Re is proportional to $1/\nu$: it is an indicator of the type of regime of the flow (Munson et al. 2013). At low Reynolds number, viscous effects are prevailing and the flow is laminar; in particular, its velocity stays relatively low. On the contrary, at moderate to high Reynolds number, convective forces become dominant and the flow is turbulent. The theoretical and numerical study of (1) is notoriously much harder in the latter situation, and still leaves room for many open questions. In the present, introductory work, we limit ourselves to the low Reynolds

number regime (namely, $Re = 200$ is used in the practical examples of Section 5, although values up to 1000 have provided satisfactory numerical results as well).

Remark 1 Let us say a few words about the functional setting and well-posedness of the stationary Navier-Stokes system (1). When the viscosity ν is large enough, i.e. the Reynolds number Re is low, (1) is well-posed. It has a unique weak solution $(\mathbf{u}, p) \in H^1(\Omega)^d \times L_0^2(\Omega)$, where $L_0^2(\Omega) := \{p \in L^2(\Omega), \int_{\Omega} p dx = 0\}$, in the sense that the variational problem (2) is fulfilled; see Temam (1977), Chapter II about these matters. In the following, we systematically assume ν to be large enough so that (1) is well-posed.

2.2 Statement of the shape optimization problem

In the context of Section 2.1, the shape optimization problem of interest reads

$$\min_{\Omega \in \mathcal{O}_{\text{ad}}} J(\Omega) \text{ s.t. } G(\Omega) = 0. \quad (3)$$

Here, the objective criterion $J(\Omega)$ may stand for

- The energy $E(\Omega)$ dissipated by the fluid owing to the work of viscous forces, i.e.

$$E(\Omega) = \int_{\Omega} \sigma(\mathbf{u}, p) : e(\mathbf{u}) dx = 2\nu \int_{\Omega} \|e(\mathbf{u})\|^2 dx, \quad (4)$$

- A least-square discrepancy

$$D(\Omega) = \frac{1}{2} \int_{\Gamma_{\text{out}}} |\mathbf{u} - \mathbf{u}_{\text{ref}}|^2 ds \quad (5)$$

between the velocity \mathbf{u} of the fluid, solution to (1), and a given reference profile \mathbf{u}_{ref} . Such criteria are often involved in shape optimization-based methods for the detection or the reconstruction of an obstacle immersed in a fluid from the data of boundary measurements (Badra et al. 2011; Litman et al. 1998).

As we have mentioned in Section 2.1, all the considered domains enclose the inlet Γ_{in} and the outlet Γ_{out} as (fixed) subsets of their boundaries, so that the free boundary Γ is the only region of $\partial\Omega$ subject to optimization. Accordingly, the set \mathcal{O}_{ad} of admissible domains featured in (3) reads:

$$\begin{aligned} \mathcal{O}_{\text{ad}} &= \{\Omega \subset \mathbb{R}^d, \text{ open, smooth and bounded, such that} \\ \Gamma_{\text{in}} \cup \Gamma_{\text{out}} &\subset \partial\Omega\} \end{aligned} \quad (6)$$

Last but not least, as far as the constraint functional $G(\Omega)$ is concerned, we shall restrict ourselves to equality constraints on the volume $\operatorname{Vol}(\Omega) = \int_{\Omega} dx$ or the perimeter $\operatorname{Per}(\Omega) = \int_{\partial\Omega} ds$ of shapes, namely:

$$G(\Omega) = \operatorname{Vol}(\Omega) - V_T, \text{ or } G(\Omega) = \operatorname{Per}(\Omega) - P_T$$

for some given volume or perimeter target values V_T and P_T .

Remark 2 The existence of global minimizers of problems of the form (3) is a long-standing question in shape optimization theory, not only in the context of fluid mechanics, but already in simpler situations, bringing into play the conductivity equation, or the linearized elasticity system. Let us simply mention that, in order to guarantee the existence of optimal shapes, two classical remedies consist in either restricting the set of admissible shapes (for instance by adding constraints on the perimeter, or the regularity of shapes), or on the contrary in enlarging this set, so that it includes ‘density functions’, and not only ‘black and white’ shapes. See for instance Bucur and Buttazzo (2002), Henrot and Pierre (2005), Sokołowski and Zolésio (1992) about these issues, or Henrot and Privat (2008), Henrot and Privat (2010), Bergounioux and Privat (2013) in the context of fluid mechanics.

Often, in numerical practice, one is rather interested in searching for local minimizers of (3), which are close to an initial guess inspired by physical intuition. These are the ‘optimal’ shapes which are typically delivered by local optimization methods, such as the steepest-descent algorithms used in the present article.

2.3 Shape sensitivity analysis using Hadamard’s boundary variation method

Most optimization algorithms—such as steepest-descent methods—rely on the knowledge of the derivatives of the objective and constraint functionals. As we have already hinted at in the introduction, two different paradigms exist in the context of PDE constrained optimization problems of the form (3). In a nutshell, in ‘discretize-then-optimize’ approaches, the optimized domain is first discretized into a set of design variables (for instance, the vertices of a mesh); the PDE system (1) becomes finite-dimensional (it is e.g. discretized using a Finite Element method), and its coefficients depend on the design variables; accordingly, the objective and constraint functionals $J(\Omega)$ and $G(\Omega)$ are functions of the design variables, and the derivatives of these discrete functionals are calculated. On the contrary, ‘optimize-then-discretize’ approaches advocate to calculate the derivatives of $J(\Omega)$ and $G(\Omega)$ at the continuous level; the resulting theoretical formulae are then discretized by relying on a discretization of the domain and of the PDE system (1).

The approach described in this article belongs to the second category, and therefore requires to compute derivatives with respect to the domain. Several ways exist to define a notion of shape derivative, and we rely on Hadamard’s boundary variation method, a brief sketch of

which is now provided; see for instance to Henrot and Pierre (2005), Chap. 5, or Allaire (2007), Murat and Simon (1976) for in-depth expositions. See also Novotny and Sokołowski (2012) for an overview of the rival notion of *topological derivative*, and Amstutz (2005) for the calculation of topological derivatives in the context of fluid mechanics.

In the framework of Hadamard’s method, the sensitivity of a function of the domain is assessed with respect to small perturbations of its boundary: variations of a given shape Ω are considered in the form

$$\Omega_\theta = (\text{Id} + \theta)(\Omega), \quad (7)$$

where $\theta : \mathbb{R}^d \rightarrow \mathbb{R}^d$ is a ‘small’ vector field, and Id is the identity mapping from \mathbb{R}^d into itself; see Fig. 2 for an illustration.

Since admissible shapes $\Omega \in \mathcal{O}_{ad}$ are smooth and only Γ is subject to optimization, it is natural that θ belong to the set Θ_{ad} of admissible perturbations defined by:

$$\Theta_{ad} = \left\{ \theta : \mathbb{R}^d \rightarrow \mathbb{R}^d \text{ smooth, } \theta = 0 \text{ on } \Gamma_{\text{in}} \cup \Gamma_{\text{out}} \right\};$$

so that variations (7) of admissible shapes stay admissible.

Definition 1 A function of the domain $F(\Omega)$ is shape differentiable at $\Omega \in \mathcal{O}_{ad}$ if the underlying mapping $\theta \mapsto F(\Omega_\theta)$, from Θ_{ad} into \mathbb{R} , is differentiable at $\theta = 0$ (in the sense of Fréchet). The corresponding derivative is denoted by $\theta \mapsto F'(\Omega)(\theta)$, and the following Taylor expansion holds:

$$F(\Omega_\theta) = F(\Omega) + F'(\Omega)(\theta) + o(\theta) \quad (8)$$

where $o(\theta) \rightarrow 0$ as $\theta \rightarrow 0$.

When it comes to shape derivatives, the first result of interest deals with the volume and perimeter functionals; see Allaire (2007), Henrot and Pierre (2005) for a proof.

Theorem 1 Let Ω be a smooth shape. Then,

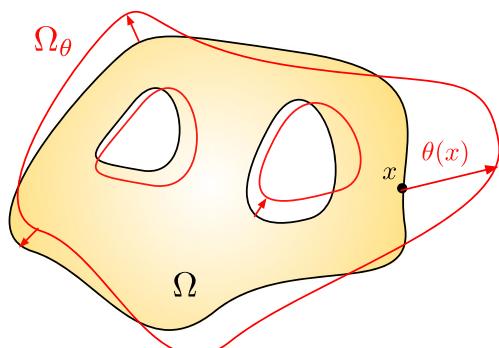

Fig. 2 Example of a variation Ω_θ of a shape Ω

- (i) The volume $\text{Vol}(\Omega)$ is shape differentiable and its derivative reads:

$$\forall \boldsymbol{\theta} \in \Theta_{ad}, \text{Vol}'(\Omega)(\boldsymbol{\theta}) = \int_{\Gamma} \boldsymbol{\theta} \cdot \mathbf{n} ds.$$

- (ii) The perimeter $\text{Per}(\Omega)$ is shape differentiable and its derivative reads:

$$\forall \boldsymbol{\theta} \in \Theta_{ad}, \text{Per}'(\Omega)(\boldsymbol{\theta}) = \int_{\Gamma} \kappa \boldsymbol{\theta} \cdot \mathbf{n} ds,$$

where $\kappa : \partial\Omega \rightarrow \mathbb{R}$ is the mean curvature of $\partial\Omega$.

Calculating shape derivatives of functions of the form (4) or (5) is a little harder, since they bring into play the solution of a partial differential equation posed on Ω (in the present case, the Navier-Stokes system (1)). This can however be managed by using quite classical adjoint techniques from optimal control theory. Again, we refer to Allaire (2007) for a comprehensive introduction to such techniques in the context of shape optimization, and to Appendix A for a sketch of proof.

Theorem 2 Let $\Omega \in \mathcal{O}_{ad}$; then,

- (i) The energy dissipation $E(\Omega)$ given by (4) is shape differentiable and its derivative reads:

$$\begin{aligned} \forall \boldsymbol{\theta} \in \Theta_{ad}, E'(\Omega)(\boldsymbol{\theta}) = & \int_{\Gamma} (-2v\mathbf{e}(\mathbf{u}) : e(\mathbf{u}) \\ & + 2v\mathbf{e}(\mathbf{u}) : e(\mathbf{v}_e)) \boldsymbol{\theta} \cdot \mathbf{n} ds, \end{aligned} \quad (9)$$

where (\mathbf{v}_e, q_e) is an adjoint state, defined as the solution of the linear PDE

$$\left\{ \begin{array}{ll} -v\Delta\mathbf{v}_e + (\nabla\mathbf{u})^T\mathbf{v}_e - (\nabla\mathbf{v}_e)\mathbf{u} + \nabla q_e \\ \qquad\qquad\qquad = -2v\Delta\mathbf{u} & \text{in } \Omega, \\ \text{div}(\mathbf{v}_e) = 0 & \text{in } \Omega, \\ \mathbf{v}_e = 0 & \text{on } \Gamma \cup \Gamma_{in}, \\ \sigma(\mathbf{v}_e, q_e)\mathbf{n} + (\mathbf{u} \cdot \mathbf{n})\mathbf{v}_e = 4v\mathbf{e}(\mathbf{u})\mathbf{n} & \text{on } \Gamma_{out}. \end{array} \right. \quad (10)$$

- (ii) The least-square functional $D(\Omega)$ defined by (5) is shape differentiable and its derivative reads:

$$\forall \boldsymbol{\theta} \in \Theta_{ad}, D'(\Omega)(\boldsymbol{\theta}) = \int_{\Gamma} 2v\mathbf{e}(\mathbf{u}) : e(\mathbf{v}_d) \boldsymbol{\theta} \cdot \mathbf{n} ds, \quad (11)$$

where the adjoint system for (\mathbf{v}_d, q_d) reads

$$\left\{ \begin{array}{ll} -v\Delta\mathbf{v}_d + (\nabla\mathbf{u})^T\mathbf{v}_d - (\nabla\mathbf{v}_d)\mathbf{u} + \nabla q_d = 0 & \text{in } \Omega, \\ \text{div}(\mathbf{v}_d) = 0 & \text{in } \Omega, \\ \mathbf{v}_d = 0 & \text{on } \Gamma \cup \Gamma_{in}, \\ \sigma(\mathbf{v}_d, q_d)\mathbf{n} + (\mathbf{u} \cdot \mathbf{n})\mathbf{v}_d = \mathbf{u} - \mathbf{u}_{ref} & \text{on } \Gamma_{out}. \end{array} \right. \quad (12)$$

Remark 3 1. As is customary in shape optimization—and in optimal control in general—, the adjoint systems (10) and (12) are linear, while the original Navier-Stokes system (1) is non linear.

2. From the mathematical point of view, the adjoint systems (10) and (12) are well-posed in suitable functional spaces when the parameter v is assumed to be large enough (see e.g. Henrot and Privat 2010).

Like those of the functions $\text{Vol}(\Omega)$, $\text{Per}(\Omega)$, $E(\Omega)$ and $D(\Omega)$ involved in Theorems 1 and 2, the shape derivative of a fairly general class of shape functionals $F(\Omega)$ has the generic form:

$$F'(\Omega)(\boldsymbol{\theta}) = \int_{\Gamma} \phi \boldsymbol{\theta} \cdot \mathbf{n} ds =: (\phi, \boldsymbol{\theta} \cdot \mathbf{n})_{L^2(\Gamma)}, \quad (13)$$

where the scalar function $\phi : \Gamma \rightarrow \mathbb{R}$ is the ‘shape gradient’ of F with respect to the $L^2(\Gamma)$ inner product. This statement is referred to as the *Structure theorem* for shape derivatives; see Henrot and Pierre (2005), §5.9. In particular, $F'(\Omega)(\boldsymbol{\theta})$ depends only on the values of the normal component $\boldsymbol{\theta} \cdot \mathbf{n}$ on the free boundary Γ ; this reflects the intuitive fact that tangential deformations of Ω leave the values of $F(\Omega)$ unchanged at first order.

For further reference, the structure (13) makes it easy to infer descent directions for $F(\Omega)$. Indeed, if $\boldsymbol{\theta}$ coincides with $-\phi\mathbf{n}$ on Γ , it readily follows from (8) that, for $t > 0$ small enough:

$$F(\Omega_{t\boldsymbol{\theta}}) = F(\Omega) - t \int_{\Gamma} \phi^2 ds + o(t) < F(\Omega). \quad (14)$$

3 Numerical methods

In this section, we describe in more detail the numerical methods involved in the resolution of the shape optimization problem (3).

