Preface

This UQ Handbook comes at a time when predictive science is emerging at the confluence of computational, physical, and mathematical sciences. Although UQ appears to be an umbrella term, perhaps due in part to the breadth, novelty, and interdisciplinary nature of the field, it is driven by real challenges of practical importance involving the interplay between physics, modeling, computational hardware, algorithmic complexity, and decisions.

This Handbook provides a glimpse into these new frontiers of uncertainty quantification.

This project was a collaborative effort. The section editors, Drs. Wei Cen, Habib Najm, Bertrand Iooss, Tony Cox, Jim Stewart, and Michael McKerns, provided their own perspective on the Handbook's content and are responsible for both its breadth and cohesion. The editorial staff at Springer provided professional and insightful assistance with diligence and patience. The Handbook would not have been possible without the authors who did all the heavy lifting. We are grateful for their hard work and their confidence.

Contents

Volume 1

Part I Introduction to Uncertainty Quantification	1
1 Introduction to Uncertainty Quantification.....	3
Roger Ghanem, David Higdon, and Houman Owhadi	
Part II Methodology	7
2 Bayes Linear Emulation, History Matching, and Forecasting for Complex Computer Simulators	9
Michael Goldstein and Nathan Huntley	
3 Inference Given Summary Statistics	33
Habib N. Najm and Kenny Chowdhary	
4 Multi-response Approach to Improving Identifiability in Model Calibration	69
Zhen Jiang, Paul D. Arendt, Daniel W. Apley, and Wei Chen	
5 Validation of Physical Models in the Presence of Uncertainty	129
Robert D. Moser and Todd A. Oliver	
6 Toward Machine Wald	157
Houman Owhadi and Clint Scovel	
7 Hierarchical Models for Uncertainty Quantification: An Overview .	193
Christopher K. Wikle	
8 Random Matrix Models and Nonparametric Method for Uncertainty Quantification.....	219
Christian Soize	
9 Maximin Sliced Latin Hypercube Designs with Application to Cross Validating Prediction Error	289
Yan Chen, David M. Steinberg, and Peter Qian	

10	The Bayesian Approach to Inverse Problems	311
	Masoumeh Dashti and Andrew M. Stuart	
11	Multilevel Uncertainty Integration	429
	Sankaran Mahadevan, Shankar Sankararaman, and Chenzhao Li	
12	Bayesian Cubic Spline in Computer Experiments	477
	Yijie Dylan Wang and C. F. Jeff Wu	
13	Propagation of Stochasticity in Heterogeneous Media and Applications to Uncertainty Quantification	497
	Guillaume Bal	
14	Polynomial Chaos: Modeling, Estimation, and Approximation	521
	Roger Ghanem and John Red-Horse	

Volume 2

Part III	Forward Problems	553
15	Bayesian Uncertainty Propagation Using Gaussian Processes	555
	Ilias Bilionis and Nicholas Zabaras	
16	Solution Algorithms for Stochastic Galerkin Discretizations of Differential Equations with Random Data	601
	Howard Elman	
17	Intrusive Polynomial Chaos Methods for Forward Uncertainty Propagation	617
	Bert Debusschere	
18	Multiresolution Analysis for Uncertainty Quantification	637
	Olivier P. Le Maître and Omar M. Knio	
19	Surrogate Models for Uncertainty Propagation and Sensitivity Analysis	673
	Khachik Sargsyan	
20	Stochastic Collocation Methods: A Survey	699
	Dongbin Xiu	
21	Sparse Collocation Methods for Stochastic Interpolation and Quadrature	717
	Max Gunzburger, Clayton G. Webster, and Guannan Zhang	
22	Method of Distributions for Uncertainty Quantification	763
	Daniel M. Tartakovsky and Pierre A. Gremaud	
23	Sampling via Measure Transport: An Introduction	785
	Youssef Marzouk, Tarek Moselhy, Matthew Parno, and Alessio Spantini	

24	Compressive Sampling Methods for Sparse Polynomial Chaos Expansions	827
	Jerrad Hampton and Alireza Doostan	
25	Low-Rank Tensor Methods for Model Order Reduction	857
	Anthony Nouy	
26	Random Vectors and Random Fields in High Dimension: Parametric Model-Based Representation, Identification from Data, and Inverse Problems	883
	Christian Soize	
27	Model Order Reduction Methods in Computational Uncertainty Quantification	937
	Peng Chen and Christoph Schwab	
28	Multifidelity Uncertainty Quantification Using Spectral Stochastic Discrepancy Models	991
	Michael S. Eldred, Leo W. T. Ng, Matthew F. Barone, and Stefan P. Domino	
29	Mori-Zwanzig Approach to Uncertainty Quantification	1037
	Daniele Venturi, Heyrim Cho, and George Em Karniadakis	
30	Rare-Event Simulation	1075
	James L. Beck and Konstantin M. Zuev	
Part IV	Introduction to Sensitivity Analysis	1101
31	Introduction to Sensitivity Analysis	1103
	Bertrand Iooss and Andrea Saltelli	
32	Variational Methods	1123
	Maelle Nodet and Arthur Vidard	
33	Design of Experiments for Screening	1143

About the Editors

Roger Ghanem is the Gordon S. Marshall Professor of Engineering Technology at the University of Southern California where he holds joint appointments in the Departments of Civil and Environmental Engineering and Aerospace and Mechanical Engineering. He has a Ph.D. in Civil Engineering from Rice University. Prior to joining USC, he had served as member of the faculty of civil engineering at both Johns Hopkins University and SUNY Buffalo. Ghanem's expertise is in probabilistic modeling and computational stochastics with focus on high-dimensional formulations and polynomial chaos methods.

His recent work has addressed issues of hierarchical and concurrent coupling in stochastic problems through manifold learning and adaptation. Ghanem has served as president of the Engineering Mechanics Institute (EMI) of ASCE and currently serves on the Executive Council of the US Association for Computational Mechanics (USACM) and as Chair of the SIAM Activity Group on Uncertainty Quantification. He is elected fellow of EMI, USACM, and AAAS.

David Higdon is a Professor in the Social and Decision Analytics Laboratory with the Biocomplexity Institute at Virginia Tech. Previously, he spent 14 years as a scientist or group leader of the Statistical Sciences Group at Los Alamos National Laboratory. He is an expert in Bayesian statistical modeling of environmental and physical systems, combining physical observations with computer simulation models for prediction and inference. His research interests include space-time modeling; inverse problems in a variety of physical applications; statistical modeling in ecology, environmental science, and biology; multiscale statistical models; distributed methods for Markov chain Monte Carlo and posterior exploration; statistical computing; and Monte Carlo and simulation-based methods. Dr. Higdon has served on several advisory groups concerned with statistical modeling and uncertainty quantification and co-chaired

Monte Carlo and posterior exploration; statistical computing; and Monte Carlo and simulation-based methods. Dr. Higdon has served on several advisory groups concerned with statistical modeling and uncertainty quantification and co-chaired

the NRC Committee on Mathematical Foundations of Validation, Verification, and Uncertainty Quantification. He is currently the Editor in Chief for the SIAM-ASA *Journal on Uncertainty Quantification*. Dr. Higdon holds a B.A. and M.A. in Mathematics from the University of California, San Diego, and a Ph.D. in Statistics from the University of Washington.

Houman Owhadi is Professor of Applied and Computational Mathematics and Control and Dynamical Systems in the Computing and Mathematical Sciences Department at the California Institute of Technology. Houman Owhadi's work lies at the interface between applied mathematics, probability, and statistics. At the center of his work are fundamental problems such as the optimal quantification of uncertainties in the presence of limited information, statistical inference/game theoretic approaches to numerical analysis and algorithm design, multiscale analysis with non separated scales, and the geometric integration of structured stochastic systems.

Introduction to Uncertainty Quantification

Roger Ghanem, David Higdon, and Houman Owhadi

Contents

1 Introduction	3
----------------------	---

1 Introduction

Technology, in common with many other activities, tends toward avoidance of risks by investors. Uncertainty is ruled out if possible. People generally prefer the predictable. Few recognize how destructive this can be, how it imposes severe limits on variability and thus makes whole populations fatally vulnerable to the shocking ways our universe can throw the dice.

Frank Herbert (*Heretics of Dune*)

This handbook of Uncertainty Quantification (UQ) consists of six chapters, each with its own chapter editor. The choice of these chapters reflects a convergence

of opinions on part of the editors in chief and organizes the handbook around methodological developments, algorithms for the statistical exploration of the forward model, sensitivity analysis, risk assessment, codes of practice, and software. Most inference problems of current significance to the UQ community can be assembled using building blocks from these six components. The contributions consist of overview articles of interest both to newcomers and veterans of UQ.