3.1 Description of the numerical setting and outline of the algorithm

Each shape Ω is represented by means of a simplicial mesh \mathcal{T} , composed of K (closed) simplices T_1, \dots, T_K (i.e. triangles in $2d$, tetrahedra in $3d$), and I vertices $\mathbf{x}_1, \dots, \mathbf{x}_I$. The mesh \mathcal{T} is computational in the sense of Finite Elements, that is:

- The T_k form a cover of $\overline{\Omega}$, i.e. $\overline{\Omega} = \bigcup_{k=1}^K T_k$,
- The T_k do not overlap, i.e. the intersection between the interiors of T_k and $T_{k'}$ is empty whenever $k \neq k'$,
- The mesh \mathcal{T} is *conforming*; for instance, in two dimensions, the intersection between any two triangles

T_k and $T_{k'}$, $k \neq k'$, is either empty, or it is a vertex, or an edge of \mathcal{T} .

See Fig. 3 for illustrations of these notions.

In the following, we shall often consider sequences of shapes Ω^n and meshes \mathcal{T}^n , and we denote with a n superscript all the entities (vertices \mathbf{x}_i^n , simplices T_k^n , numbers of vertices I^n and simplices K^n) of \mathcal{T}^n .

So as to emphasize the needed numerical methods in the resolution of (3), we now give a deliberately hazy sketch of the main stages; a practical version is given in Section 3.7.

- **Initialization:** The initial domain Ω^0 is equipped with a mesh \mathcal{T}^0 .
- **For $n = 0, \dots$ until convergence:**

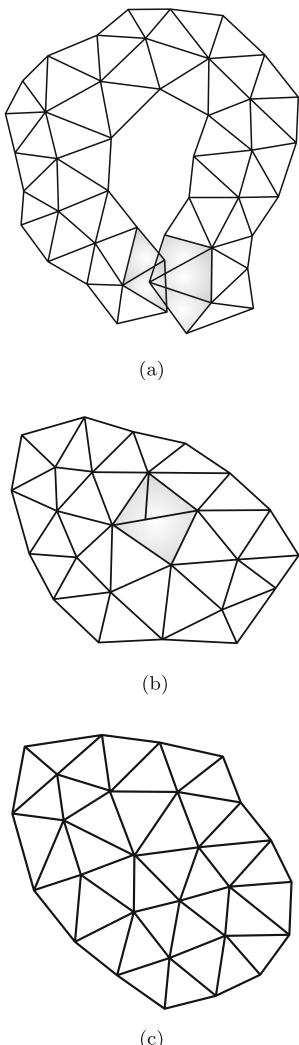

Fig. 3 Examples of **a** a mesh with overlapping triangles (in gray); **b** a mesh with non overlapping, yet non conforming triangles (in gray); **c** a computational mesh

1. Compute the solution (\mathbf{u}, p) of the Navier-Stokes (1), and the adjoint state (\mathbf{v}, q) , solution of (10) or (12) on Ω^n , using the mesh \mathcal{T}^n .
2. Compute the shape derivatives of $J(\Omega)$ and $G(\Omega)$ (see Theorems 1 and 2) and infer a descent direction θ^n for the optimization problem (3).
3. Choose a sufficiently small time step τ^n and update the shape Ω^n into the new shape $\Omega^{n+1} := (\text{Id} + \tau^n \theta^n)(\Omega^n)$; a mesh \mathcal{T}^{n+1} of Ω^{n+1} is obtained.

This program raises a number of issues:

- The numerical resolution of the systems (1), (10) and (12) is by no means trivial; Section 3.2 below is devoted to this issue.
- The calculation of a descent direction for $J(\Omega)$ which allows to satisfy the constraint $G(\Omega)$ demands the use of an adapted optimization algorithm, which is described in Section 3.3.
- The deformation of the mesh \mathcal{T}^n of Ω^n into a computational mesh \mathcal{T}^{n+1} of Ω^{n+1} is a difficult task. We describe in Section 3.4 the stakes of mesh deformation, and in Section 3.5 a strategy for calculating a nice shape gradient which eases this purpose.

3.2 Numerical resolution of the Navier-Stokes equations

The numerical resolution of the Navier-Stokes system (1) with the Finite Element method is faced with two relatively independent difficulties. The first one is related to the treatment of the nonlinear convective term $(\mathbf{u} \cdot \nabla)\mathbf{u}$; the second one is quite common in the resolution of saddle-point problems: it is about the choice of adequate Finite Element spaces for the discretization of the velocity \mathbf{u} and pressure p . Notice that the adjoint systems (10) and (12) are linear, so their resolution is not concerned by the first issue, but it is by the second one. We only discuss the case of the nonlinear Navier-Stokes system (1) in this section, which is in all regards more difficult.

3.2.1 Dealing with the nonlinear convective term using Newton's method

We rely on a fairly standard Newton method for nonlinear problems. Writing (1) in the abstract form

$$A(\mathbf{u}, p) = 0, \quad (15)$$

Newton's method achieves the solution as the limit of the sequence (\mathbf{u}^k, p^k) , where each update $(\delta\mathbf{u}^k, \delta p^k)$ between

the steps k and $(k + 1)$ is calculated as the solution to the linearized version of (15) around (\mathbf{u}^k, p^k) :

$$d_{(\mathbf{u}^k, p^k)} A(\delta \mathbf{u}^k, \delta p^k) = -A(\mathbf{u}^k, p^k), \quad (16)$$

where $d_{(\mathbf{u}^k, p^k)} A$ is the linearization of the mapping $(\mathbf{u}, p) \mapsto A(\mathbf{u}, p)$ at (\mathbf{u}^k, p^k) . In the particular case of interest for us, the iterative procedure (16) reads as follows:

- Initialization:** The pair (\mathbf{u}^0, p^0) is the solution to the Stokes counterpart of (1) (i.e. the version of (1) where the non linear term is omitted):

$$\begin{cases} -\nu \Delta \mathbf{u}^0 + \nabla p^0 = 0 & \text{in } \Omega, \\ \operatorname{div}(\mathbf{u}^0) = 0 & \text{in } \Omega, \\ \mathbf{u}^0 = \mathbf{u}_{\text{in}} & \text{on } \Gamma_{\text{in}}, \\ \mathbf{u}^0 = 0 & \text{on } \Gamma, \\ \sigma(\mathbf{u}^0, p^0)\mathbf{n} = 0 & \text{on } \Gamma_{\text{out}}. \end{cases} \quad (17)$$

- For** $k = 1, \dots, (\mathbf{u}^{k+1}, p^{k+1})$ is obtained by

$$(\mathbf{u}^{k+1}, p^{k+1}) = (\mathbf{u}^k, p^k) + (\delta \mathbf{u}^k, \delta p^k),$$

where $(\delta \mathbf{u}^k, \delta p^k)$ is the solution to the linear system (viz. (16)),

$$\begin{cases} -\nu \Delta(\delta \mathbf{u}^k) + (\mathbf{u}^k \cdot \nabla)(\delta \mathbf{u}^k) + ((\delta \mathbf{u}^k) \cdot \nabla)\mathbf{u}^k \\ + \nabla(\delta p^k) = \nu \Delta \mathbf{u}^k - (\mathbf{u}^k \cdot \nabla)\mathbf{u}^k - \nabla p^k & \text{in } \Omega, \\ \operatorname{div}(\delta \mathbf{u}^k) = 0 & \text{in } \Omega, \\ \delta \mathbf{u}^k = 0 & \text{on } \Gamma \cup \Gamma_{\text{in}}, \\ \sigma(\delta \mathbf{u}^k, \delta p^k)\mathbf{n} = 0 & \text{on } \Gamma_{\text{out}}, \end{cases} \quad (18)$$

which is sometimes referred to as the Oseen system.

- Ending criterion:** The algorithm ends when

$$e^k < \varepsilon_{\text{stop}}, \text{ with}$$

$$e^k := \sqrt{\frac{\|\delta \mathbf{u}^k\|_{L^2(\Omega)^d}^2 + \|\nabla(\delta \mathbf{u}^k)\|_{L^2(\Omega)^{d \times d}}^2}{\|\mathbf{u}^k\|_{L^2(\Omega)^d}^2 + \|\nabla \mathbf{u}^k\|_{L^2(\Omega)^{d \times d}}^2}} \quad (19)$$

for a fixed, user-defined tolerance $\varepsilon_{\text{stop}}$.

This ending criterion is inspired from (Girault and Raviart 1986, Chapter 6), where the sequence (\mathbf{u}^k, p^k) is proved to converge quadratically to the solution of (1), provided the initial pair (\mathbf{u}^0, p^0) is ‘close’ enough to the latter. In other terms, the error e^k behaves as $e^{k+1} \approx (e^k)^2$. In practice, only 3 or 4 iterations are required to fulfill (19) with $\varepsilon_{\text{stop}} = 10^{-10}$.

Let us mention that many other methods are available for the numerical resolution of (1), such as the Oseen iteration method, the Least-Square gradient method, the Peaceman-Rachford method (an increment of the Least-Square gradient method), with different assets and drawbacks which we do not discuss here; see Girault and Raviart (1986).

On a different note, Newton-like algorithms are well-known to experience difficulties as far as convergence is

concerned, especially when the initial state is ‘far’ from the sought solution; in our context of the numerical resolution of the Navier-Stokes system (1), this is likely to happen in the case of moderate-to-high Reynolds numbers, where the solution (\mathbf{u}^0, p^0) to the Stokes equation (17) is ‘too far’ from that (\mathbf{u}, p) to (1). In such a case, one may resort to mixed strategies (e.g. starting with the Oseen iteration method for some iterations, then branching with the Newton method), or continuation methods (which advocate to increase steadily the Reynolds number) to improve and make the convergence process more robust. As we have already mentioned, the model examples considered in this article (see Section 5) arise in the regime of low Reynolds number, and we did not run into the need for such elaborated strategies.

Remark 4 In practice, we do not solve exactly (17), but the slightly modified version

$$\begin{cases} -\nu \Delta \mathbf{u}^0 + \nabla p^0 = 0 & \text{in } \Omega, \\ \operatorname{div}(\mathbf{u}^0) + \varepsilon p^0 = 0 & \text{in } \Omega, \\ \mathbf{u}^0 = \mathbf{u}_{\text{in}} & \text{on } \Gamma_{\text{in}}, \\ \mathbf{u}^0 = 0 & \text{on } \Gamma, \\ \sigma(\mathbf{u}^0, p^0)\mathbf{n} = 0 & \text{on } \Gamma_{\text{out}}. \end{cases} \quad (20)$$

where ε is a very small parameter (typically $\varepsilon = 10^{-6}$). The reason is that only the gradient of p^0 is involved in the system (17), which is not well-posed as a result: p^0 is only defined up to a constant; see Remark 17. In contrast, (20) is well-posed; the matrix associated to its resolution by the Finite Element method is positive definite, which allows to use efficient numerical linear algebra solvers; see e.g. (Girault and Raviart 1986, Chapter 4) about this approach. The same trick applies to (18).

3.2.2 Choice of the Finite Element discretization

When it comes to the numerical resolution of linear saddle point problems of the form (17) or (18), one should pay attention to the choice of the Finite Element spaces used for the discretization of the unknown velocity \mathbf{u} and pressure p . In our case, (17) and (18) are solved with the Finite Element method in mixed velocity-pressure formulation, using \mathbb{P}_2 Lagrange elements for the velocity \mathbf{u} and \mathbb{P}_1 Lagrange elements for the pressure p . This choice as regards Finite Element spaces is one among those ensuring that the so-called *Brezzi inequality* holds, and thereby that the discrete linear systems corresponding to (17) and (18) are invertible. Details about numerical methods for the resolution of saddle point problems can be found in Donea and Huerta (2003) or Ern and Guermond (2013).

3.3 The augmented Lagrangian algorithm for equality-constrained problems

In order to drive the numerical resolution of (3), we rely on the augmented Lagrangian method, a basic sketch of which is provided; we refer to Nocedal and Wright (2006) §17.4 for detailed explanations.

The augmented Lagrangian algorithm transforms the constrained optimization problem (3) into the series of unconstrained problems (hereafter indexed by the superscript n):

$$\inf_{\Omega \in \mathcal{O}_{ad}} \mathcal{L}(\Omega, \ell^n, b^n), \quad (21)$$

where

$$\mathcal{L}(\Omega, \ell, b) = J(\Omega) - \ell G(\Omega) + \frac{b}{2} G(\Omega)^2 \quad (22)$$

In the definition of the augmented Lagrangian \mathcal{L} , the parameter b is a (positive) penalty factor for the violation of the constraint $G(\Omega) = 0$, and ℓ is an estimate of the Lagrange multiplier associated with this constraint in (3).

The augmented Lagrangian algorithm intertwines the search for the minimizer Ω^n of $\Omega \mapsto \mathcal{L}(\Omega, \ell^n, b^n)$ for fixed values of ℓ^n and b^n , and the update of these coefficients according to the rule:

$$\ell^{n+1} = \ell^n - b^n G(\Omega^n), \text{ and } b^{n+1} = \begin{cases} \alpha b^n & \text{if } b < b_{\text{target}}, \\ b^n & \text{otherwise;} \end{cases} \quad (23)$$

in other terms, starting from a ‘small’ value b^0 , the penalty b is increased by a user-defined factor $\alpha > 1$ during the first iterations of the optimization process, until the maximum,

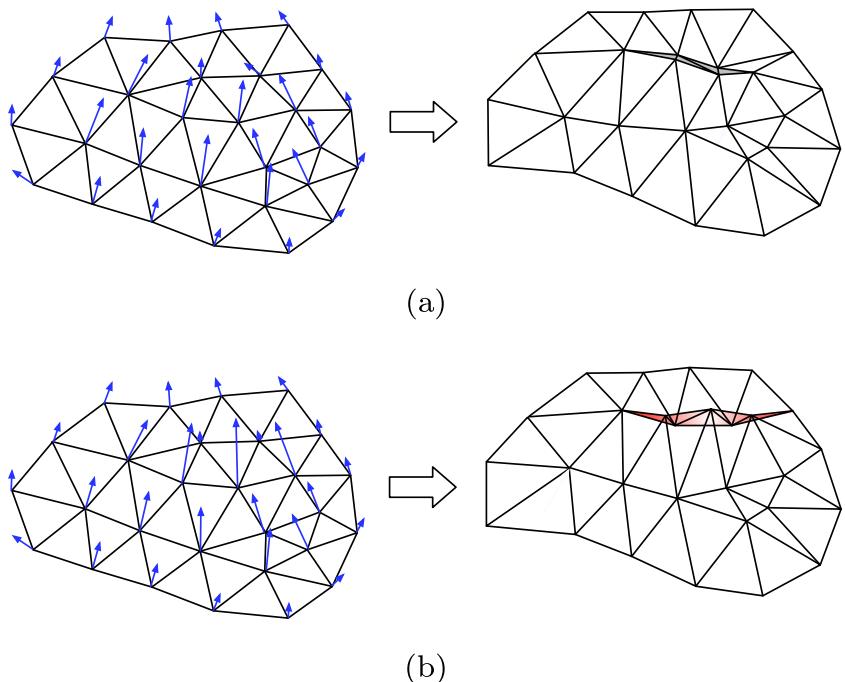

‘large’ value b_{target} is reached: this smooth increase of b urges the optimized domain to fulfill the constraint in an increasingly stringent way in the course of the optimization process; see Section 5 for the actual values used in our implementation.

We again refer to Nocedal and Wright (2006) for an insight about this procedure; let us simply mention that ℓ^n is an increasingly accurate approximation of the Lagrange multiplier for the constraint $G(\Omega) = 0$ featured in (3). Notice also that the penalty coefficient b^n is multiplied by a user-defined constant $\alpha > 1$ during the first iterations of the algorithm, and that it is kept fixed afterwards. In particular, the augmented Lagrangian strategy does not require b^n to tend to infinity so to enforce the constraint $G(\Omega) = 0$; this guarantees a better conditioning of (21) with respect to the naive quadratic penalty method (featuring only the first and last terms in the definition of \mathcal{L} in (21)).

In our context, where the computational burden of minimizing $\Omega \mapsto \mathcal{L}(\Omega, \ell, b)$ is significant, we rely on the following practical implementation of these ideas which limits the number of iterations of the optimization method.

- **Initialization:** Start from an initial shape Ω^0 and coefficients ℓ^0 and b^0 .
- **For** $n = 0, \dots$ **until convergence**
 - choose a descent direction θ^n for $\Omega \mapsto \mathcal{L}(\Omega, \ell^n, b^n)$,
 - take τ^n small enough so that $\mathcal{L}((\text{Id} + \tau^n \theta^n)(\Omega^n), \ell^n, b^n) < \mathcal{L}(\Omega^n, \ell^n, b^n)$, and set $\Omega^{n+1} = (\text{Id} + \tau^n \theta^n)(\Omega^n)$.

Fig. 4 Examples of **a** a mesh getting very stretched (gray elements); **b** a mesh developing overlaps (red elements) in the course of its deformation

- update the coefficients ℓ^n and b^n of the augmented Lagrangian \mathcal{L} according to (23).

3.4 Mesh-related issues

Assume for one moment that a descent direction θ^n for (3) and a descent step τ^n have been found at the n^{th} iteration of the procedure described in Section 3.1; we are faced with the realization of the operation $\Omega^n \mapsto \Omega^{n+1} = (\text{Id} + \tau^n \theta^n)(\Omega^n)$. If \mathcal{T}^n is the mesh of Ω^n , the natural way to carry it out reads:

$$\mathbf{x}_i^n \mapsto \mathbf{x}_i^{n+1} := \mathbf{x}_i^n + \tau^n \theta^n(\mathbf{x}_i^n), \quad i = 1, \dots, I^n, \quad (24)$$

while the connectivities of the mesh are unchanged, i.e. the considered mesh \mathcal{T}^{n+1} of Ω^{n+1} is made of the same simplices as \mathcal{T}^n , but their vertices are relocated according to θ^n .

Unfortunately, this simple procedure is likely to give rise to very stretched (i.e. almost flat) elements within a few iterations. This is problematic since the accuracy of the resolution of PDE with the Finite Element method greatly depends on the *quality* of the elements in the mesh, i.e. on their being close to equilateral (Ciarlet 2002). It may also happen that the mesh becomes overlapping in the course of the deformation; see Fig. 4 for an illustration of such configurations.

Hence, the numerical resolution of (1) may become very inaccurate (not to say impossible) as the computational mesh is successively deformed, causing the whole optimization process to stop prematurely. To circumvent this drawback, we rely on two ingredients:

- The emergence of stretched elements in \mathcal{T}^n may be postponed: in the transformation of Ω^n into Ω^{n+1} (practically, that of \mathcal{T}^n into \mathcal{T}^{n+1} via (24)), only the values of θ^n on the boundary Γ^n determine the new domain Ω^{n+1} ; in the numerical framework, the values of θ^n inside Ω^n are only used to relocate the internal vertices of \mathcal{T}^n . In particular, these internal values of θ^n may be chosen freely, in a way that makes \mathcal{T}^{n+1} of good quality insofar as possible, as we describe in the next Section 3.5.
- When the quality of the mesh becomes poor, i.e. in our context when the volume of one of its elements becomes very small, i.e.

$$\min_{k=1, \dots, K^n} |T_k^n| < \varepsilon_{\text{mesh}},$$

where $\varepsilon_{\text{mesh}}$ is a user-defined parameter (see Frey and George 2008 Chap. 18 for more details, in particular about other possible quality measures of a mesh,

which could be easily implemented in FreeFem++), a remeshing of \mathcal{T}^n is carried out: in a nutshell,

- ‘Too long’ edges are split,
- The endpoints of ‘too short’ edges are merged,
- The connectivities of ill-shaped triangles (e.g. nearly flat triangles) are swapped,
- Vertices are moved,

as long as the overall quality of the mesh is improved. See Fig. 5 for an illustration of these operations.

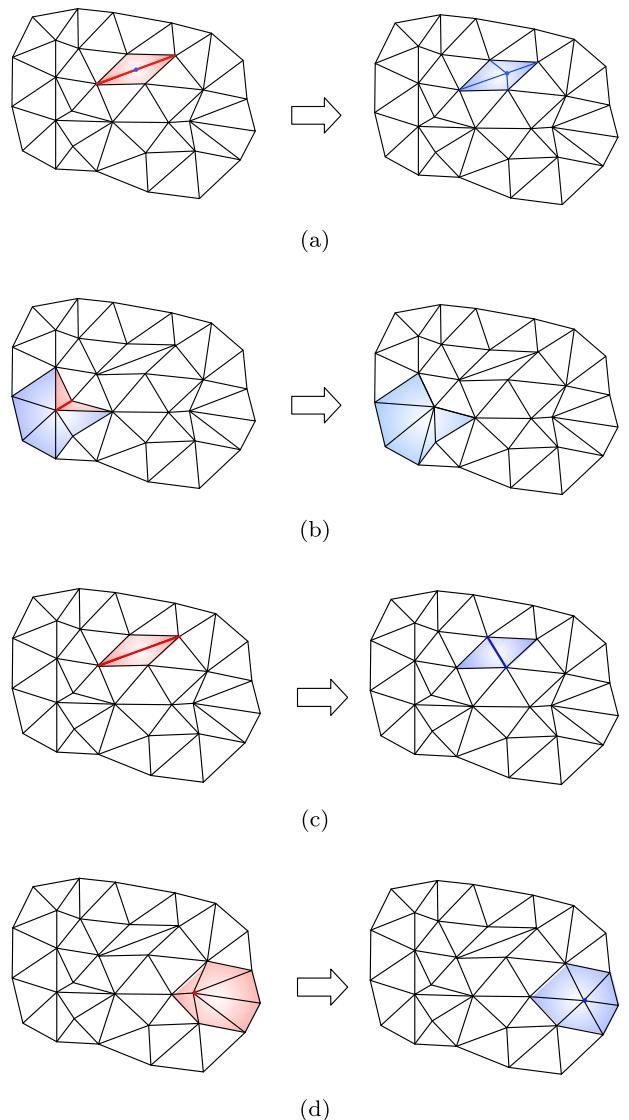

Fig. 5 Illustrations of the remeshing operations described in Section 3.4: **a** splitting of a ‘long’ edge; **b** collapse of the two endpoints of a ‘short’ edge; **c** swap of the connectivities of a configuration of two ill-shapes triangles; **d** relocation of one vertex

From the practical implementation viewpoint, this complex series of operations is conveniently carried out owing to the `movemesh` command in FreeFem++.

3.5 Extension-regularization of the shape gradient

As we have seen, our optimization procedure amounts to a series of minimizations of functionals of the form (21), which we generically denote by $F(\Omega)$ in the present section. We have seen in Section 2.3 that a natural candidate for a descent direction is

$$\boldsymbol{\theta} = -\phi \mathbf{n}, \quad (25)$$

where the scalar function $\phi : \Gamma \rightarrow \mathbb{R}$ is the $L^2(\Gamma)$ -shape gradient of $F(\Omega)$, which is identified from the shape derivative of this functional via (13).

Unfortunately, this choice is generally ill-suited for at least two reasons:

- (i) Strictly speaking, (25) only makes sense on the boundary Γ of the actual shape Ω , while the numerical setting requires the velocity field $\boldsymbol{\theta}$ to be defined on Ω as a whole, see (24).
- (ii) The $L^2(\Gamma)$ shape gradient ϕ of $F(\Omega)$ may be very irregular, especially in the areas surrounding Γ_{out} because of the change in boundary conditions occurring there. This may cause numerical artifacts when it comes to the mesh procedure (24); see for instance (Mohammadi and Pironneau 2010) §6.2.4. It is therefore often desirable to smooth the velocity field $\boldsymbol{\theta}$ on Γ before performing (24).

The popular *extension-regularization* procedure provides alternative ways to calculate a descent direction $\boldsymbol{\theta}$ for $F(\Omega)$ from the knowledge of the shape derivative $F'(\Omega)(\boldsymbol{\theta})$ while overcoming both difficulties; see e.g. Burger (2003), De Gournay (2006), Dogan et al. (2007). The basic idea consists in identifying a shape gradient for $F(\Omega)$ from its shape derivative $F'(\Omega)(\boldsymbol{\theta})$ (see (13)) by means of a different inner product $(\cdot, \cdot)_V$ than $(\cdot, \cdot)_{L^2(\Gamma)}$, acting on a (Hilbert) space V of more regular vector fields, defined on Ω as a whole. More precisely, one searches for $\boldsymbol{\theta} \in V$ such that for all test functions $\boldsymbol{\psi} \in V$,

$$(\boldsymbol{\theta}, \boldsymbol{\psi})_V = F'(\Omega)(\boldsymbol{\psi}) \quad (26)$$

Doing so ensures that:

$$F'(\Omega)(-\boldsymbol{\theta}) = -(\boldsymbol{\theta}, \boldsymbol{\theta})_V < 0,$$

which together with (14) guarantees that $\boldsymbol{\theta}$ is also a descent direction for $F(\Omega)$.

To be quite precise, in our context, we rely on the space

$$V = \{\mathbf{v} \in H^1(\Omega)^d, \mathbf{v}|_{\Gamma_{\text{in}} \cup \Gamma_{\text{out}}} = 0, \nabla_{\Gamma} \mathbf{v} \in L^2(\Gamma)^d\},$$

where $\nabla_{\Gamma} f := \nabla f - (\nabla f \cdot \mathbf{n})\mathbf{n}$ is the tangential gradient of a (smooth) function f ; V is equipped with the inner product $(\cdot, \cdot)_V$ defined by

$$\begin{aligned} \forall \boldsymbol{\theta}, \boldsymbol{\psi} \in V, (\boldsymbol{\theta}, \boldsymbol{\psi})_V = \gamma \int_{\Omega} A e(\boldsymbol{\theta}) : e(\boldsymbol{\psi}) dx \\ + (1 - \gamma) \int_{\Gamma} \nabla_{\Gamma} \boldsymbol{\theta} \cdot \nabla_{\Gamma} \boldsymbol{\psi} ds. \end{aligned} \quad (27)$$

Definition (27) features two contributions, balanced by the parameter $\gamma \in (0, 1]$:

- The first term in (27) is inspired by the linearized elasticity equations. Here, A is Hooke's law, acting on symmetric matrices e with size $d \times d$,

$$Ae = 2\mu e + \lambda \text{tr}(e),$$

where λ and μ are the Lamé coefficients of the fictitious elastic material. This choice—which is widespread in meshing (Baker 2002; Dobrzynski and Frey 2008) to help in keeping a mesh with fine quality—is motivated by the intuition that elastic displacements tend to induce little compression (i.e. local change in the volume).

- The second term in (27) corresponds to the Laplace-Beltrami operator on Γ . Its role is to enforce the smoothness of the descent direction $\boldsymbol{\theta}$ on Γ ; see for instance Dogan et al. 2007.

With these definitions at hand, the desired ‘regularized’ shape gradient $\boldsymbol{\theta}$ is calculated by solving (26) with a standard Finite Element method on a mesh of Ω .

Remark 5 In our implementation, the Lamé parameters λ, μ of the elastic material used for the extension-regularization procedure are homogeneous over Ω . Notice that the above strategy could be easily improved by considering *inhomogeneous* elasticity coefficients λ, μ , for instance coefficients characterized by a larger Young's modulus (which measures the resistance to traction and compression efforts) in regions where the mesh of Ω has stretched elements, so to penalize the relative compression rate they undergo.

Remark 6 A perhaps more natural idea consists in choosing

$$V = \left\{ \mathbf{v} \in H^1(\Omega)^d, \mathbf{v}|_{\Gamma_{\text{in}} \cup \Gamma_{\text{out}}} = 0 \right\},$$

with associated inner product:

$$(\boldsymbol{\theta}, \boldsymbol{\psi})_V = \gamma \int_{\Omega} \nabla \boldsymbol{\theta} : \nabla \boldsymbol{\psi} dx + \int_{\Omega} \boldsymbol{\theta} \cdot \boldsymbol{\psi} dx,$$

where $\gamma > 0$ is a ‘small’ parameter. In this context, (26) amounts to solving the regularizing, elliptic system:

$$\begin{cases} -\gamma \Delta \theta + \theta = 0 & \text{in } \Omega, \\ \theta = 0 & \text{on } \Gamma_{\text{in}} \cup \Gamma_{\text{out}}, \\ \gamma \frac{\partial \theta}{\partial \mathbf{n}} = -\phi \mathbf{n} & \text{on } \Gamma. \end{cases} \quad (28)$$

However easy to implement, this choice is less efficient than (27) insofar as it does not show the same efficiency in preventing the emergence of stretched elements; see the example in Section 5.3 about this point.

3.6 Calculation of the curvature

Most of the numerical methods involved in the resolution of the shape optimization problem (3) imply the calculations of the normal vector \mathbf{n} and the curvature κ of the boundary $\partial\Omega$ of a shape Ω (see for instance Theorem 1). In practice, these quantities are evaluated from the discrete geometry of a mesh \mathcal{T} of Ω , which is not a completely straightforward task. In this section, following (Frey and George 2008), we describe a simple, yet robust method to achieve this goal in the case of two space dimensions: $d = 2$. Similar approximations hold in the general case, which involve more tedious notations.