Scientific progress proceeds in increments, and its transformative jumps invariably entail falsifying prevalent theories. This involves comparing predictions from theory with experimental evidence. While this recipe for advancing knowledge remains as effective today as it has been throughout history, its two key ingredients carry within them a signature of their own time and are thus continually evolving. Indeed, both predicting and observing the physical world, the two main ingredients of the scientific process, reflect our perspective on the physical world and are delineated by technology.

The pace of innovation across the whole scientific spectrum, coupled with previously unimaginable capabilities to both observe and analyze the physical world, has heightened the expectations that the scientific machinery can anticipate the state of the world and can thus serve to improve comfort and health and to mitigate disasters.

Uncertainty quantification is the rational process by which proximity between predictions and observations is characterized. It can be thought of as the task of determining appropriate uncertainties associated with model-based predictions. More broadly, it is a field that combines concepts from applied mathematics, engineering, computational science, and statistics, producing methodology, tools, and research to connect computational models to the actual physical systems they simulate. In this broader interpretation, UQ is relevant to a wide span of investigations. These range from seeking detailed quantitative predictions for a well-understood and accurately modeled engineering systems to exploratory investigations focused on understanding trade-offs in a new or even hypothetical physical system.

Uncertainty in model-based predictions arises from a variety of sources including (1) uncertainty in model inputs (e.g. parameters, initial conditions, boundary conditions, forcings), (2) model discrepancy or inadequacy due to the difference between the model and the true system, (3) computational costs, limiting the number of model runs and supporting analysis computations that can be carried out, and (4) solution and coding errors. Verification can help eliminate solution and coding errors. Speeding up a model by replacing it with a reduced order model is a strategy for trading off error/uncertainty between (2) and (3) above. Similarly, obtaining additional data, or higher quality data, is often helpful in reducing uncertainty due to (1) but will do little to reduce uncertainty from other sources. The multidisciplinary nature of UQ makes it ripe for exploiting synergies at the intersection of a number of disciplines that comprise this new field. More specifically, for instance,

- Novel application of principles and approaches from different fields can be combined to produce effective, synergistic solutions for UQ problems,
- The features and nuances of a particular application typically call for specific methodological advances and approaches.
- Novel solutions and approaches often appear from adapting concepts and algorithms from one field of research to another in order to solve a particular UQ problem.
- The concept of “codesign” – building and representing computational models, and analysis approaches and algorithms with HPC architecture in mind – is natural in UQ research, leading to novel solutions in UQ problems.
- Every effort to quantify uncertainty can be leveraged to make new studies – modeling efforts, data collections, computational approaches, etc. – more accurate and/or more efficient.

Managing these trade-offs to the best effect, considering computational costs, personnel costs, cost of data acquisition, etc., depends on the goals of the investigation, as well as the characteristics of the models involved. Unlike more data-driven fields, such as data mining, machine learning, and signal processing, UQ is more commonly focused on leveraging information from detailed models of complex physical systems. Because of this, UQ brings forward a unique set of issues regarding the combination of detailed computational models with experimental or observational data. Quite often the availability of this data is limited, tilting the balance toward leveraging the computational models. Key considerations in UQ investigations include

- The amount and relevance of the available system observations,
- The accuracy and uncertainty accompanying the system observations,
- The complexity of the system being modeled,
- The degree of extrapolation required for the prediction relative to the available observations and the level of empiricism encoded in the model,
- The computational demands (run time, computing infrastructure) of the computational model,
- The accuracy of the computational model’s solution relative to that of the mathematical model (numerical error),
- The accuracy of the computational model’s solution relative to that of the true system (model discrepancy),
- The existence of model parameters that require calibration using the available system observations,
- The availability of alternative computational models to assess the impact of different modeling schemes or implementations on the prediction.

The concept of a well-posed UQ problem is nucleating in response to the flurry of activities in this field. In particular, whether UQ can be framed as a problem

in approximation theory on product spaces, or as an optimization problem that relates evidence to decisions, or as a Bayesian inference problem with likelihoods constrained by hierarchical evidence, points to a convergence of mathematical rigor, engineering pragmatism, and statistical reasoning, all powered by developments in computational science.

Our initial intent for this introductory chapter was to present a common notation that ties a common thread throughout the handbook. This proved premature, and the diversity of these contributions points to a still nascent field of UQ. Although, at present, UQ lacks a coherent general presentation, much like the state of probability theory before its rigorous formulation by Kolmogorov in the 1930s, the potential for such a development is clear, and we hope that this handbook on UQ will contribute to its development by presenting an overview of fundamental challenges, applications, and emerging results.

Part II

Methodology

Bayes Linear Emulation, History Matching, and Forecasting for Complex Computer Simulators

2

Michael Goldstein and Nathan Huntley

Abstract

Computer simulators are a useful tool for understanding complicated systems. However, any inferences made from them should recognize the inherent limitations and approximations in the simulator's predictions for reality, the data used to run and calibrate the simulator, and the lack of knowledge about the best inputs to use for the simulator. This article describes the methods of emulation and history matching, where fast statistical approximations to the computer simulator (emulators) are constructed and used to reject implausible choices of input (history matching). Also described is a simple and tractable approach to estimating the discrepancy between simulator and reality induced by certain intrinsic limitations and uncertainties in the simulator and input data. Finally, a method for forecasting based on this approach is presented. The analysis is based on the Bayes linear approach to uncertainty quantification, which is similar in spirit to the standard Bayesian approach but takes expectation, rather than probability, as the primitive for the theory, with consequent simplifications in the prior uncertainty specification and analysis.

1 Introduction

One of the main tools for studying complex real-world phenomena is the creation of mathematical models for such phenomena, typically implemented as computer simulators. There is a growing field of study which is concerned with the uncertainties arising when computer simulators are used to make inferences about real-world behavior. Two characteristic features of this field are, firstly, the need to analyze uncertainties for simulators which are slow to evaluate and, secondly, the need to recognize and assess the difference between the simulator and the physical system which the simulator purports to represent. In this article, the Bayes linear approach to the assessment of uncertainty for such problems is described. This Bayes linear approach has been successfully applied in a variety of areas, including oil reservoir management [3], climate modeling [17], and simulators of galaxy formation [16]. The aim of this paper is to present a survey of the common general methodology followed in each such application.

The structure of the article is as follows. First, the Bayesian analysis of computer simulators for physical systems is discussed, and the role of Bayes linear analysis in this context is described and motivated. This is followed by a discussion of the issues arising when the simulator is slow to evaluate and the role of emulation in such problems. Next, ways to assess the structural discrepancy arising from the mismatch between the simulator and the physical system are described. These methods are then used in the context of history matching, namely, finding collections of simulator evaluations which are consistent with historical observations, within the levels of uncertainty associated with the problem. Finally, the role of the simulator in forecasting within the Bayes linear framework is described. The running example used to illustrate the development is based around flood modeling. This example has the merit that the code is freely available as an R package, so that the interested reader may try out the type of analysis described and compare it to alternative approaches to the same problems. This work was supported by NERC under the PURE research program.

2 Example: Rainfall Runoff Simulator

The running example is of a rainfall runoff simulator, that is, a simulator that predicts stream flow in a river. The particular simulator considered in this article is FUSE (The authors thank their colleagues, from the NERC PURE program, Wouter Buytaert, Nataliya Bulygina, and in particular Claudia Vitolo, for their help in running and interpreting the FUSE simulator.) (Framework for Understanding Structural Errors), described in [2], which can be downloaded for R from R-Forge at https://r-forge.r-project.org/R/?group_id=411. FUSE was designed as a toolbox of different modeling choices (there are 1248 different simulators available in FUSE), but in this article, only one (model 17) is considered. For brevity, this specific simulator within FUSE is referred to throughout simply as “FUSE.”

FUSE takes as its input a time series of average rainfall across the catchment in question, on whatever time scale one desires, and a time series of “potential evapotranspiration” on the same time scale. Its output is a time series of predicted stream flow, on the same scale. For this example, the simulator was run using data from the Pontbren catchment in Wales; the dataset is freely available from the Centre for Ecology & Hydrology (<https://eip.ceh.ac.uk/>). After some processing, the data consist of hourly readings over approximately 15 months, where the rainfall data is derived from six rainfall gauges giving readings every 10 min, and the evapotranspiration is calculated hourly using the Penman-Monteith equation [12]. The output is compared to hourly readings of stream flow at a gauge near the end of the catchment.

FUSE models water storage as consisting of three compartments, the size of which is governed by three corresponding parameters. Flow into, out of, and between these compartments are governed by simple equations that rely on five further parameters. Finally, a time delay, governed by one parameter, is applied to the predicted stream flow. Full details of these equations can be found in [2].