Let \mathbf{x}_i be a vertex of \mathcal{T} lying on $\partial\Omega$, and let \mathbf{x}_{i-1} (resp. \mathbf{x}_{i+1}) be the vertex on $\partial\Omega$ located immediately before (resp. after) \mathbf{x}_i when $\partial\Omega$ is oriented counterclockwise; see Fig. 6.

In this situation, the tangent vector $\mathbf{t}(\mathbf{x}_i)$ to $\partial\Omega$ at \mathbf{x}_i is calculated as:

$$\mathbf{t}(\mathbf{x}_i) = \frac{\overrightarrow{\mathbf{x}_{i+1}\mathbf{x}_{i-1}}}{|\overrightarrow{\mathbf{x}_{i+1}\mathbf{x}_{i-1}}|},$$

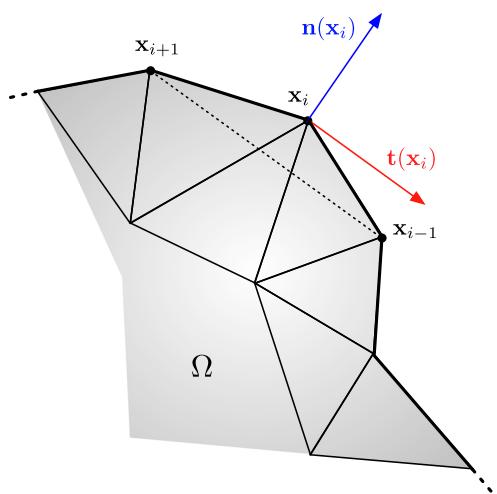

Fig. 6 Calculation of the tangent and normal vectors to $\partial\Omega$ from the data of a triangular mesh

and the unit normal vector $\mathbf{n}(\mathbf{x}_i)$ to $\partial\Omega$ at \mathbf{x}_i , pointing outward Ω is estimated as the rotate of $\mathbf{t}(\mathbf{x}_i)$:

$$\mathbf{n}(\mathbf{x}_i) = \begin{pmatrix} -t_2(\mathbf{x}_i) \\ t_1(\mathbf{x}_i) \end{pmatrix}.$$

Thence, the curvature radius $r(\mathbf{x}_i)$ at \mathbf{x}_i is approximated as:

$$r(\mathbf{x}_i) = \frac{1}{4} \left(\frac{\overrightarrow{\mathbf{x}_i\mathbf{x}_{i-1}} \cdot \overrightarrow{\mathbf{x}_i\mathbf{x}_{i-1}}}{-\mathbf{n}(\mathbf{x}_i) \cdot \overrightarrow{\mathbf{x}_i\mathbf{x}_{i-1}}} + \frac{\overrightarrow{\mathbf{x}_i\mathbf{x}_{i+1}} \cdot \overrightarrow{\mathbf{x}_i\mathbf{x}_{i+1}}}{-\mathbf{n}(\mathbf{x}_i) \cdot \overrightarrow{\mathbf{x}_i\mathbf{x}_{i+1}}} \right), \quad (29)$$

and the curvature $\kappa(\mathbf{x}_i)$ at \mathbf{x}_i is simply $\kappa(\mathbf{x}_i) = \frac{1}{r(\mathbf{x}_i)}$ if none of the denominators featured in (29) equals 0 (it is set to 0 otherwise).

3.7 Algorithmic description of the implemented method

We are now ready to provide a precise sketch of the shape optimization algorithm arising from the previous considerations. The brief account below follows exactly the steps of the file `main.edp` of the (commented) supplied code.

1. **Initialization.**
 - The initial shape $\Omega^0 \in \mathcal{O}_{ad}$ is equipped with a triangular mesh \mathcal{T}^0 .
 - Select initial values for the coefficients $\ell^0, b^0 > 0$ of the augmented Lagrangian algorithm.
2. **Main loop: for $n = 0, \dots$**
 - (i) Calculate the solution (\mathbf{u}^n, p^n) to the Navier-Stokes system (1) on the mesh \mathcal{T}^n of Ω^n by using the material in Section 3.2.
 - (ii) Calculate the solution (\mathbf{v}^n, q^n) to the adjoint system (10) or (12) on Ω^n .
 - (iii) Calculate the $L^2(\Gamma^n)$ shape gradient ϕ^n of $\Omega \mapsto \mathcal{L}(\Omega, \ell^n, b^n)$ by using Theorem 2.
 - (iv) Infer a descent direction θ^n for $\Omega \mapsto \mathcal{L}(\Omega, \ell^n, b^n)$ by solving (26) on the mesh \mathcal{T}^n .
 - (v) Find a descent step τ^n such that
$$\mathcal{L}((\text{Id} + \tau^n \theta^n)(\Omega^n), \ell^n, b^n) < \mathcal{L}(\Omega^n, \ell^n, b^n) \quad (30)$$
(possibly up to a small tolerance)
 - (vi) Move the vertices of \mathcal{T}^n according to τ^n and θ^n :
$$\mathbf{x}_i^{n+1} = \mathbf{x}_i^n + \tau^n \theta^n(\mathbf{x}_i^n) \quad (31)$$
 - If the resulting mesh is invalid, go back to step (v), and use a smaller value for τ^n ,
 - Else, the positions (31) define the vertices of the new mesh \mathcal{T}^{n+1} .
 - (vii) If the quality of \mathcal{T}^{n+1} is too low, use a local remeshing as described in Section 3.4.
 - (viii) Update the augmented Lagrangian parameters according to (23).
3. **Ending criterion.** Stop if
$$\|\theta^n\|_{L^2(\Gamma^n)} < \varepsilon_{\text{stop}}$$
Return Ω^n .

4 Practical implementation of the shape optimization algorithm

In this section, we describe the practical code used in the numerical experiments of Section 5. In addition to the detailed comments accompanying the sources, we focus our discussion on the parts that should be modified for the user to implement a different geometric or physical situation (i.e. to change the initial shape, the objective function, the shape derivative, etc.).

The user is supposed to have installed the free software FreeFem++. This environment allows to solve partial differential equations by the Finite Element method from the input of their variational formulation via an adapted pseudo-language. We recommend using the latest release, although our programs work with any version above 3.42. FreeFem++ is available at

<http://www.freefem.org/ff++/>,

and it comes along with a comprehensive documentation (Hecht et al. 2005).

4.1 Organization of the repository and of the program

Our code may be downloaded from the address:

<https://github.com/flomnes/optiflow>.

The main repository is organized as follows:

- The folder ./meshes contains the mesh files associated to the initial shapes of the test cases of Section 5: mesh1.mesh, mesh2.mesh, etc.
- The FreeFem++ source code used to generate these meshes is in the file geometry.edp.
- As the name suggests, the file main.edp contains the main routines of the optimization process.

- The file macros.edp contains several useful macros; see Section 4.3.
- The file curvature.edp gathers the routines involved in the calculation of the mean curvature κ of shapes; see Section 4.5.
- The files run_case.sh and run_all.sh are shell scripts containing the sample command lines needed to launch any, or all of the proposed test cases in Section 5.

4.2 Main parameters

The main program, written in the file main.edp, is executed by using the command line

FreeFem++ --param1 value1 ... main.edp,

where --param1, ... are the computational parameters of the considered test case; see Table 1.

Seven geometric settings (associated to different meshes of the initial shape and applied boundary conditions) are implemented in our code, corresponding to values of the config parameter ranging from 1 to 7. The precise command lines used to launch these examples are supplied in the file run_case.sh. The first five configurations correspond to the numerical results of Section 5.

4.3 Main macros

Our program relies on macros insofar as possible: it is a convenient way in FreeFem++ to ensure that the various operations carried out resemble their mathematical counterparts. The shortcuts that are consistently used throughout the implementation are stored in the file macros.edp; see Listing 1 for a sample.

Table 1 Main parameters passed on the command line

--config	Number of the considered test-cases; config ranges from 1 to 7
--navsto	The Stokes (resp. Navier-Stokes) system models the flow if navsto is 0 (resp. 1)
--tau	Value of τ , initial step in the gradient descent, see (24)
--errc	Value of the stopping criterion $\varepsilon_{\text{stop}}$
--gamma	Value of the regularization parameter γ ; see (27)
--beta	The constraint function $G(\Omega)$ is $\text{Vol}(\Omega)$ if beta is 1, and $\text{Per}(\Omega)$ if beta is 0.
--delta	The objective $J(\Omega)$ is the dissipated energy (4) if delta is 1, and the least-square discrepancy (5) if delta is 0.
--binit	Initial value for the penalty parameter b in (22)
--btarget	Limiting value for b
--cv	Desired constraint (volume or perimeter) over initial value for the constraint $G(\Omega)$
--optraff	0 for no remeshing, 1 for remeshing when necessary
--raffin	Value of the raff parameter used in the routines for mesh adaptation (see Section 4.8)

```

1 /* Strain tensor */
2 macro EPS(u, v) [dx(u), 1./2*(dx(v)+dy(u)),
   1./2*(dx(v)+dy(u)), dy(v)] // EOM
3
4 /* Jacobian matrix */
5 macro GRAD(u, v) [dx(u), dy(u), dx(v), dy(v)]
   // EOM
6
7 /* (u \cdot \nabla) V */
8 macro UgradV(u1,u2,v1,v2) [ [u1,u2]*[dx(v1),
   dy(v1)], [u1,u2]*[dx(v2),dy(v2)] ] // EOM

```

Listing 1 Several macros (from `macros.edp`)

4.4 Definition of the geometry and of the Finite Element setting

The meshes associated to the proposed test cases are supplied in the folder `./meshes`. The mesh Th corresponding to the considered situation (i.e. associated to the actual value of the `config` parameter) is read at the beginning of the `main.edp` file; see Listing 2.

```

1 /* Load initial mesh */
2 string meshname = "meshes/mesh"+config+".mesh"
3 ;
4 cout << "Loading mesh " << meshname << "...";
5 Th = readmesh(meshname);
6 cout << "done." << endl;
6 cout.flush;

```

Listing 2 Reading the initial shape (from `main.edp`)

The Finite Element spaces on the mesh Th are then defined as in Listing 3.

```

1 fespace Qh(Th,P1);
2 fespace Vh(Th,P2);
3
4 Vh ux, uy, vx, vy, wx, wy, dux, duy, uxx,
   uyy, clx, cly;
5 Qh p,q, mx, dpx, dpy, dp, qq, phix, phiy,
   kappa, phi, psi;

```

Listing 3 Definition of the Finite Element spaces and functions (from `main.edp`)

These meshes may be generated using the code in the file `geometry.edp`, which can easily be modified and adapted to describe a different physical setting.

For instance, the code in Listing 4 allows to create the mesh of the initial shape in the bend test case of Section 5.1; see Fig. 9 (top).

4.5 Practical calculation of the mean curvature

The routines dedicated to the calculation of the mean curvature κ of the boundary of the optimized shape

```

1 /* Bend with orthogonal inlet and outlet */
2 if (config==1) {
3   border in(t=0,1){x=param(0,1./3,t);
   y=0;
   label=2;};
4
5   border sig1(t=0,1){
6     x=circlearcx(1,2./3,pi,pi/2,t);
7     y=circlearcy(0,2./3,pi,pi/2,t);
8     label=3;};
9
10  border out(t=0,1){x=1;
11    y=param(2./3,1,t);
12    label=1;};
13
14  border sig2(t=0,1){
15    x=circlearcx(1,1,pi/2,pi,t);
16    y=circlearcy(0,1,pi/2,pi,t);
17    label=3;};
18
19 Th=buildmesh(in(pp/2)+sig1(pp)
20           +out(pp/2)+sig2(pp));
21 Th=adaptmesh(Th,IsMetric=1,1./30);
20 }

```

Listing 4 Creation of the initial mesh in the bend example of Section 5.1 (from `geometry.edp`)

are a little involved. They are gathered in the file `curvature.edp` and in principle, they do not need to be modified.

The calculation of κ in `main.edp` is then carried out along the lines of Listing 5.

```

1 kappa=0;
2 calculconnect(Th,ordre);
3 courbure(Th,ordre,kappa[]);
4 kappa=kc*kappa;

```

Listing 5 Calculation of the mean curvature in `main.edp`

4.6 Resolution of the flow equations

As outlined in Section 3.2, the Navier-Stokes equations are solved iteratively thanks to the Newton method.

To achieve this, the Stokes equation is first defined as a variational problem; see Listing 6 and Remark 4:

```

1 problem stokes([ux, uy, p], [vx, vy, q]) =
2   int2d(Th)(2*mu*tr(EPS(ux,uy))*EPS(vx,vy) - p
   * div(vx,vy))
3   +int2d(Th)(div(ux,uy)*q)
4   -int2d(Th)(p*q*epsilon)
5   +on(3,ux=0,uy=0)
6   +on(1,ux=clx, uy=cly);

```

Listing 6 Variational problem for the Stokes system (from `main.edp`)

The Navier-Stokes system is solved for the velocity and pressure $[ux, uy, p]$ by using the macro `ns` reprinted in Listing 7. In a nutshell, the Stokes system is solved as

```

1  macro ns () {
2  /* Only solve when necessary if ns has
3 never been executed or if the mesh
4 has changed since the last resolution */
5  if (solvefluid) {
6  /* Initialize Newton loop with the solution of
    Stokes */
7  stokes;
8  /* If we want to solve Navier–Stokes,
9 iterate successive Oseen problems */
10 if(navsto) {
11  int n;
12  real err=0;
13  cout << "Navier–Stokes";
14  /* Newton Loop */
15  for(n=0; n< 15; n++) {
16  solve Oseen([dux ,duy ,dp ],[vx ,vy ,qq ]) =
17  int2d(Th)(2*nu*tr(EPS(dux ,duy ))*EPS(vx ,
    vy)
18  + tr(UgradV(dux ,duy , ux , uy ))*[vx ,
    vy]
19  + tr(UgradV(ux ,uy ,dux ,duy ))*[vx ,vy
    ]
20  - div(dux ,duy )*qq - div(vx ,vy)*dp
21  - epsilon*dp*qq)
22  +int2d(Th)(2*nu*tr(EPS(ux ,uy ))*EPS(vx ,vy
    )
23  + tr(UgradV(ux ,uy , ux , uy ))*[vx ,
    vy]
24  - div(ux ,uy )*qq - div(vx ,vy)*p
25  - epsilon*p*qq)
26  +on(1,3,dux=0,duy=0);
27
28  ux [] += dux [];
29  uy [] += duy [];
30  p[] += dp [];
31  err = sqrt(int2d(Th)(tr(GRAD(dux ,duy ))*
    GRAD(dux ,duy ) + tr([dux ,duy ])*[dux ,duy
    ]) / int2d(Th)(tr(GRAD(ux ,uy ))*GRAD(ux
    ,uy ) + tr([ux ,uy ])*[ux ,uy ]));
32  cout << "...";
33  cout.flush();
34  if(err < arrns) break;
35  }
36  /* Newton loop has not converged */
37  if(err > arrns) {
38  cout << "NS Warning : non convergence :
    err = " << err << " / eps = " <<
    epsilon << endl;
39  }
40  cout << endl;
41 /* It is not necessary to solve ns until the
mesh is moved or adapted */
42 solvefluid = 0;
43 nflsolved++;
44 }
45 } //EOF

```

Listing 7 Resolution of the flow equations (from main.edp)

an initial guess; then, if the parameter `navsto` is set to 1, a loop is performed during which the Oseen equation is solved for the increment `[dux, duy, dp]`, from which `[ux, uy, p]` is updated.

4.7 Calculation of the objective function and of the shape derivative

The considered objective function $J(\Omega)$ in (3) is the energy dissipation (4) if the parameter `delta` is set to 1, and a least-square difference (5) between the fluid velocity and a target velocity if `delta` is 0. These are calculated from the macro in Listing 8.

```

1 /* Objective function = weighted sum of energy
   dissipation and least-square difference
   with a
   prescribed flow */
2 macro J() (2*delta*mu*int2d(Th)(tr(EPS(ux ,uy ))
3 *EPS(ux ,uy )) + ((1.-delta)/2)*int1d(Th ,2)
((ux-uxx)^2+(uy-uyy)^2)) //EOM

```

Listing 8 Macro for the objective function (from macros.edp)

Likewise, the constraint function $G(\Omega)$ is $\text{Vol}(\Omega)$ if `beta` is 1, and $\text{Per}(\Omega)$ if `beta` is 0; these are calculated from the macro in Listing 9.

```

1 /* Constraint function = weighted sum of
   volume and perimeter */
2 macro contr(Th) (beta*int2d(Th)(1.)
3 +(1.-beta)*int1d(Th)(1.)) //EOM

```

Listing 9 Macro for the constraint function (from macros.edp)

Thence, the value of the augmented Lagrangian functional is calculated by means of the macro `EL`, reprinted in Listing 10.

```

1 /* Augmented Lagrangian */
2 macro EL() (J/J0 + 1*(contr(Th) - ctarget)/c0
3 + b/2 * ((contr(Th) - ctarget)^2)/(c0^2))
//EOM

```

Listing 10 Macro for the augmented Lagrangian (from macros.edp)

At each iteration of the optimization loop (see Section 4.8 below), the adjoint states `[vx, vy, q]` are calculated as the solution to (10) if `delta` is 1 or (12) if `delta` is 0. This is achieved by calling the macro `adjoint` reprinted in Listing 11. Notice the presence of the `navsto` variable in the variational problem for the adjoint states, corresponding to the term induced by the non linearity of the flow equation (1) if `navsto` equals 1.

The shape derivatives of the considered objective and constraint functions $J(\Omega)$ and $G(\Omega)$, and that of the augmented Lagrangian $\mathcal{L}(\Omega, \ell, b)$ are then computed, again, thanks to a set of macros defined in the file `macros.edp`; see Listing 12.

```

1 macro adjoint() {
2   solve probadjoint([vx, vy, q], [wx, wy, qq])
3   =
4   int2d(Th) (2*nu*tr(EPS(vx, vy))*EPS(wx, wy)
5   -q*div(wx, wy)
6   -qq*div(vx, vy)
7   +navsto*(tr(UgradV(wx, wy, ux, uy))*[
8     vx, vy]+tr(UgradV(ux, uy, wx, wy)))*[
9     vx, vy]))
10 +int2d(Th)(-4*nu*delta*tr(EPS(ux, uy))*EPS(wx,
11   wy))
12 +int1d(Th,2)(-(1-delta)*((ux-uxx)*wx+(uy-uyy)
13   *wy))
14 +on(1,3,5, vx=0, vy=0);
15 } //EOM

```

Listing 11 Macro for the resolution of the adjoint system (from main.edp)

```

1 /* Strain tensor */
2 macro EPS(u, v)
3   [dx(u), 1./2*(dx(v)+dy(u)),
4   1./2*(dx(v)+dy(u)), dy(v)] // EOM
5 /* Shape derivative of the objective function */
6 macro IJ()
7   (-2*delta*nu*tr(EPS(ux, uy))*EPS(ux, uy)
8   +2*nu*tr(EPS(ux, uy))*EPS(vx, vy)) //EOM
9 /* Shape gradient of the constraint function */
10 macro gradC() (beta*1+(1.-beta)*kappa) //EOM
11 /* Shape-gradient of the Lagrangian */
12 macro gradDF()
13   (IJ/J0 + 1*gradC/c0
14   +b*gradC*(contr(Th)-ctarget)/(c0^2)) //EOM

```

Listing 12 Macros for shape derivatives (from macros.edp)

The shape gradient of the augmented Lagrangian on Γ is then extended to the whole computational mesh using the regulbord macro; the result of which is stored in the variable [dpx, dpy]; see Listing 13.

```

1 macro regulbord() {
2   solve regb([dpx, dpy],[phix, phiy]) =
3   int2d(Th)(gamma*tr(SIG(dpx, dpy))*EPS(phix,
4   phiy))
5   +int1d(Th,3)(gamma*tr(gradT(dpx))*gradT(
6   phix))
7   +int1d(Th,3)(gamma*tr(gradT(dpy))*gradT(
8   phiy))
9   +int1d(Th,3)(gradDF*dotN(phix, phiy))
10  +int1d(Th,4)(1./epspen*dotN(dpx, dpy)*dotN(
11    phix, phiy))
12  +on(1, 2, dpx=0)
13  +on(1, 2, dpy=0);
14 } //EOM

```

Listing 13 Macro for the extension-regularization procedure of the shape gradient (from main.edp)

4.8 Main optimization loop : gradient descent with line search

Last but not least, we now discuss our implementation of the algorithm of Section 3.7 for the resolution of the shape optimization problem (3), properly speaking.

This is achieved by means of two nested loops; see Listings 14 and 15. The main, outermost loop, reprinted in Listing 14, drives the update of the shape. At the beginning of each iteration, the actual shape is stored in the mesh Th2; then the direct and adjoint problems are solved thanks to the macros ns and adjoint respectively (see Line 4);

```

1 /* The algorithm stops when jj reaches jjmax
2 or the ending criterion is low enough */
3 for (jj = 0; (sv > errc) && (jj < jjmax); jj
4  ++) {
5   Th2 = Th; // Keep a copy of the mesh
6   ns; // Solve the NS equation if needed
7   adjoint; // Solve the adjoint system
8   /* Solve the velocity extension/
9   regularization problem to get the
10  descent direction;
11  the descent direction is [dpx,dpy] */
12  regulbord;
13  L0 = EL; // Value of the augmented
14  Lagrangian
15  tau1 = tau;
16
17  /* Inner loop for line search */
18  ****
19  ** Linear seach loop: see Listing 15 below **
20  ****
21
22  /* Maximum number of iterations has been
23  reached, and no decrease in the value of
24  the augmented Lagrangian is observed */
25  if (kk == kkmax) {
26    cout << "Warning : L_{n+1}>L_n (L0 = "
27    << L0 << ", 1 = " << 1 << ")" << endl;
28  }
29
30  /* L^2 norm of the shape gradient, used as
31  the ending criterion */
32  sv = sqrt(int1d(Th,3)(dpx^2+dpy^2));
33
34  /* Print output */
35  r << J << " " << EL << " " << contr(Th) <<
36  " " << 1 << " " << sv << " " << b << " "
37  << minarea << endl;
38
39  /* Update of the values of the coefficients
40  of the augmented Lagrangian */
41  l = l + b * (contr(Th) - ctarget);
42
43  /* Increase b if it is less than bttarget */
44  if (b < bttarget) {
45    b *= alpha;
46  }
47  cout << "jj = " << jj << endl;
48 }

```

Listing 14 Main loop of the optimization algorithm (from main.edp)

```

1  for (kk = 0; kk < kkmax; kk++) {
2    cout << "movemesh tau = " << tau1 << endl;
3    minarea = checkmovemesh(Th2, [x + tau1*dpx,
4                                  y + tau1*dpy]);
5
6    /* Try to adapt the mesh in case one of the
7     triangles becomes degenerate */
8    if (optraff) {
9      /* No adaptation if the minimal area is
10       larger than parameter minarea0 or if
11       we already tried remeshing 3 times in
12       this loop */
13      if (minarea > minarea0 || adaptcount >= 3) {
14        Th = movemesh(Th2, [x + tau1*dpx, y +
15                             tau1*dpy]);
16        solvefluid = 1;
17      }
18      else {
19        cout << "*** ADAPTMESH *** minarea = "
20             << minarea << " minarea0 = " <<
21             minarea0 << endl;
22        Th = adaptmesh(Th, hmax=raff, hmin=raff /
23                        sqrt(2), ratio=1.5);
24        cout << " new minarea = " << minarea <<
25             endl;
26        minarea = checkmovemesh(Th2, [x + tau1 *
27                                     dpx, y + tau1*dpy]);
28        solvefluid = 1;
29        kappa = 0;
30        calculconnect(Th, ordre);
31        adaptcount++;
32      }
33
34      if (adaptcount >= 3) {
35        cout << "Too many consecutive mesh
36         adaptations. Giving up mesh
37         adaptation" << endl;
38    }
39    else {
40      Th = movemesh(Th2, [x + tau1*dpx, y + tau1
41                           *dpy]);
42      solvefluid = 1;
43    }
44

46     shape */
47    courbure(Th, ordre, kappa[]);
48    kappa = kc * kappa;
49
50    /* Solve the Navier-Stokes and adjoint
51     equations on the new shape */
52    ns;
53
54    /* New value of the objective function */
55    L1 = EL;
56    tau1 /= 2;
57    cout << "L = " << L1 << " / L0 = " << L0 <<
58      " (variation = " << 100*(L1-L0)/L0 <<
59      "%)" << endl;
60
61    /* Accept iteration as soon as the value of
62     the augmented Lagrangian is decreased */
63    if (L1 < L0) {
64      break;
65    }
66  }

```

Listing 15 Line search in the optimization algorithm (from main.edp)

a descent direction $[dpx, dpy]$ from the actual shape Th2 is inferred by using the macro `regulbord` (Line 8). Meanwhile, the performance L_0 —i.e. the value of the augmented Lagrangian—of Th2 is calculated (Line 9).

Then, starting from the input parameter τ_au an appropriate value of the time step $\tau_{\text{au}1}$ is found by the inner loop of Listing 15, which is described below.

This inner loop results in a mesh Th of the new shape; the coefficients ℓ^n and b^n of the augmented Lagrangian are eventually updated (Line 29). This main loop stops if either the maximum number of iterations j_{jmax} is reached or if the ending criterion

$$\text{sv} \leq \text{errc}$$

is fulfilled; see Line 23 in Listing 14 and Section 3.7.

Let us now describe the inner loop, which is nothing but a basic line search procedure for finding a suitable value of the time step $\tau_{\text{au}1}$; see Listing 15. This procedure is initialized while $\tau_{\text{au}1}=\tau_\text{au}$, τ_au being a user-defined value. At each iteration of the inner loop, the current shape Th2 is deformed along the descent direction $[dpx, dpy]$ for a time $\tau_{\text{au}1}$; this yields a new, ‘attempt’ mesh Th (Lines 6–30).

This shape Th is then evaluated: the flow equations are solved on Th (see Line 37), and the value L_1 of the augmented Lagrangian associated to Th is calculated (Line 40). If L_1 is smaller than the value L_0 of the augmented Lagrangian of the current shape Th2 , the loop ends, and the ‘attempt’ mesh Th is accepted as the updated shape. Otherwise, the procedure is repeated from the beginning once the value of $\tau_{\text{au}1}$ has been divided by 2.

Note that, if after $\text{kkmax}=10$ iterations of the line search procedure, none of the produced ‘attempt’ meshes Th has produced a value L_1 of the augmented Lagrangian smaller than L_0 , the last iteration $\text{kk} = \text{kkmax}$ is accepted nevertheless; the step used in this case being $\tau/2^{10}$, Th is then very close to Th2 .

One final word about remeshing is in order. If the `optraff` input parameter equals 1, then whenever the mesh of the shape is deformed, the minimum area of an element in the tentative mesh Th is compared to the parameter `minarea0` (see Lines 6–30 in Listing 15). If smaller, the mesh is adapted thanks to the `adaptmesh` command of FreeFem++ (Line 14 in Listing 15). The resulting mesh has edges with length comprised between `raff` and `raff/sqrt(2)`, where `raff` stems from the `raffinit` parameter from the command line.

Note that, if mesh adaptation occurs, the connectivity of the boundary has to be calculated anew by calling `calculconnect` (viz. line 33), so that the routines described in Section 4.5 may be used to calculate the curvature of the shape (Table 2).

Table 2 CPU time for the numerical examples of Section 5

5 Numerical illustrations

In this section, we present five two-dimensional applications of the numerical algorithm presented in Section 3.7. The geometric configurations associated to these examples are represented in Fig. 7, and the parameters used in the different test cases (initial parameters of the augmented Lagrangian algorithm, target volume, etc.) are reported in Table 3. The approximate CPU time when running each example on a workstation with an Intel Core i5-7600T @ 2.80 GHz CPU is indicated in Table 2.

5.1 Minimization of the dissipated energy in a bend

Our first benchmark example is concerned with the optimization of the shape of a pipe with orthogonal inlet and outlet, as depicted in Fig. 7a; see for instance (Clabuk and Modi 1992; Borrvall and Petersson 2003). In a nutshell, this test case answers the question:

How to build a pipe with fixed volume that spends the least amount of energy to convey a fluid from Γ_{in} to Γ_{out} ?

The inlet flow is given by the parabolic profile (Fig. 8)

$$\mathbf{u}_{in}(x_1, x_2) = \left((1 - x_2) \left(\frac{2}{3} - x_2 \right), 0 \right).$$

Starting from the initial shape Ω^0 represented in Fig. 9 (top), we minimize the work of viscous forces, i.e. $J(\Omega) = E(\Omega)$, as defined by (4), under the volume constraint $\text{Vol}(\Omega) = V_T$, where $V_T = \text{Vol}(\Omega^0)$, i.e. the target volume is that of Ω^0 .