In summary, FUSE is run by providing a time series of rainfall, a time series of evapotranspiration, nine parameters, and finally an initial condition that specifies how much water is in the compartments at the beginning. Figure 2.1 shows an

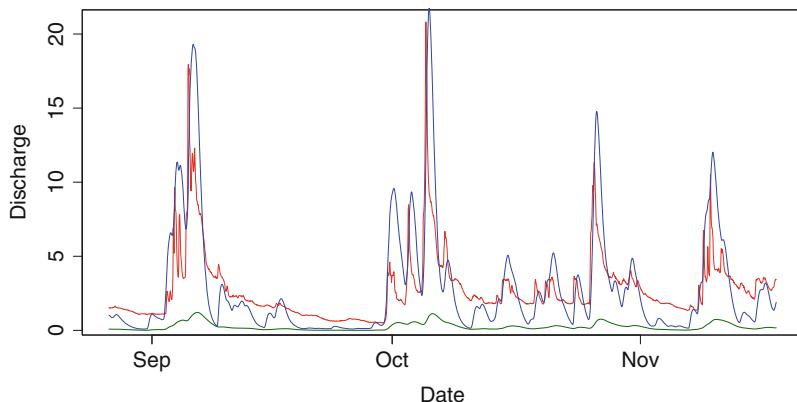

Fig. 2.1 Observed discharge (red) compared with FUSE runs for two choices of parameters

example of FUSE output for a decent choice of parameters (blue line) and a very poor choice of parameters (green line) compared with observed stream flow (red line) for a small section of the data.

3 The Bayesian Analysis of Computer Simulators for Physical Systems

This article is concerned with problems in which computer simulators are used to represent physical systems. Each simulator can be conceived as a function $f(x)$, where x is an input vector representing properties of the physical system and $f(x)$ is an output vector representing system behavior. Typically, some of the elements of x represent unknown physical properties of the system, some are tuning parameters to compensate for approximations in the simulator, and some are control parameters which correspond to ways in which system behavior may be influenced by external actions.

Analysis of simulator behavior provides qualitative insights into the behavior of the physical system. Usually, it is of interest to identify “appropriate” (in some sense) choices, x^* , for the system properties x and to assess how informative $f(x^*)$ is for actual system behavior, y . Often, historical observations, z , observed with error, are available, corresponding to a historical subvector, y_h , of y , which may be used both to test and to constrain the simulator, by comparison with the corresponding subvector $f_h(x)$ of $f(x)$. Typically, there is ensemble of simulator evaluations $F_{[n]} = (f(x_1), \dots, f(x_n))$ made at an evaluation set of input choices $x_{[n]} = (x_1, \dots, x_n)$ which is used to help address these questions.

There are many uncertainties associated with this analysis. The parameter values are unknown, and there are uncertainties in the forcing functions, boundary conditions, and initial conditions required to evaluate the simulator. Many simulators have random outputs. The complexity of the underlying mathematics forces the solutions of the system equations to be approximated. Typically, computer simulators are slow to evaluate, and so the value of the function $f(x)$ must be treated as unknown for all x except for the design values $x_{[n]}$. The data to which the simulator is matched is only observed with error. Even if all of these considerations could be addressed precisely, the computer simulator would still be an imperfect representation of the physical system.

A common representation for simulator discrepancy in practice is to suppose that there is an appropriate choice of system properties x^* (currently unknown), so that $f(x^*)$ contains all the information about the system, expressed as the relation

$$y = f(x^*) + \epsilon \quad (2.1)$$

where ϵ is a random vector expressing the uncertainty about the physical system that would remain were the simulator to be evaluated at x^* . Typically, ϵ is taken to be independent of f and of x^* , though modifications to this form are discussed in later sections. The variance of an individual component ϵ_i expresses one’s confidence in

the ability of the simulator to reproduce the corresponding physical process, while the correlation between components of ϵ expresses the similarity between different types of structural error, for example, whether underpredictions for the simulator in the past suggest that the simulator will continue to underpredict in the future. For many problems, whether this formulation is appropriate is, itself, the question of interest, that is, the goal is to determine whether there are any choices of input parameters for which the simulator outputs are in rough agreement with the system observations in the sense of consistency with (2.1).

The specification is completed by a relationship between observations z and historical system values y_h , which often is taken to be of form

$$z = y_h + e \quad (2.2)$$

where e is the vector of observational errors, taken to be independent of all other quantities in the problem.

A Bayesian analysis of such a problem therefore requires, as a minimum, prior probability distributions over the input space x , over the function values $f(x)$, for each x , and over the simulator discrepancy ϵ , and a likelihood function for e . In principle, given all of these specifications, a full probabilistic synthesis of all the sources of information in the problem can be made, to identify appropriate inputs, make effective forecasts of future system behavior, and select control parameters to optimize the ability to meet the targets of system control. For systems of moderate size and complexity, this approach is tractable, powerful, and successful.

For complex, high-dimensional problems, however, the approach encounters various difficulties. In such cases, the computations for learning from data tend to be technically difficult and time consuming, as the likelihood surface is extremely complicated, and any full Bayes calculation may be extremely non-robust and highly dependent on the initial prior specification. It is difficult to specify meaningful prior distributions over high-dimensional spaces, and the nature of the calculations makes it difficult to carry out a full sensitivity analysis on the various features of the probabilistic specification which may contribute strongly to the final inferences. Such difficulties are particularly acute when repeat evaluations of the inferential process must be made, for example, when using the prior specification to generate informative choices for the simulator design $x_{[n]}$ or using the inferential construction to facilitate real-time control of the physical process being modeled. Such complexities lead, in practice, to the use of conventional conjugate prior forms which sacrifice fidelity to one's best scientific judgements in order to simplify the technicalities of the calculations. In cases where one wishes to avoid the introduction of somewhat arbitrary simplifying assumptions, such an approach may be deemed unsatisfactory.

Much of the complexity of the standard Bayesian approach derives from the extreme level of detail which is required for a full probabilistic specification of all of the uncertainties in the problem. Therefore, it is important to recognize that there is a choice as to the primitive chosen as the basis of the stochastic analysis and that this choice determines the complexity of the calculations that are required for the analysis, as is now described.

4 Bayes Linear Analysis

The conventional Bayesian approach takes probability as the primitive quantity around which all analyses are constructed. However, it is possible to construct an alternative approach to Bayesian inference in which expectation, rather than probability, acts as the primitive. This approach is termed Bayes linear analysis, because of the linearity properties of expectation. For a careful and detailed exposition of the notion of expectation as the appropriate primitive for the subjectivist theory, see [6]. In this work, de Finetti chooses expectation over probability, as if probability is primitive, then all of the probability statements must be made before any of the expectation statements can be, whereas if expectation is primitive, then as many or as few expectation statements as one chooses can be made, so that there is the option of restricting attention to whatever subcollection of specifications one is both willing and able to specify in a meaningful fashion.

Full Bayes analysis can be very informative if conducted carefully, both in terms of the prior specification and the analysis. Bayes linear analysis is partial but easier, faster, and more robust. The approaches may be considered as complementary and use made of either, or both, depending on the requirements of the problem at hand. In this article, attention is restricted to the Bayes linear formulation.

The Bayes linear approach is (relatively) simple in terms of belief specification and analysis, as it is based only on the mean, variance, and covariance specification which is taken as primitive. Just as Bayes analysis is based around a single updating equation, the Bayes linear approach is based around the notion of Bayes linear adjustment. $E_z(y)$, $\text{Var}_z(y)$ are the expectation and variance for the vector y adjusted by the vector z . These quantities are given by

$$E_z(y) = E(y) + \text{Cov}(y, z)\text{Var}(z)^{-1}(z - E(z)), \quad (2.3)$$

$$\text{Var}_z(y) = \text{Var}(y) - \text{Cov}(y, z)\text{Var}(z)^{-1}\text{Cov}(z, y). \quad (2.4)$$

One may view Bayes linear adjustment in two ways. Firstly, this may be viewed as a fast approximation to a full Bayes analysis based on linear fitting. Secondly, one may view the Bayes linear approach as giving the appropriate analysis under a direct partial specification of means, variances, and covariances, where expectation is treated as primitive. This view is based on an axiomatic treatment of temporal coherence [7]. In this view, full Bayes analysis is simply a special case where expectations of families of indicator functions are specified, and probabilistic conditioning is simply the corresponding special case of (2.3). For a full account of the Bayes linear approach, see [11].

5 Emulation

Uncertainty analysis based on computer simulators is particularly challenging in the common situation where the simulator takes a long time to evaluate for a single choice of input parameters. In such problems, the value of the simulator $f(x)$ must

be treated as unknown unless x is a member of the evaluation set, $x_{[n]}$. In such problems, one's uncertainty as to the value of $f(x)$ must be assessed for each x which is not a member of $x_{[n]}$. This uncertainty specification is often referred to as an emulator for the simulator.

Within the Bayes linear formulation, the emulator is usually described in terms of (i) an expectation function, $E(f(x))$, which acts as a fast approximation to the simulator; (ii) a variance function, $\text{Var}(f(x))$, which acts as an assessment of the level of approximation introduced by replacing the simulator by this fast alternative; and (iii) a covariance function, $\text{Cov}(f(x), f(x'))$, which describes the similarity between different simulator evaluations and therefore determines the amount of information about general simulator values $f(x)$ that is available from the evaluation ensemble $F_{[n]}$.

A common choice for the emulator, for an individual component $f_i(x)$ of $f(x)$, is to express the function as

$$f_i(x) = \sum_j \beta_{ij} g_{ij}(x) + u_i(x). \quad (2.5)$$

In (2.5), $B = \{\beta_{ij}\}$ are unknown scalars and $g_{ij}(x)$ are known deterministic functions of x (e.g., polynomials). $Bg(x)$ expresses global variation in $f_i(x)$, namely, those features of the surface which can be assessed by making simulator evaluations anywhere in the input space. Therefore, the functional forms g_{ij} must be chosen, and also a second-order specification for the elements of B is required.

As $f_i(x)$ is continuous in x , the residual function $u_i(x)$ is also a continuous function. $u_i(x)$ expresses local variation, namely, those aspects of the surface which can only be learned about by making evaluations of the simulator within a subregion near x . Typically, $u_i(x)$ is represented as a second-order stationary stochastic process, with a correlation function which expresses the notion that the correlation between the value of u_i for any two values x, x' is an increasing function of the distance between the two input values. A common choice is the squared exponential, which is used for the illustrations in this article, and is of form

$$\text{Corr}(u_i(x), u_i(x')) = \exp\left(-\left(\frac{\|x - x'\|}{\theta_i}\right)^2\right). \quad (2.6)$$

This form corresponds to a judgement that the function is very smooth. There are many choices for the form of the correlation function and a wide literature on the merits of different choices [15]. How important this choice is depends largely on the proportion of the uncertainty that can be attributed to the global portion of the emulator. In this article, an approach in which a lot of effort is expended on the choice of global fit is favored. Firstly, this is because the choice of appropriate residual correlation function is a difficult problem, largely because, in practice, most functional outputs display different degrees of smoothness in different regions of the input space. Therefore, reducing dependence on this choice

is often prudent. Secondly, as shall be described, much of the analysis is greatly simplified by having a substantial component of the variation described by the global surface.

An emulator is fit based on an analysis of the evaluation ensemble $F_{[n]}$ in combination with expert judgements as to the form of the response surface. There are as many ways to build the emulator as there are methodologies for statistical modeling of complex functions; a good introduction is [13] and see, for example, [15]. A simple approach, which often is reasonably successful, is to choose the functional forms g_{ij} by least squares fitting and then to fit the correlation function for each $u_i(x)$ to the residuals from the least squares fit, either by some method such as maximum likelihood or by some trial-and-error method based on cross-validation or other forms of assessment of quality of fit. Whichever approach taken, one must apply careful diagnostic testing to ensure reliability of the emulator, see, for example, [1].

Often, the simulator will include parameters that have been judged, by some combination of expert judgement and statistical analysis, to have minor influence on component $f_i(x)$. In such cases, it is often profitable to remove these parameters from the mean function and from u_i . That is, if the parameter set is partitioned into active parameters x_A and inactive parameters x_I for a particular component f_i , then the emulator becomes

$$f_i(x) = \sum_j \beta_{ij} g_{ij}(x_A) + u_i(x_A) + \delta_i(x_I). \quad (2.7)$$

The variance of δ_i can be estimated by running the simulator at different values of x_I for fixed x_A . Typically, this variance will be small relative to that of u_i ; if not, it is questionable whether x_I is truly inactive.

Such methods require sufficient simulator evaluations to support the assessment of the emulator. If the simulator is slow to evaluate, then it is often possible to develop a joint uncertainty model, where $f(x)$ is combined with a fast approximate version, $\tilde{f}(x)$ say, based on reducing the level of detail in the representation of the input space or approximating the simulator solver, for example, by increasing the time step or reducing the number of iterations of the solution algorithm. Many evaluations of $\tilde{f}(x)$ can then be made, to fit an emulator of the form

$$\tilde{f}_i(x) = \sum_j \tilde{\beta}_{ij} g_{ij}(x) + \tilde{u}_i(x) \quad (2.8)$$

The form (2.8) acts as a prior specification for $f_i(x)$. Then, a relatively small evaluation set $F_{[n]}$ can be chosen, which, in combination with a representation of the relationship between the forms of the global surface in the two simulators, for example,

$$\beta_{ij} = \alpha_i \tilde{\beta}_{ij} + \gamma_{ij}, \quad u_i(x) = \alpha \tilde{u}_i(x) + r_i(x) \quad (2.9)$$

enables adjustment of the prior emulator to an appropriate posterior emulator for $f_i(x)$. This approach is effective because, in general, it takes far more function evaluations to identify the appropriate forms $g_{ij}(x)$ than to quantify the various coefficients of the model, particularly if it is possible to fit regression components which account for a large component of global variation. See [5] for a description and illustration of this approach and, in particular, of the role of the prior construction over the fast simulator in constructing an efficient small sample evaluation set $F_{[n]}$ on the slow simulator.

6 Example: Emulating FUSE

Instead of attempting to emulate the entire FUSE output, it is more instructive as an example to consider instead the emulation of a few interesting summaries. As well as being simpler, this focuses on quantities that are both physically meaningful and can be emulated well. The quantities of interest will be the maximum stream flow (denoted f_1) and the total stream flow (denoted f_2) in the period from hours 7800 to 8800. This corresponds roughly to September to October in Fig. 2.1.

The evaluation set $x_{[n]}$ is drawn from the hypercuboid of plausible parameter values suggested in [2, Table 3], using a maximin Latin hypercube, rescaling all parameters so they take values in $[0, 1]$. The value of n used was 1000; in practice, this is rather more than is usually necessary to build an emulator, but the speed of the model allows such a large set to be used conveniently. The simulator is then run at each parameter choice in $x_{[n]}$ to give a set of simulated quantities $f_1(x_{[n]})$, $f_2(x_{[n]})$.

Least squares fitting was used to find good choices of $g_{ij}(x)$ in (2.5). The first observation was that it was difficult to find any good global fit for f_2 , with the best attempt giving an adjusted R^2 of only 0.65. This is unlikely to be sufficient to build a good emulator. So initially, an emulator was built for f_1 only – f_2 is revisited later in the account.

For f_1 , the maximum discharge, the best model found was a cubic fit, giving adjusted R^2 of around 0.9. Looking more closely at this model suggested that a transformation of parameter $x_{(8)}$ to its logarithm might be profitable. Doing this not only allowed a simplification to a quadratic fit but also increased the R^2 to 0.958. So, the form of the emulator is now given by

$$f_1(x) = \beta_1 + \sum_{j=1}^9 \beta_{1jj} x_{(j)}^2 + \sum_{j=1}^9 \sum_{k < j} \beta_{1jk} x_{(j)} x_{(k)} + \sum_{j=1}^9 \beta_{1j} x_{(j)} + u_1(x). \quad (2.10)$$

The next step is to seek inactive variables. These can be suggested through stepwise selection, removing at each step the variable that has the smallest influence. Following such a strategy for this example suggested removing parameters $x_{(2)}$, $x_{(4)}$, $x_{(6)}$, and $x_{(7)}$, with the R^2 falling only to 0.95 after all are removed. Removing a fifth variable (either $x_{(3)}$ or $x_{(5)}$) would reduce the R^2 to 0.94; this is still a small change

but it was decided not to remove any further variables. Thus, the final form of the emulator is, following (2.7),

$$f_1(x) = \beta_1 + \sum_{j \in A} \beta_{1jj} x_{(j)}^2 + \sum_{\substack{k, j \in A \\ k < j}} \beta_{1jk} x_{(j)} x_{(k)} + \sum_{j \in A} \beta_{1j} x_{(j)} + u_1(x_A) + \delta_1(x_I) \quad (2.11)$$

where $A = \{1, 3, 5, 8, 9\}$ and recalling that $x_{(8)}$ is still the logarithm of the original parameter.