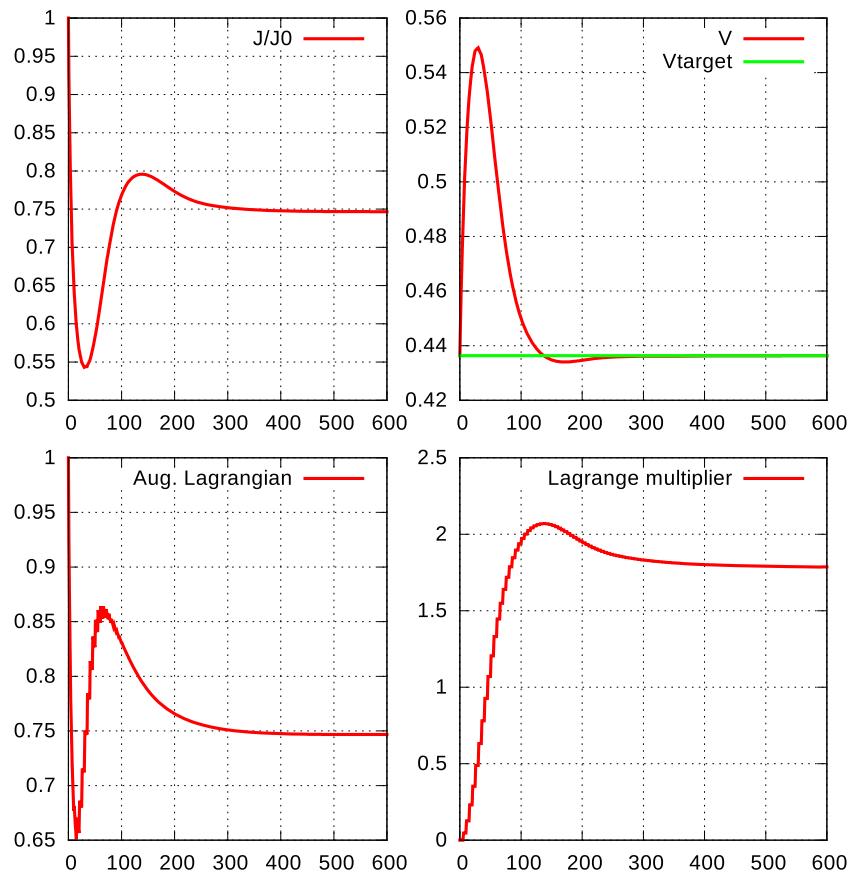

The results are displayed on Fig. 9, and the associated convergence histories are included in Fig. 8. The dissipated

From left to right: desired volume over initial volume, desired perimeter over initial perimeter, regularization parameter, initial gradient step, stopping criterion, initial Lagrange multiplier, initial value of b , target value of b

Fig. 8 Convergence histories of (from left to right, top to bottom) $J(\Omega)$, $\text{Vol}(\Omega)$, $\mathcal{L}(\Omega, \ell, b)$ and ℓ^n in the bend optimization example of Section 5.1

viscous energy decreases by roughly 25% during the process, and as expected, the optimized design looks like a straight pipe. It is worth mentioning that theoretical arguments in Henrot and Privat (2010) support this observation for a very close model.

Eventually, let us mention that this test case is fairly insensitive to the computation parameters ℓ^0 and τ , which makes it the easiest of all five to run.

5.2 Minimization of the dissipated energy in a ramified structure with volume constraint

Our second example is a simple model for the ramified structure of a human lung. It can be considered as an extension of the study in de La Sablonière et al. (2011).

The situation is that of Fig. 7b, where incoming parabolic profiles are imposed on each component of Γ_{in} . More precisely, Γ_{in} is the reunion of four disjoint line segments; for any of these segments, let us denote by (x_1^A, x_2^A) and (x_1^B, x_2^B) the two ending points, which are assumed to be distributed counterclockwise on Γ_{in} . The imposed inlet flow on the considered segment is then defined by:

$$\mathbf{u}_{\text{in}}(x_1, x_2) = s(1-s) \begin{pmatrix} -(x_2^B - x_2^A) \\ x_1^B - x_1^A \end{pmatrix}$$

where $s = \frac{x_1^A - x_1}{x_1^A - x_1^B} = \frac{x_2^A - x_2}{x_2^A - x_2^B}$ so that in particular \mathbf{u}_{in} is oriented toward inside Ω : $\mathbf{u}_{\text{in}} \cdot \mathbf{n} \leq 0$ on Γ_{in} .

In this context, we again aim at optimizing the energy dissipated owing to viscous effects, i.e. $J(\Omega) = E(\Omega)$, under the volume constraint $\text{Vol}(\Omega) = V_T$, where $V_T = \text{Vol}(\Omega_0)$.

The results are presented in Fig. 10, and the associated convergence histories are those in Fig. 11. Interestingly enough, ramifications appear in the course of the iterations and the optimized shape is much smoother than the initial one. These results are also in accordance with those obtained in de La Sablonière et al. (2011).

This example shows large mesh deformations, which justifies the importance of using a good extension-regularization procedure, such as that introduced in Section 2.3.

5.3 Minimization of the dissipated energy in a ramified structure with perimeter constraint

This third example arises in the exact same physical context as that of Section 5.2 (again, see Fig. 11). The only difference with the latter is that we now impose a constraint on the perimeter of shapes: $\text{Per}(\Omega) = P_T$, with $P_T = 0.97 \text{Per}(\Omega^0)$. The convergence histories of the computation are reported on Fig. 12, and the shape at several intermediate stages is represented on Fig. 13.

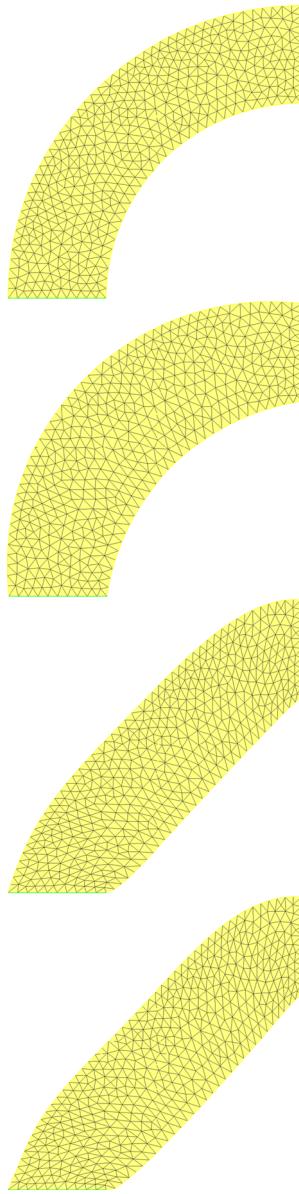

Fig. 9 Intermediate shapes Ω^n obtained in the bend optimization example of Section 5.1 at iterations (from top to bottom) $n = 0, 5, 100$ and 500

Let us emphasize the role of the regularizing parameter γ featured in the definition of the extension-regularization inner product (27). In this example (as in the previous ones), the $L^2(\Gamma)$ shape gradient of $E(\Omega)$ is not smooth in the vicinity of the transitions between parts of the boundary bearing different types of boundary conditions (that is, the transitions between Γ_{in} , Γ_{out} or Γ). Therefore, if no regularization of this gradient is applied ($\gamma = 1$ in (27)), mesh intersections appear within a few iterations in this region. This phenomenon is illustrated in Fig. 14 below: all parameters retain the same values except for γ , which is changed to 1. The mesh irregularities are caused by an irregular shape gradient, and are not observed for $0 < \gamma < 1$.

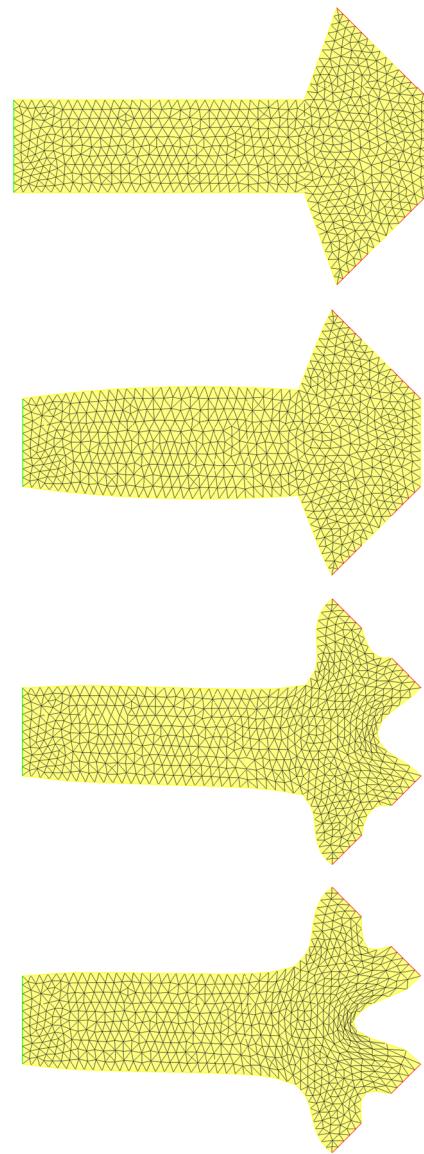

Fig. 10 From top to bottom, successive shapes Ω^n at iterations $n = 0, 5, 240, 1000$ in the dissipated energy minimization example in a ramified structure with volume constraint of Section 5.2

5.4 Minimization of the discrepancy with a reference velocity profile

Our third example considers pipes Ω in the situation depicted on Fig. 7c, where the parabolic profile

$$\mathbf{u}_{\text{in}}(x_1, x_2) = (x_2(1 - x_2), 0) \quad (30)$$

is imposed on the inlet Γ_{in} . Our aim is to optimize the shape of Ω with respect to the least-square criterion $J(\Omega) = D(\Omega)$ given by:

$$D(\Omega) = \int_{\Gamma_{\text{out}}} |\mathbf{u} - \mathbf{u}_{\text{ref}}|^2 ds, \quad (31)$$

Fig. 11 Convergence histories of (from left to right, top to bottom) $J(\Omega)$, $\text{Vol}(\Omega)$, $\mathcal{L}(\Omega, \ell, b)$ and ℓ^n in the dissipated energy minimization example in a ramified structure of Section 5.2

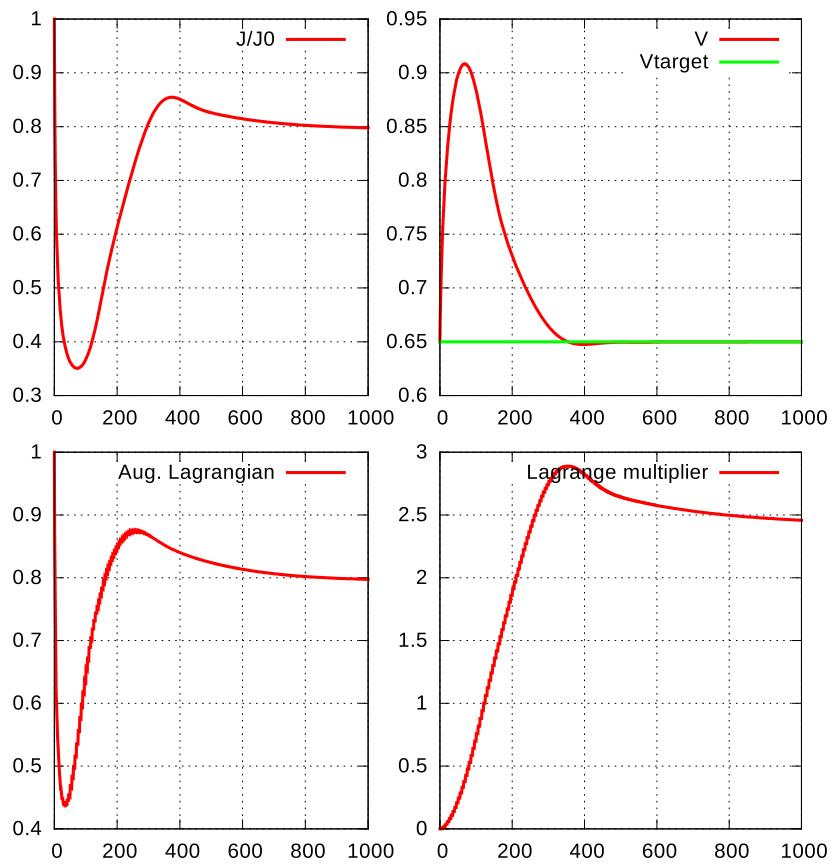

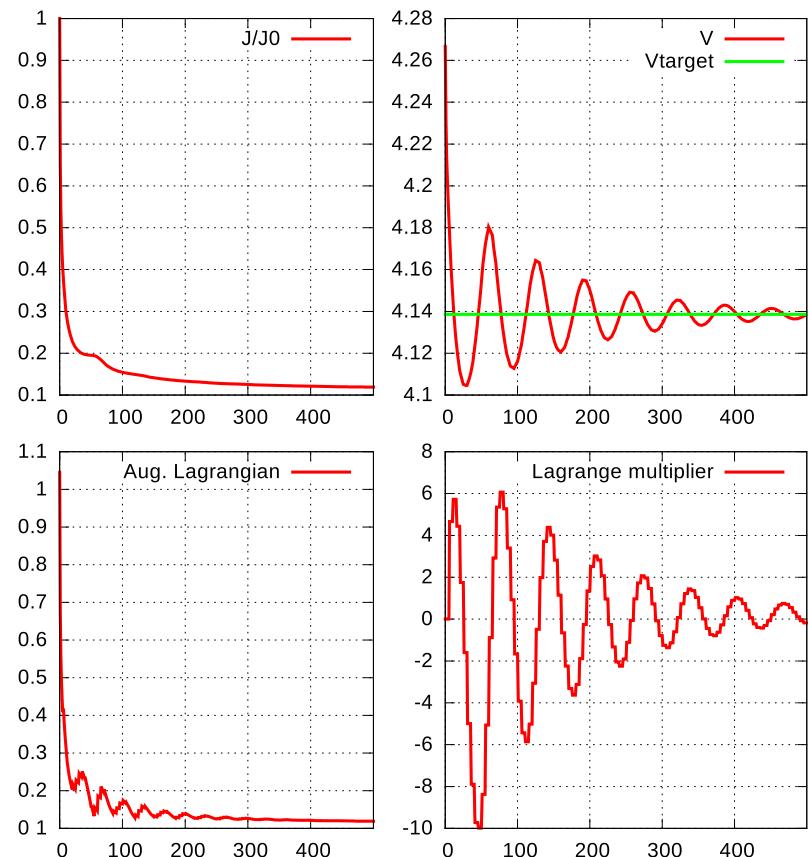

Fig. 12 Convergence histories of (from left to right, top to bottom) $J(\Omega)$, $\text{Per}(\Omega)$, $\mathcal{L}(\Omega, \ell, b)$ and ℓ^n in dissipated energy minimization in a ramified structure example of Section 5.3

where the reference profile \mathbf{u}_{ref} is the velocity of the fluid, solution to (1), associated to the same incoming flow (30), on the reference domain Ω_{ref} defined by:

$$\Omega_{\text{ref}} := \left\{ (x_1, x_2) \in \mathbb{R}^2, 0 \leq x_1 \leq \frac{3}{2}, f_{\text{ref}}(x_1) \leq x_2 \leq f_{\text{ref}}(x_1) + 1 \right\},$$

with

$$f_{\text{ref}}(x_1) = \frac{1}{5}x_1 \left(\frac{3}{2} - x_1 \right).$$

In other terms, in this test-case, the resolution of the optimization problem (3) aims to recover the shape of the