This is almost everything needed to perform the Bayes linear adjustment in (2.3) and (2.4). The goal is to predict the value f_1 of the simulator at some new parameter choice x , using the values $f_1(x_{[n]})$ calculated earlier. Thus, in the Bayes linear adjustment equations, $f_1(x)$ plays the role of y , and $f_1(x_{[n]})$ plays the role of z .

Applying the Bayes linear adjustment in (2.3) and (2.4) requires prior specifications for the relevant expectations and variances. It is assumed a priori that $E(u_1(x)) = 0$, $E(\delta_1(x)) = 0$ and that both $\text{Var}(u_1(x))$ and $\text{Var}(\delta_1(x))$ do not depend on x . Correlation between $u_1(x)$ and $u_1(x')$ is given by (2.6), and it is assumed that there is no correlation between $\delta_1(x)$ and $\delta_1(x')$. If there was suitable expert knowledge and little data, the remaining values would have to be carefully elicited from the experts. In this example, however, there is little expert knowledge, but there are lots of simulator runs. It is therefore reasonable to use some of the estimates from the least squares fit: for $E(\beta_{1j})$ and $\text{Var}(\beta_{1j})$, the corresponding estimates from the fit can be used (where with 1000 runs, the variances will be very low), and for $\text{Var}(u_1)$, the residual variance can be used. This leaves only $\text{Var}(\delta_1)$: this is estimated by fixing values of x_A and running the simulator for a range of x_I . These runs gave an estimate for $\text{Var}(\delta_1)$ of 3×10^{-5} , which is very small compared with f_1 (usually around 3). This therefore gives some confidence that this estimation method should be sufficient.

Only one quantity remains to be assessed: θ_1 . Following the argument from [16] that, for an emulator whose mean function is a polynomial of order p , a plausible choice for θ_1 is $1/(p+1)$, an initial choice of $1/3$ was tried, which was then refined by cross-validation. For a given value of θ_1 , for each x_i in $x_{[n]}$, one can calculate $E_{f_1(x_{[-i]})}(f_1(x_i))$ and $\text{Var}_{f_1(x_{[-i]})}(f_1(x_i))$ using the other elements $x_{[-i]}$ of $x_{[n]}$ to perform the adjustment. Here, $E_{f_1(x_{[-i]})}(f_1(x_i))$ is the adjusted expectation (see (2.3)) for $f_1(x_i)$ having observed $f_1(x_j)$ for each other x_j in $x_{[n]}$, and $\text{Var}_{f_1(x_{[-i]})}(f_1(x_i))$ is the corresponding adjusted variance (see (2.4)). Then, one can check whether $E_{f_1(x_{[-i]})}(f_1(x_i))$ is close to $f_1(x_i)$, relative to the size of $\text{Var}_{f_1(x_{[-i]})}(f_1(x_i))$. If the prediction is many standard deviations away from $f_1(x_i)$ for many x_i , this suggests a problem with the model: either it is not fit for purpose, or the correlations implied by θ_1 are too strong. On the other hand, if all the predictions are very close to $f_1(x)$ relative to the size of the standard deviations, this suggests that the adjusted variance at many points is too low. This could happen because the correlation between nearby points is being underestimated, and hence a higher θ_1 could be tried to give accurate predictions with a lower variance.

The choice $\theta_1 = 1/3$ leads to the latter case: the emulator successfully predicts all 1000 points to within 3 standard deviations, but almost all points are predicted to within 1 standard deviation and indeed over 80 % of the points are predicted to within 0.5 standard deviations. That is, the emulator variance is too conservative, which would lead to poor performance in the history-matching process later. This could be because θ_1 is too small. Indeed, increasing θ_1 to 0.45 gave more sensible variances and predicted 98 % of the simulations within three standard deviations.

There are several reasons why one might be comfortable with 98 % accuracy. In a sample of 1000, one would expect some predictions to be so inaccurate anyway. Further, more investigation of the parameters that led to poor predictions revealed that they were mostly simulations that gave very high or very low values for f_1 , and the emulator was correctly predicting that these parameters would give extreme values. The only failure of the emulator was in underestimating quite how extreme these were. As shall soon be seen, the two main dangers of an inaccurate emulator are predicting f_1 to be close to reality when it is in fact far away or predicting f_1 to be far from reality when it is in fact close. For this emulator, these cases occur only very rarely.

As a summary of this validation, Fig. 2.2 shows an example of the predictions (black line), three standard deviation bounds (blue lines), and observed values (red line) for predicting 100 parameter choices from the other 900. Observe that large differences between predictions and observations do indeed occur when the adjusted variance is high.

To conclude this section, note that, once the fit has been performed, the updates in (2.3) and (2.4) are performed very quickly. Inverting $\text{Var}(f_1(x_{[n]}))$ needs only be done once, so for a particular candidate point x , the only computations are

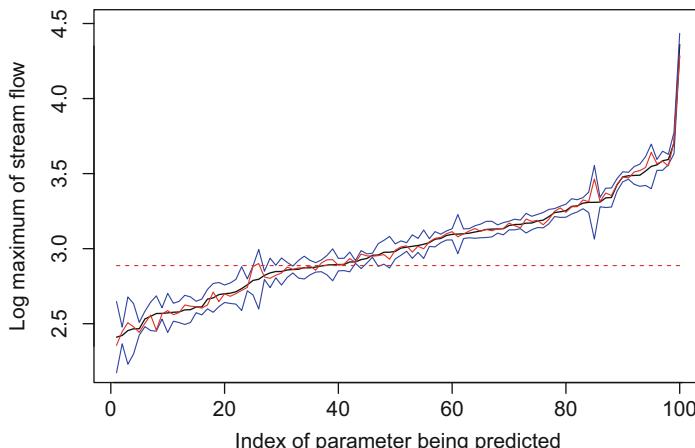

Fig. 2.2 Emulator of $f_1(x)$ (black line) with three standard deviation bounds (blue lines), together with observed value of $f_1(x)$, for 100 parameter choices, predicted from 900 other simulator runs. The horizontal dashed line represents the observed log maximum of stream flow

calculating distances between x and $x_{[n]}$ and then performing a matrix multiplication. Thus, the emulator can be evaluated at very many locations. Even for a simulator as fast as FUSE this is useful; for slower simulators it is invaluable.

7 Model Discrepancy

A physical model is a description of the way in which system properties (the inputs to the model) affect system behavior (the outputs of the model). This description involves two basic types of simplification.

Firstly, the properties of the system are approximated, as these properties are too complicated to describe fully, and anyway they are not completely understood. Secondly, the rules for finding system behavior, given system properties, are approximated, because of necessary mathematical simplifications, simplifications for numerical tractability, and because the physical laws which govern the process are not fully understood.

Neither of these approximations invalidates the modeling process. Problems only arise when these simplifications are forgotten, and the uncertainty analysis of the simulator is confused with the corresponding uncertainty analysis for the physical system itself. As a basic principle, it is always better to recognize than to ignore uncertainty, even if modeling and analysis of such uncertainty is difficult and partial. Thus, it is important to recognize that models do not produce statements about reality, however carefully they are analyzed. Such statements require structural uncertainty assessment, taking account the mismatch between the simulator and the physical system.

One may distinguish two types of model discrepancy, internal and external. The term internal discrepancy is used to refer to any aspect of structural discrepancy whose magnitude can be assessed by experiments on the computer simulator. Internal discrepancy analysis gives a lower bound on the structural uncertainty that must be introduced into the simulator analyses.

How internal discrepancy is assessed depends on the access that one has to the simulator code and one's ability and willingness to carry out the relevant experiments. For example, many simulators assess, at each time point, a state vector from which the system outputs are evaluated, and then propagate the state vector to the next time point by various system rules. If it is straightforward to access the state vector, then it may be possible to introduce an additional stochastic term into the state vector propagation to express uncertainty as to the principles underlying this process. In the flood example, the forcing functions and initial conditions are varied. Also assessed is the effect of allowing various simulator parameters, considered constant within the simulator, to vary slowly over time.

The term external discrepancy relates to all of those aspects of structural discrepancy that have not been addressed by one's assessments for internal discrepancy. In particular, it relates to the inherent limitations of the modeling process embodied in the simulator, based on missing or misconceived aspects of the physical simulator. There are no experiments on the simulator which may reveal the magnitude of this

discrepancy. It is determined by a combination of expert judgements and statistical estimation.

A common representation for simulator discrepancy in practice is to use the form (2.1). Typically, ϵ is taken to be independent of f and of x^* , though there are many possible modifications to this form. For example, (2.1) combines the internal and external discrepancy into a single quantity. However, if the two aspects of discrepancy have been carefully assessed separately, then discrepancy term may be separated into two components, each with their own second-order structure. For example, one might treat the variance of the internal portion of ϵ as a scale parameter dependent on x^* , which is assessed by computer experiments.

More generally, the external discrepancy may be quantified by careful assessment of the reasons for the failure of the simulator to match with reality. One formalism that allows expression of this difference is through what is termed reified modeling (from reify – to treat an abstract concept as if it was real). In this approach, the reason that the simulator is informative for the physical system is considered to be that it is an informative, but imperfect, representation for the actual relationships between system properties and system behavior. The reified model f^* is one's best expression of such relationships. It is not possible to build and evaluate f^* , but it can be emulated.

Therefore, a more careful construction of external discrepancy proceeds by separating the discrepancy between the simulator and the physical system into two parts. The first is the difference between f and f^* and the second is the difference between $f^*(x^*)$ and the system behavior y . There are many ways to construct an emulator for f^* . The simplest is to build it on top of the emulator for f . Suppose that the emulator for f is given by (2.5). Then an emulator for f^* might take the form

$$f^*(x, w) = B^* g(x) + u^*(x) + u^*(x, w)$$

where one might model one's judgements relating B and B^* in a similar manner to (2.9) and specify a correlation function relating $u(x)$ and $u^*(x)$, while treating $u^*(x, w)$, with additional parameters, w , as uncorrelated with the remaining terms in the emulator. For discussion and illustration of reification, including a treatment of structured reification which incorporates systematic modeling for all aspects of simulator deficiency whose effects one wishes to represent explicitly, see [9].

8 Example: Model Discrepancy for FUSE

This article uses a simple method for estimating internal discrepancy, following a similar approach to [10]. The strengths of this method are that it is easy to apply, does not involve any complicated theory or calculations, can incorporate expert knowledge where available but can be performed without any, is trivially parallelizable, and does not require a huge number of simulator runs (although

would still not be suitable for a very slow simulator). The main disadvantage is that the estimate derived is likely to be crude, as shall be seen in later sections.

The core idea is to identify aspects of internal discrepancy, make suitable perturbations of these aspects, run the simulator for each perturbation, and assess the variability of this output. The aspects perturbed in this example were the rainfall and evapotranspiration time series, the initial condition, and the parameter vector. The details of the perturbations themselves can be found in the Appendix. Once the perturbation method is determined, the procedure used is as follows.

1. Select an evaluation parameter set $x_{[n]}$.
2. Generate m perturbations of each type.
3. Combine these to form m overall perturbations.
4. Run the simulator at each x_j in $x_{[n]}$ and each combined perturbation (giving $n \times m$ total simulator runs).
5. For each run, calculate the quantities of interest f_i (in this example, log maximum and total stream flow in the relevant region).
6. For each x_j and each quantity of interest, calculate the standard deviation of the set of m simulations.
7. Take the maximum of these as the estimate of internal discrepancy for each quantity of interest.
8. Check whether the perturbations tend to bias the results in one direction or the other. This does not occur in the example. Were it to occur, then the later assumption that the expected value of internal discrepancy is zero would not be valid.

The justification for taking the maximum rather than, say, the mean, is that the estimate for internal discrepancy should be conservative, because it could be that x^* is in the region of high internal discrepancy. Indeed, it could be argued that even the maximum is not conservative enough, since only a small number of parameters have been sampled. In this example, the authors' experiences with the model suggested that the region of high internal discrepancy was unlikely to include x^* , so the maximum was considered to be acceptable.

Running such perturbations for $n = 50$ and $m = 300$, the log maximum of discharge yielded a maximum internal discrepancy variance of 0.124^2 . Observe that this is very high relative to the emulator variances from earlier. In practice, this will often be the case; later, one way of refining this estimate is considered.

9 History Matching

A typical Bayesian approach to the analysis of relations (2.1) and (2.2) treats the quantity x^* as a true but unknown parameter, specifies a prior distribution for x^* , and carries out a simulator calibration exercise to derive the posterior distribution of x^* given z . However, in many problems, for example, the rainfall runoff simulator being used as an illustration, it may not be believed that there is a unique true but

unknown choice for x^* . Indeed, it is often possible that there are no good choices for x^* , due to deficiencies in the simulator.

A simple alternative to calibration is “history matching.” This method describes the identification of all input choices x for which the match of the simulator to the data is judged to be consistent with the uncertainty expressed in relations (2.1) and (2.2). Sometimes, this analysis will be sufficient for the problem at hand. At other times, it may serve as a precursor to a more traditional simulator calibration. As full Bayes calibration analysis is technically difficult and non-robust for large and complex simulators, it is usually helpful to identify the region of the input space which offers acceptable fits to the data, firstly, to act as a check on the simulator, by testing whether there are any input values for which the simulator gives an acceptable match to the data, and, secondly, to (massively) reduce the search space for the Bayesian algorithm.

The history match is carried out by assessing, for each x , the number of standard deviations between z and $f(x)$. If x is one of the members x_i of the evaluation set, $x_{[n]} = (x_1, \dots, x_n)$, then the value of $f(x)$ is known so that the variance of $(z - f(x))$ is the sum of the observation variance and the discrepancy variance. For each other value of x , instead z must be compared to the emulator mean for $f(x)$, and the difference, $(z - E(f(x)))$, has variance $V(x)$ given by the sum of the observation, discrepancy, and emulator variance.

For each value x , the number of standard errors between z and $E(f(x))$ can be assessed. This distance is expressed as an “implausibility” measure. For example, taking a single component $f_i(x)$ corresponding to data output z_i , a potential implausibility measure is

$$I_{(i)}(x) = \frac{|z_i - E(F_i(x))|^2}{V_i(x)}. \quad (2.12)$$

Large values of $I_{(i)}(x)$ suggest that it is “implausible” that this choice of x will give an acceptable representation of the observed data. Small values of $I_{(i)}(x)$ are consistent with the possibility that x will offer an acceptable representation, but could simply correspond to very large values of the emulator variance, so these values may not necessarily be viewed as plausible. Because the emulator is fast to evaluate, the implausibility measure is correspondingly fast to evaluate as x is varied.

The implausibility calculation can be performed on individual outputs or by using the corresponding multivariate calculation over subvectors. The implausibilities are then combined. For example, one might assess $I_M(x) = \max_i I_{(i)}(x)$ and consider that an input x would not be an acceptable choice if it gave a poor fit to any of the outputs of interest. It is a matter of judgement as to the magnitude of $I(x)$ that is considered unacceptable. There are various probabilistic heuristics that may be used as guidance in this judgement, for example, the “3 σ rule,” which states that for any continuous, unimodal distribution, at least 95 % of the probability lies within 3 standard deviations of the mean (see [14]).

Removing all input points, judged implausible leaves a “non-implausible” subregion of the input space. Efforts may now be refocused on this subregion, by making more simulator runs, refitting the emulator, and repeating the analysis over this subregion, to reduce further the non-implausible region. This cycle of resampling, re-emulating, and reducing the non-implausible space by use of implausibility measures can be repeated until the implausible region cannot be reduced any further.

A key feature that makes history matching so much more tractable than the standard Bayesian analysis is that there is no need to match to all of the data at once. At the beginning, some of the outputs will be relatively straightforward to emulate, while others will be much more difficult, as they demonstrate many different modes of behavior over the input space. Therefore, the initial waves of history matches are based around subvectors whose elements are both straightforward to emulate and physically meaningful. Reducing the size of the input space leads to focussing on parameter values which are constrained to correspond, in at least some aspects, to the actual behavior of the physical system. This means that then various of the other outputs will become straightforward to emulate. Thus, the size of the non-implausible region is progressively reduced by gradually expanding the collection of outputs to which the simulator can be matched. This process may be viewed as an iterative global search for the collection of all choices of x^* which would give acceptable fits to historical data. For examples and discussion of history matching, see, for example, [3] and [16].

10 Example: History Matching FUSE

Most of the components needed in (2.12) are now in place. The emulator gives $E_{f_1(x_{[n]})}(f_1(x))$ for any x . From the data, $z_1 = 2.89$. $V_1(x)$ is the sum of the emulator variance (calculated earlier), the measurement error (assessed as $(1/30)^2$ for the gauges in question), and the model discrepancy. This final component is a sum of the internal discrepancy (estimated as 0.124^2 earlier) and the external discrepancy, assessed informally as the same as the measurement error. Observe that the internal discrepancy is much higher than the external discrepancy and the measurement error, so the exact choices for these two quantities should be expected to have relatively minor influence on the history match.