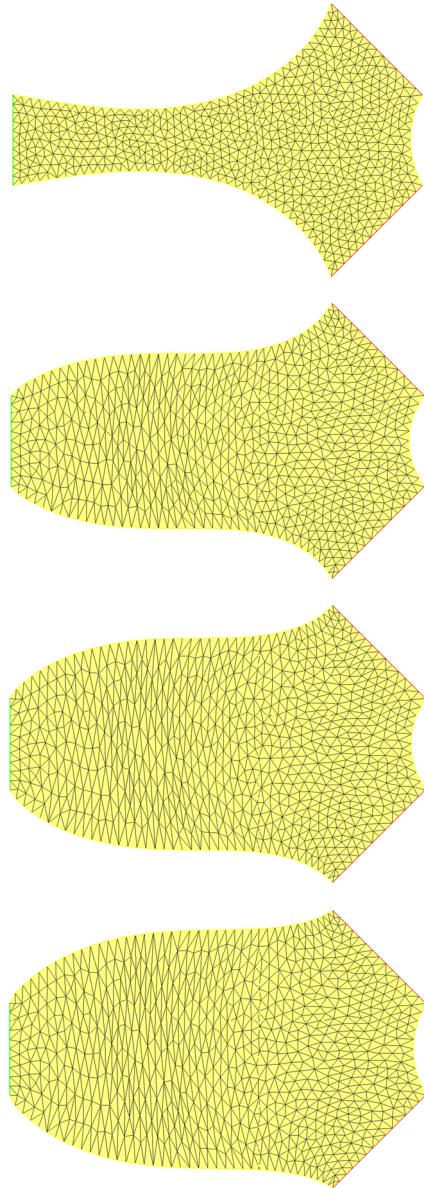

Fig. 13 From top to bottom, successive shapes Ω^n at iterations $n = 0, 100, 250, 500$ in the energy dissipation example in a ramified structure with perimeter constraint of Section 5.3

reference domain Ω_{ref} from the sole knowledge of the velocity profile \mathbf{u}_{ref} on Γ_{out} . By construction, (3) has at least one solution $\Omega = \Omega_{\text{ref}}$, since $D(\Omega_{\text{ref}}) = 0 \leq D(\Omega)$ for all $\Omega \in \mathcal{O}_{ad}$; however, this solution may not be unique. Note also that, obviously, other choices are possible as far as the reference profile \mathbf{u}_{ref} is concerned, but depending on whether this choice is ‘physical’ or not, it may not be possible to realize the latter. The above choice of \mathbf{u}_{ref} ensures that $D(\Omega)$ should be “small” upon convergence of the numerical resolution of (3).

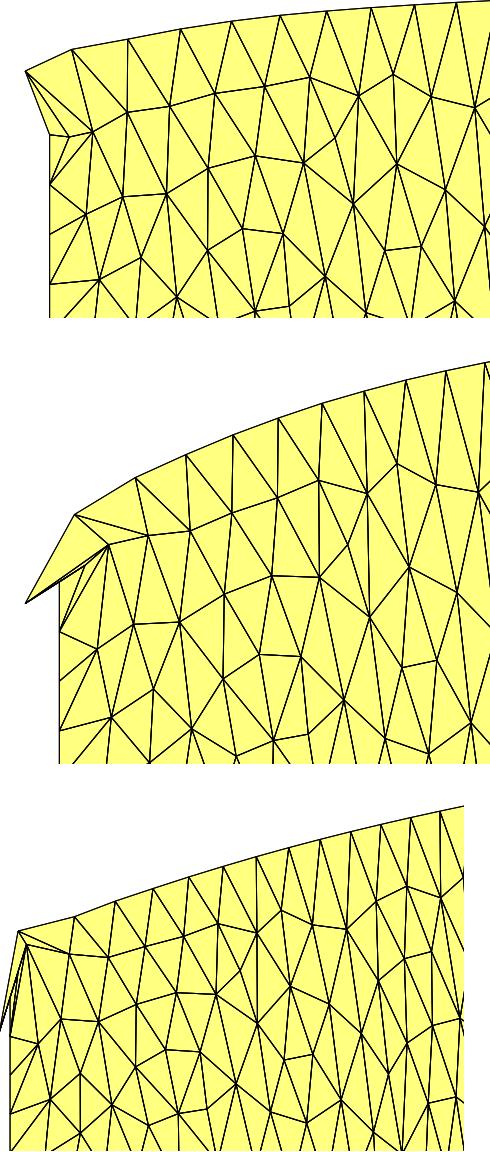

Fig. 14 Examples of mesh deteriorations. Zooms on the upper left corner of the intermediate shapes Ω^n obtained in the ramified structure example of Section 5.3, by removing regularization (which corresponds to choosing the parameter $\gamma = 1$ in (27)). From top to bottom, iterations $n = 15, 60$ and 130 . This figure shows the necessity to choose $\gamma \neq 1$ to avoid mesh deteriorations caused by irregular displacement fields

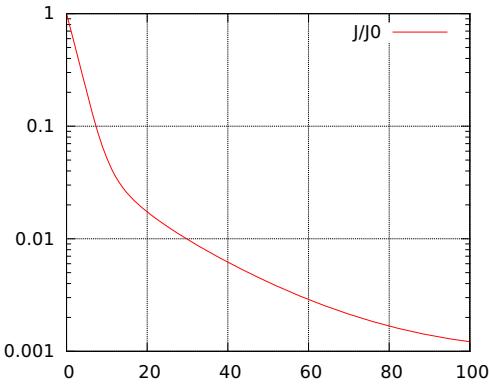

Fig. 15 Convergence history of $J(\Omega)$ in the least-square criterion minimization example of Section 5.4

The considered shape optimization problem in this case is unconstrained—i.e. no occurrence of the constraint $G(\Omega)$ appears in (3); from the numerical viewpoint, the framework of Section 3.7 reduces to a simple gradient algorithm: $b = \ell_0 = 0$ (Fig. 15 and 16).

Several intermediate shapes in the resolution of (3) and the reference shape Ω_{ref} are presented on Fig. 17, and the corresponding one-dimensional profiles of the components u_1 and u_2 of the velocity \mathbf{u} of the fluid on Γ_{out} are

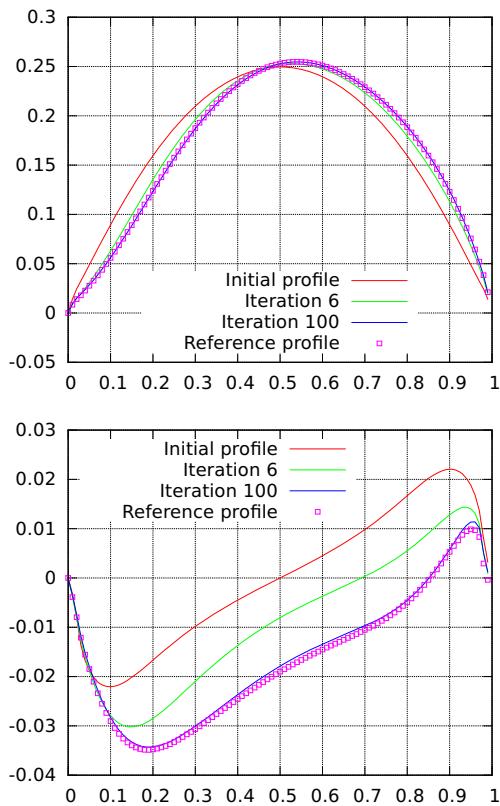

Fig. 16 One-dimensional profiles of (top) u_1 and (bottom) u_2 on Γ_{out} at several stages in the example of Section 5.4

reported on Fig. 16. These profiles get closer and closer to their reference counterparts as the algorithm reaches convergence, and the value of the minimized least-square criterion $D(\Omega)$ decreases to roughly 0.1% of its initial value,

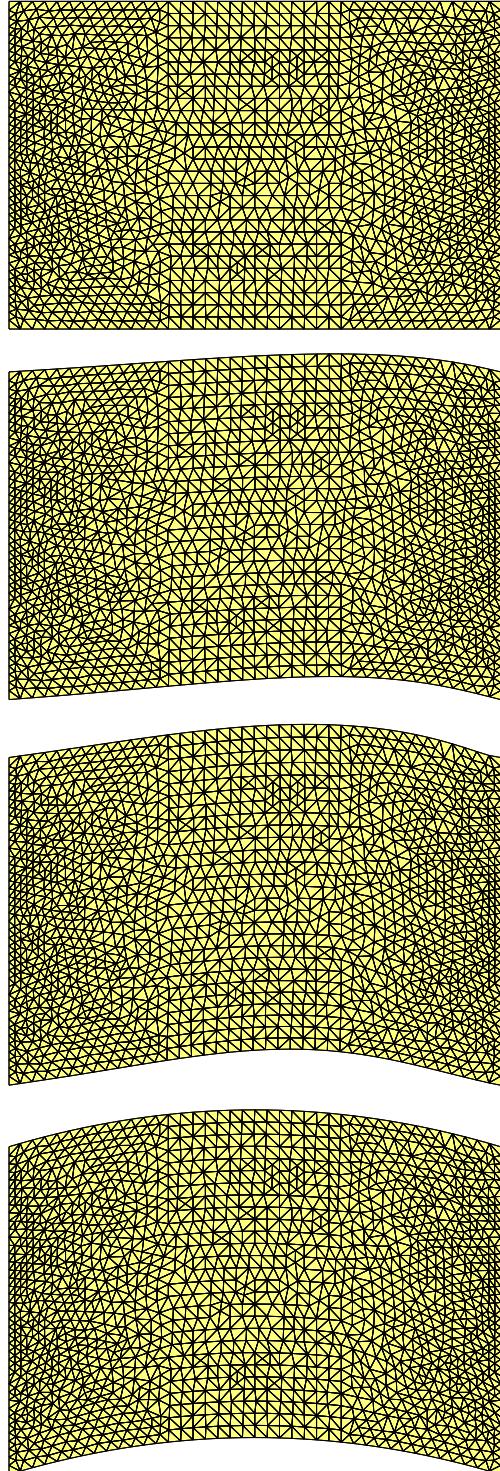

Fig. 17 From top to bottom, successive shapes Ω^n at iterations $n = 0, 6, 100$ and reference shape in the least-square criterion minimization example of Section 5.4

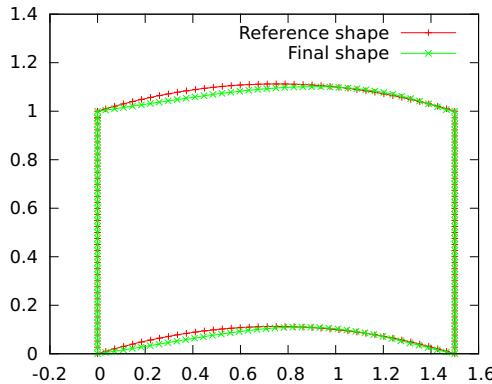

Fig. 18 Boundary of the reference shape and shape at convergence in the least-square criterion minimization example of Section 5.4

see the convergence history in Fig. 15. A close inspection of Fig. 18 reveals that the optimized shape Ω does not match with the reference Ω_{ref} . This example as well as other, unreported tests carried out using different reference shapes Ω_{ref} show that the latter is matched properly by the result Ω from the optimization process in the region close to the boundary Γ_{out} , but that both shapes differ significantly far from this region. This can be explained by the fact that at low Reynolds number, the upstream flow has little influence

on the downstream flow; see Burkardt et al. (2002) for a related observation.

Assuming that there exist more than one shape Ω satisfying $D(\Omega) = 0$, an interesting problem would be to find one satisfying this property while minimizing the dissipated energy $E(\Omega)$ given by (4), namely:

$$\min_{\Omega} \in \mathcal{O}_{\text{ad}} E(\Omega) \text{ s.t. } D(\Omega) = 0.$$

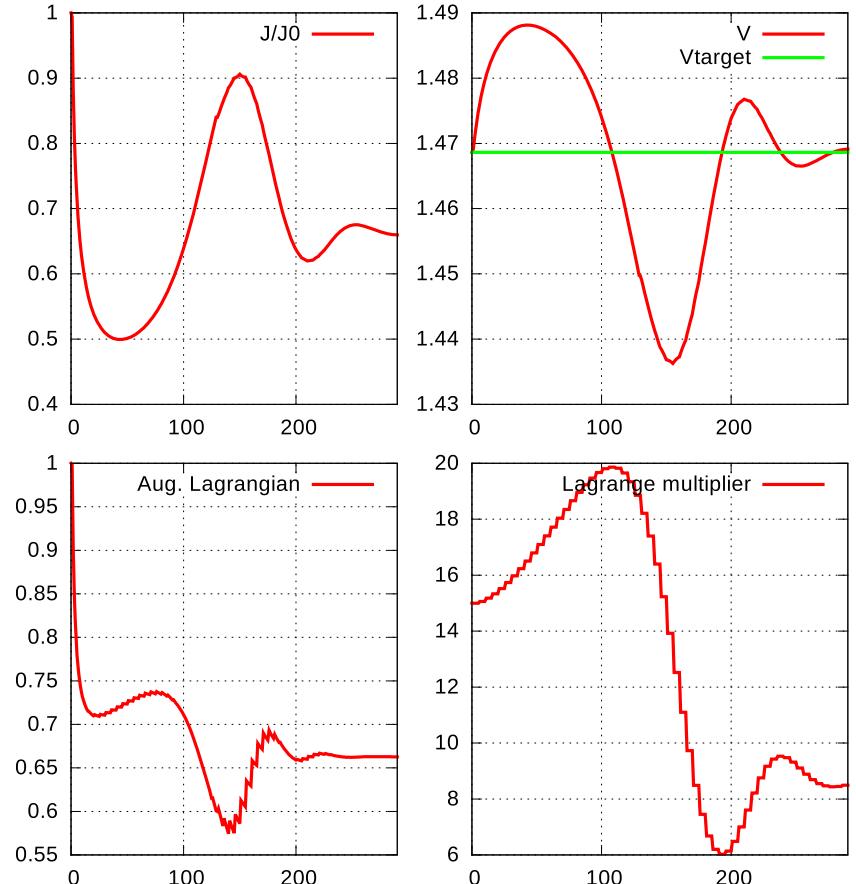

The interested reader may investigate this problem for instance with the help of the tools and program presented in this article.