Visualizing history matching is difficult in many dimensions, but useful two-dimensional plots of implausibility can be drawn. Consider a grid on the five-dimensional active parameter space, with say 50 grid points in each dimension, giving 50^5 points in total. For each x in this grid, $I_1(x)$ can be calculated and compared to 3^2 . Now consider the grid for only two of these five parameters. Each point in this grid corresponds to 50^3 parameters in the full grid. For each such point, the proportion of non-rejected parameters can be computed and these proportions can be plotted. The plots in Fig. 2.3 show such an approach, using parameter pairs $x_{(1)}$ and $x_{(22)}$, and $x_{(19)}$ and $x_{(22)}$. A location is colored red if most parameter choices at this pair are rejected and colored white if most are accepted. This allows

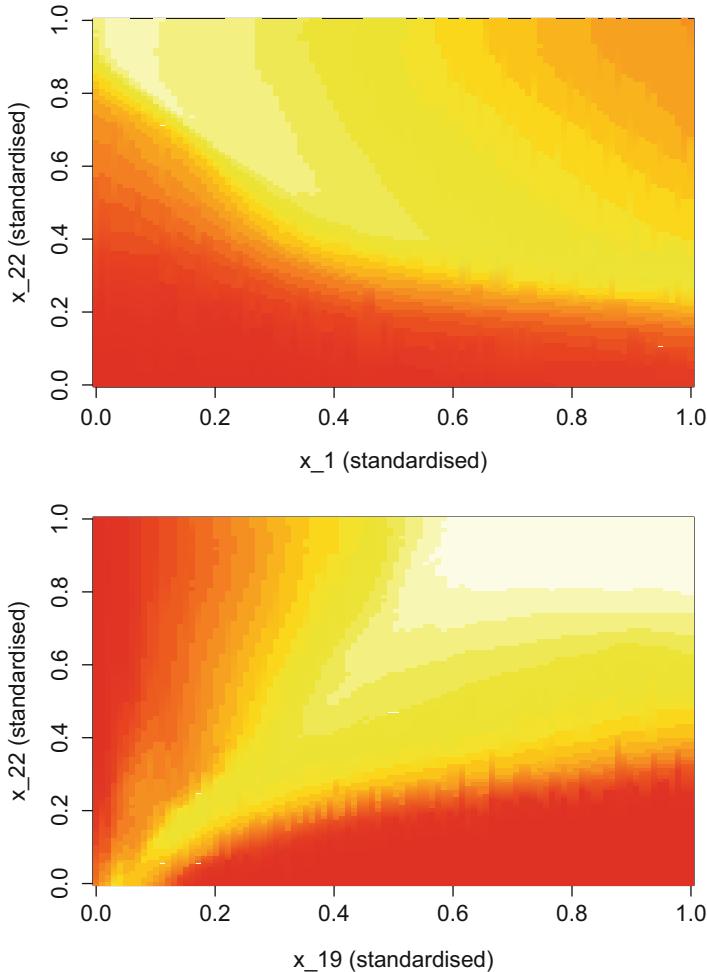

Fig. 2.3 Proportions of parameter space rejected at each pair of $(x_{(1)}, x_{(22)})$ and $(x_{(19)}, x_{(22)})$. Red represents almost all points rejected, and white represents almost all points accepted

visualization of the shape of the non-implausible region or regions. Note that this procedure involves very many calculations and requires the emulator: running the simulator at all these grid points would not be feasible even for FUSE.

The next step is to apply the standard method of refining the non-implausible region through successive “waves” of emulation and history matching. A new hypercube of $n_2 = 2000$ parameter choices $x_{[n_2]}$ was generated, and for each x in this hypercube, $I_1(x)$ from (2.12) was calculated. Any x with $I_1(x) > 9$ was removed. This leaves 1087 non-implausible parameter choices, at which the simulator is run. From this, a new emulator is built for the reduced parameter space (or, if the non-implausible space were several regions, an emulator would

be built for each region – this does not occur in this example). This new emulator takes into account only the behavior of the simulator in the reduced space and so will usually be superior fit to the global model. Given a new set of parameters, the original emulator can be used to discard some implausible parameter choices and then the new emulator used to discard even more. In this particular example, however, the second emulator has relatively little impact: from a third hypercube of 2000 parameters, 915 were discarded using the first emulator, and 44 more were discarded using the second emulator. This suggests that the possibilities of f_1 have been exhausted for the moment.

10.1 Introducing f_2

As expected, very few extra points were removed in the previous step. The next step is to bring back the quantity f_2 , the total stream flow over the period of interest; recall that this was initially difficult to emulate. Now, in the reduced space, a cubic fit is possible, giving R^2 of 0.86, with inactive parameters $x_{(4)}$, $x_{(6)}$, and $x_{(9)}$. This is sufficient to perform a history match. Assessing the nugget effect of these inactive parameters, however, suggested a high nugget variance. That is, one or more of the supposedly inactive parameters has a noticeable influence. Reactivating parameter $x_{(6)}$ improved this, although the nugget variance in this case is still not much below the measurement error, which is a concern. Reactivating other parameters, however, resulted in either a very high emulator variance or a very poor cross-validation result, depending on the choice of δ_2 . It was therefore decided to accept the nugget with parameters $x_{(4)}$ and $x_{(9)}$ inactive.

Some new quantities are required: a new measurement error (estimated as around 42.6^2 , using the assessment of measurement error at a single observation, and a similar argument for correlation as was used for the rain gauge measurement error), internal discrepancy (estimated as 251^2 in the same manner as that for f_1), and a new external discrepancy (assessed informally as $(200/3)^2$). The observed quantity z_2 is 2321. Observe that the measurement error is smaller relative to the observation than for f_1 ; this is a common feature of using total discharge rather than maximum. With an emulator, observed data, and all relevant discrepancy estimates, $I_2(x)$ from (2.12) can again be calculated for any new x .

A new hypercube of $n = 2500$ parameters was generated, and history matching was run sequentially on f_1 and then on f_2 . This yielded 1001 non-implausible parameter choices, at which the simulator was run. Using these 1001, another emulator was built for f_2 , giving a total of four emulators. In this new emulator, parameter $x_{(9)}$ became active, and now the nugget effect dropped to a near-insignificant value. Finally, a history match on 2800 new points with each emulator was performed, yielding 1086 non-implausible points. Leaving out the fourth history match would have yielded 1109 non-implausible points, so it appears that the limit of history matching on f_2 has been reached as well.

As an example, the plots from Fig. 2.3 are extended to cover each wave of history matching; this is shown in Figs. 2.4 and 2.5.

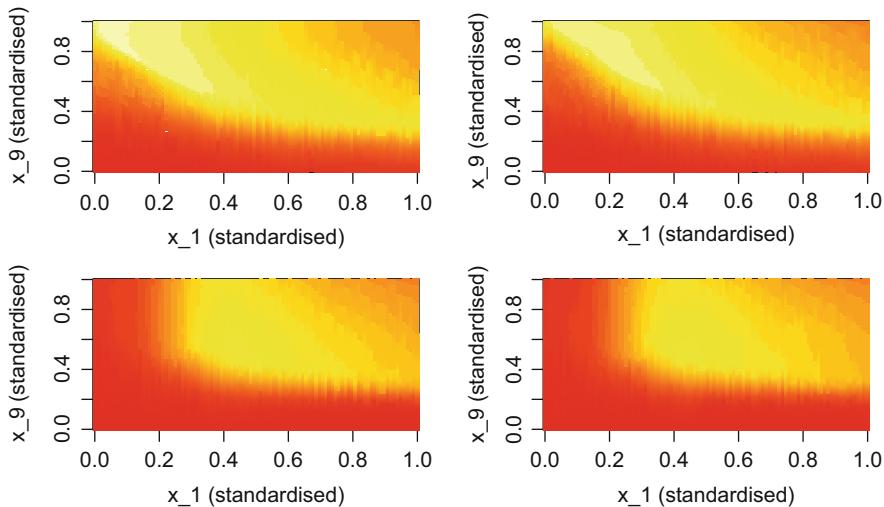

Fig. 2.4 Proportions of parameter space rejected at each pair of $(x_{(1)}, x_{(22)})$, over all four waves of history matching. Red represents almost all points rejected, and white represents almost all points accepted

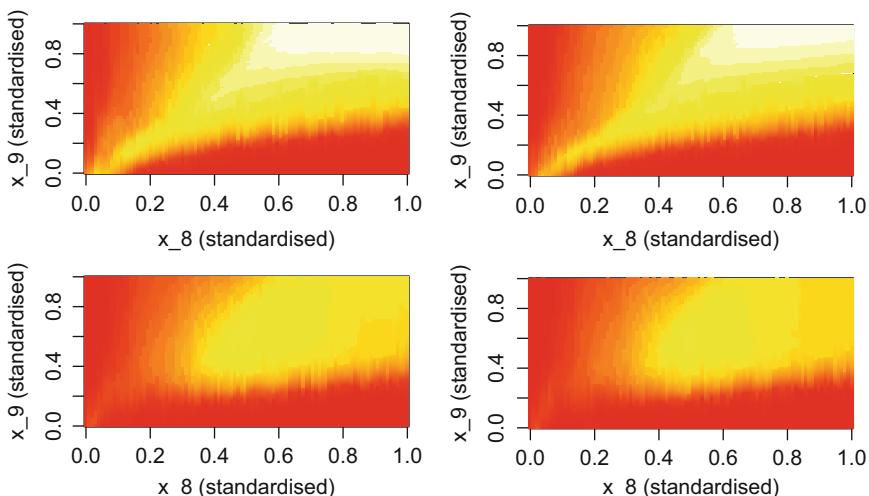

Fig. 2.5 Proportions of parameter space rejected at each pair of $(x_{(19)}, x_{(22)})$, over all four waves of history matching. Red represents almost all points rejected, and white represents almost all points accepted

Having again reached the limit of f_2 , but still with a fairly large non-imausible parameter space, the likely next step in practice would be to seek additional summaries to emulate or perhaps now attempt emulation of the whole time series at once. This would follow essentially the same pattern, so this example is not pursued further in this way.