5.5 Energy dissipation around an obstacle

In our last example, depicted on Fig. 7d, a solid obstacle is immersed in a cavity filled with a fluid, and the shapes Ω stand for the fluid domain, which is the complement of the obstacle in the cavity. Our aim is to minimize the dissipated energy in the cavity with respect to the shape of the obstacle, i.e. $J(\Omega) = E(\Omega)$ with the volume constraint $\text{Vol}(\Omega) = V_T$, $V_T = \text{Vol}(\Omega^0)$.

A very similar version of this problem is considered in Pironneau (1973) and Bourot (1974) in the context of Stokes flows. The same problem was later investigated

Fig. 19 Convergence histories of (from left to right, top to bottom) $J(\Omega)$, $\text{Vol}(\Omega)$, $\mathcal{L}(\Omega, \ell, b)$ and ℓ^n in the dissipated energy minimization example of Section 5.5

using more modern topology optimization techniques in Borrvall and Petersson (2003).

In the model situation discussed here, we impose a horizontal flow on Γ_{in} , namely

$$\mathbf{u} = \mathbf{u}_{\text{in}}(x_1, x_2) = (1, 0) \quad \text{on } \Gamma_{\text{in}},$$

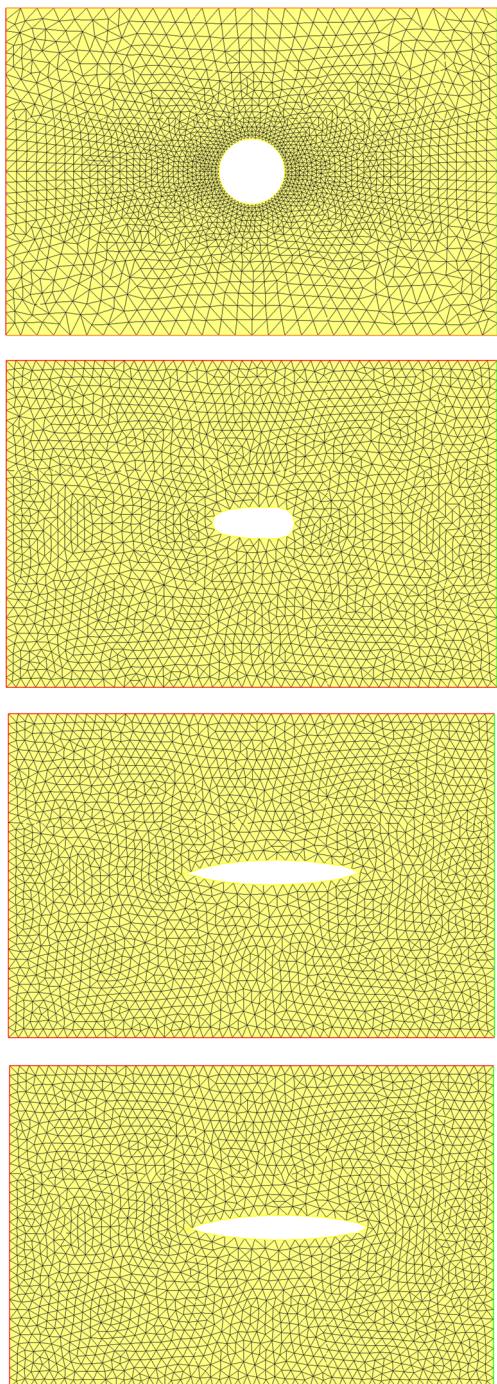

Fig. 20 From top to bottom, successive shapes Ω^n at iterations $n = 5, 100, 650$ in the dissipated energy minimization example of Section 5.5

and no-slip boundary conditions are prescribed on the boundary of the obstacle. The convergence histories are presented on Fig. 19. The resulting shape (see Fig. 20, bottom) is roughly similar to those obtained in references Bourot (1974), Borrvall and Petersson (2003), having the visual aspect of a sharp rugby ball.

Finally, let us mention that, from the numerical point of view, this test-case is the hardest to run, since ℓ_0 and τ have to be chosen carefully in order to avoid the collapse of the obstacle, which would result in an invalid mesh. From a practical point of view, this choice relies on a few trials on very coarse meshes.

6 Conclusion and perspectives

In this article, we have presented a numerical framework for shape optimization in the context of fluid mechanics, consisting of well-established techniques which we have strived to present in an elementary and pedagogical way. The resulting strategy has been successfully applied to several benchmark test cases in the literature; admittedly, the techniques involved suffer from limitations, and there is a lot of room for improvements, notably:

- As we have explained in Section 3.4, the deformation of the computational mesh according to the shape gradient throughout the iterations of the optimization process is a delicate operation. Even though the heuristics described in Section 3.5 allow to overcome this difficulty in many cases, it may still happen that at some point the computational mesh becomes invalid; this is especially likely to happen when the evolving shape changes topology (for instance, two holes merge). This stake is a burning issue in the literature, and it calls for other means to represent shapes numerically than by a computational mesh, e.g. via the level set method (Pingue et al. 2010; Challis and Guest 2009b), or the SIMP method (Kreissl et al. 2011b). To keep a valid mesh, the gradient step must also be limited to small enough values, which can make convergence slow.
- The augmented Lagrangian algorithm described in Section 3.3 is well-tailored to impose one or two equality constraints on shapes. However, many natural constraints are inequality constraints, and it may be desirable to impose several of them. In such a case, it would be necessary to rely on more elaborated constrained optimization algorithms, such a Sequential Linear Programming (SLP); see for instance Nocedal and Wright (2006) about this point.

The discussed numerical examples have been implemented in the FreeFem++ environment. We hope that it proves useful to students, researchers and industrials, as a

basis for further developments and applications, such as the study of different geometric configurations, involving for instance other optimization criteria and constraints.

Appendix A: Sketch of the proof of Theorem 2

The differentiability of the solution (\mathbf{u}, p) to the Navier-Stokes system (1) with respect to the domain is a technical, albeit quite classical matter, and we admit the result, referring for instance to Henrot and Pierre (2005) for the rigorous definition of this notion, and to Henrot and Privat (2010) or de La Sablonière et al. (2011) for this precise calculation. The derivative (\mathbf{u}', p') of (\mathbf{u}, p) with respect to the domain, in the direction $\boldsymbol{\theta} \in \Theta_{ad}$, is solution to the problem:

$$\left\{ \begin{array}{ll} -\nu \Delta \mathbf{u}' + (\nabla \mathbf{u}) \mathbf{u}' + (\nabla \mathbf{u}') \mathbf{u} + \nabla p' = 0 & \text{in } \Omega, \\ \operatorname{div}(\mathbf{u}') = 0 & \text{in } \Omega, \\ \sigma(\mathbf{u}', p') \mathbf{n} = 0 & \text{on } \Gamma_{\text{out}}, \\ \mathbf{u}' = 0 & \text{on } \Gamma_{\text{in}}, \\ \mathbf{u}' = -\left(\frac{\partial \mathbf{u}}{\partial n}\right)(\boldsymbol{\theta} \cdot \mathbf{n}) & \text{on } \Gamma. \end{array} \right. \quad (32)$$

Also, we only present the calculation of the shape derivative of the functional $D(\Omega)$ given by (5), the calculation being on any point easier in the case of $E(\Omega)$; see de La Sablonière et al. (2011) if need be.

Using the chain rule from the definition (5) of $D(\Omega)$ yields:

$$D'(\Omega)(\boldsymbol{\theta}) = \int_{\Gamma_{\text{out}}} \mathbf{u}' \cdot (\mathbf{u} - \mathbf{u}_{\text{ref}}) ds. \quad (33)$$

The main idea of the proof consists in using the adjoint state (\mathbf{v}_d, q_d) , solution to (12): performing several integrations by parts allows to eliminate the unknown derivatives (\mathbf{u}', p') from the expression (33). More precisely, multiplying the first equation in (32) by \mathbf{v}_d and integrating by parts yields

$$\begin{aligned} 0 &= \int_{\Omega} (-\nu \Delta \mathbf{u}' + (\nabla \mathbf{u}) \mathbf{u}' + (\nabla \mathbf{u}') \mathbf{u} + \nabla p') \cdot \mathbf{v}_d dx \\ &= \int_{\Omega} (2\nu e(\mathbf{u}') : e(\mathbf{v}_d) - \operatorname{div}(\mathbf{v}_d) p' + (\nabla \mathbf{u}) \mathbf{u}' \cdot \mathbf{v}_d \\ &\quad + (\nabla \mathbf{u}') \mathbf{u} \cdot \mathbf{v}_d) dx - \int_{\partial \Omega} \sigma(\mathbf{u}', p') \mathbf{n} \cdot \mathbf{v}_d ds \\ &= \int_{\Omega} (2\nu e(\mathbf{u}') : e(\mathbf{v}_d) + (\nabla \mathbf{u}) \mathbf{u}' \cdot \mathbf{v}_d + (\nabla \mathbf{u}') \mathbf{u} \cdot \mathbf{v}_d) dx \end{aligned} \quad (34)$$

where the boundary integral has vanished thanks to the boundary conditions satisfies by (\mathbf{u}', p') and (\mathbf{v}_d, q_d) .

Likewise, multiplying the first equation in (12) by \mathbf{u}' and integrating by parts, we obtain:

$$\begin{aligned} 0 &= \int_{\Omega} \left(-\nu \Delta \mathbf{v}_d + (\nabla \mathbf{u})^T \mathbf{v} - (\nabla \mathbf{v}_d) \mathbf{u} + \nabla q_d \right) \cdot \mathbf{u}' dx \\ &= \int_{\Omega} (2\nu e(\mathbf{u}') : e(\mathbf{v}_d) + (\nabla \mathbf{u}) \mathbf{u}' \cdot \mathbf{v}_d - (\nabla \mathbf{v}_d) \mathbf{u} \cdot \mathbf{u}') dx \\ &\quad - \int_{\partial \Omega} \sigma(\mathbf{v}_d, q_d) \mathbf{n} \cdot \mathbf{u}' ds. \end{aligned} \quad (35)$$

Combining Eqs. 34 and (35) leads to:

$$-\int_{\Omega} ((\nabla \mathbf{u}') \mathbf{u} \cdot \mathbf{v}_d + (\nabla \mathbf{v}_d) \mathbf{u} \cdot \mathbf{u}') dx = \int_{\partial \Omega} \sigma(\mathbf{v}_d, q_d) \mathbf{n} ds. \quad (36)$$

Now using the identity

$$\begin{aligned} \int_{\Omega} (\nabla \mathbf{v}_d) \cdot \mathbf{u} \cdot \mathbf{u}' dx &= \int_{\partial \Omega} (\mathbf{v}_d \cdot \mathbf{u}') (\mathbf{u} \cdot \mathbf{n}) ds \\ &\quad - \int_{\Omega} (\nabla \mathbf{u}') \mathbf{u} \cdot \mathbf{v}_d dx, \end{aligned} \quad (37)$$

which again follows from integration by parts, (36) rewrites:

$$\int_{\partial \Omega} (\sigma(\mathbf{v}_d, q_d) \mathbf{n} \cdot \mathbf{u}' + (\mathbf{u}' \cdot \mathbf{v}_d) (\mathbf{u} \cdot \mathbf{n})) ds = 0. \quad (38)$$

Eventually, taking into account the boundary conditions in the systems (1), (10) and (32) yields:

$$\begin{aligned} D'(\Omega)(\boldsymbol{\theta}) &= \int_{\Gamma_{\text{out}}} (\mathbf{u} - \mathbf{u}_{\text{ref}}) \cdot \mathbf{u}' ds \\ &= \int_{\Gamma_{\text{out}}} (\sigma(\mathbf{v}_d, q_d) \mathbf{n} + (\mathbf{u} \cdot \mathbf{n}) \mathbf{v}_d) \cdot \mathbf{u}' ds \\ &= - \int_{\Gamma} (\sigma(\mathbf{v}_d, q_d) \mathbf{n} + (\mathbf{u} \cdot \mathbf{n}) \mathbf{v}_d) \cdot \mathbf{u}' ds \\ &= \int_{\Gamma} (\sigma(\mathbf{v}_d, q_d) \mathbf{n} + (\mathbf{u} \cdot \mathbf{n}) \mathbf{v}_d) \cdot \frac{\partial \mathbf{u}}{\partial n} \boldsymbol{\theta} \cdot \mathbf{n} ds. \end{aligned} \quad (39)$$

We now use the boundary conditions $\mathbf{u} = 0$ and $\mathbf{v}_d = 0$ on Γ to simplify this last expression. For any tangential vector field $\boldsymbol{\tau} : \Gamma \rightarrow \mathbb{R}^d$ to Γ , they imply that $\frac{\partial \mathbf{u}}{\partial \boldsymbol{\tau}} = 0$, and so, using that $\operatorname{div}(\mathbf{u}) = 0$,

$$\frac{\partial \mathbf{u}}{\partial n} \cdot \mathbf{n} = 0 \quad (40)$$

the same relation holds for \mathbf{v}_d . Hence (39) rewrites:

$$D'(\Omega)(\boldsymbol{\theta}) = \int_{\Gamma} 2\nu e(\mathbf{v}_d) \mathbf{n} \cdot \frac{\partial \mathbf{u}}{\partial n} \boldsymbol{\theta} \cdot \mathbf{n} ds.$$

After a few algebraic manipulations based again on (40), we eventually obtain:

$$D'(\Omega)(\boldsymbol{\theta}) = \int_{\Gamma} 2\nu e(\mathbf{u}) : e(\mathbf{v}_d) (\boldsymbol{\theta} \cdot \mathbf{n}) ds, \quad (41)$$

which is the desired result, and terminates the proof of Theorem 2.