10.2 Impact of External and Internal Discrepancy

This approach can be used to investigate the influence of the various discrepancies. One question is whether the external discrepancy is too low or conversely whether the estimated internal discrepancy represents most of the model discrepancy. If the history-matching procedure was returning no or very few non-imausible parameters, this might be a sign that the external discrepancy was too low. In the example, the non-imausible region is still large, so there is no particular reason to increase the external discrepancy. Note that if a third summary f_3 was introduced, and this rejected almost all points, then there may be reason to increase the external discrepancy at earlier stages.

On the other hand, it seems likely given its relative size that the internal discrepancy is the driving factor. To investigate this, the external discrepancy was set to zero. A history match under these conditions yielded 1048 non-imausible points, compared with 1086 with external discrepancy included. As expected, these numbers are close. Given that the estimate of internal discrepancy was quite crude, but very influential, this quantity would seem to need more attention.

There is noticeable variation in the 20 estimates for internal discrepancy calculated earlier. Using the maximum of the 20 estimates at all points could therefore be significantly overestimating the internal discrepancy at many points (and underestimating at some). This could be overcome by another use of emulation. The results of the internal discrepancy experiments can be viewed as a slow computer simulator, and so the emulation framework could be used to predict the result of those experiments at any other parameter choice. This would provide an expected value and a variance for the internal discrepancy variance at any parameter choice x , which would be used in the calculation of $I_i(x)$. Pursuing this idea is outside the scope of this article.

One final investigation is to suppose that the simulator is perfect, that is, that the measurement error, internal discrepancy, and external discrepancy are all zero. Running the history-matching procedure rejects all but 3 % of the parameter space. This is very small compared with the reductions already seen. The conclusion is that the emulators are powerful, and it is the intrinsic uncertainties in the simulator and observations that are restricting the ability to remove parameter choices.

11 Forecasting

Consider the prediction of future system outcomes, y_p , from data on past system outcomes, z . In order to make a Bayes linear forecast for y_p given z , the second-order specification relating these two vectors must be constructed. z is linked to y_p through relations (2.1) and (2.2). This specification divides into two parts. The first part arises from uncertainty as to the simulator values and the appropriate choice for x^* . The mean and variance of $f(x)$, for any x , are obtained from the mean and variance functions of the emulator for f . Using these values, the mean and variance of $f(x^*)$ can be computed by first conditioning on x^* and then integrating out x^* ,

over the input region identified by history matching. These values are combined with the second-order specification for the simulator discrepancy ϵ , derived, typically, as a combination of internal and external discrepancies. Adding the observational variance for z gives the joint second-order structure required, from (2.3), (2.4), the Bayes linear adjusted mean and variance for y_p given z ; for details, see [4].

This analysis is fast and straightforward, even for high-dimensional systems. It is sufficiently tractable to serve as a basis for a general forecasting methodology including suggesting informative designs for evaluating the simulator in order to minimize forecast variance, careful sensitivity analyses to identify the impact of the various modeling assessments that have been made on the accuracy of the forecast, and real-time control of the process.

This analysis is largely based on exploiting the global variation in the emulator and is most effective when the local component of emulator variation is small. A more detailed forecast, exploiting the local component of variation, can be made by using the method of Bayes linear calibrated forecasting. In this approach, one must construct a Bayes linear assessment \hat{x} for x^* given z , evaluate the simulator at \hat{x} , to give value $\hat{f} = f(\hat{x})$, compute the covariance between \hat{f} and (z, y_p) , and construct the Bayes linear adjustment of y_p based on both z and \hat{f} ; for details, see [8].

12 Example: Forecasting for FUSE

The quantity chosen to forecast was log maximum in the next rainfall period (the period beginning in October in Fig. 2.1). Only the simplest approach to forecasting is applied in this example. Note that across the non-imausible region, the simulator typically predicts log maximum in the range 2.5–3.5 for this period (the observed value is 3.03), so this gives an idea of the best accuracy of prediction that can be hoped for.

The first step is to build an emulator for this new quantity f_3 in the non-imausible region. This proceeded as usual, using a cubic fit and $\theta_3 = 0.35$. With this emulator, along with estimates of the discrepancy for f_3 and a given x^* , a prediction for $f_3(x^*)$, and hence z_3 , could be made. The same measurement error and external discrepancy as for f_1 were used, and internal discrepancy was estimated as usual from the 20 internal discrepancy experiments.

So, given x^* , the expected value and the variance of z_3 can be calculated. Since x^* is unknown, a uniform prior over the non-imausible region is assumed (since there is no particular information to suggest a nonuniform distribution). Therefore, x^* can be integrated out to find the mean and variance of z_3 , no longer conditional on x^* .

In the example, this gives $E(z_3) = 2.93$ with a standard deviation of 0.31. As expected, the uncertainty on this estimate is high. Although the high internal discrepancy contributes to this, the main problem is the size of and variability within the non-imausible region – this contributes around 75% of the variance. In practice, this would be a sign to either assess discrepancies more carefully and history match again or to find new quantities to match.

13 Conclusion

Emulation and history matching give a powerful and tractable framework for learning about the output of a computer simulator (through the simple statistical approximation of the emulator) and good parameter choices at which to run the simulator (through the iterative procedure of history matching). Bayes linear analysis provides a theoretical basis for performing these history matches without needing a complex and computationally challenging full Bayes analysis, but still allowing incorporation of prior judgements. This framework brings together judgements about parameters and about the simulator and its shortcomings, training runs of the simulator and of faster approximate simulators, and discrepancy estimates on the simulator. As shown in the example, this can involve straightforward and computationally inexpensive calculations to quickly reduce the non-imausible space of parameters. Once this is completed, forecasting for the future follows naturally.

The example contained simple estimations of both external and internal model discrepancy. These calculations can be extended in several ways if a more careful assessment of model discrepancy is required. As discussed earlier, the external discrepancy can be explored more thoroughly by the introduction of the reified model f^* . The internal discrepancy calculations can be improved by emulating the result of the internal discrepancy experiments, that is, by building a model for the standard deviation (and possible expected value) of the internal discrepancy for each parameter choice x . This would give low internal discrepancy in region where there is reason to believe it should be low, avoiding the problem encountered in the example where the high internal discrepancies occurred in implausible regions of the parameter space.

Appendix: Internal Discrepancy Perturbations

In this appendix, a description of the internal discrepancy experiments is provided. The first step is to identify potential quantities to perturb. For FUSE, the obvious quantities to choose are the two input time series and the initial condition. Also, the parameters could be perturbed at every time step. Similarly, the state vectors could be perturbed at every step, but this was not feasible in FUSE. Other possibilities not considered here include the time scale of the simulator and the accuracy of the numerical solver.

The next step is to informally assess the potential influence of each quantity. For example, increasing all rainfall by 10% makes a large difference to the output, whereas increasing all evapotranspiration by 10% makes a smaller but noticeable difference. Meanwhile, making large changes to the initial condition leads to extremely small changes away from the start of the simulation (recall that the quantities of interest are near the end of the simulation). From these initial explorations, each quantity can be categorized: if it has very little influence, it may

not be worth perturbing; if it has a small influence, it may be worth including but not expending much effort on; if it has a large influence, it is worth carefully modeling. The outcome of this exploration for FUSE suggested that the initial condition was hardly relevant, the evapotranspiration was worth including, and the rainfall and parameter perturbations deserved more attention.

The final step is to consider how to generate perturbations of each quantity. The initial condition is ignored. For evapotranspiration, good estimates of observation uncertainty are lacking, but given the low influence of this quantity this is not too worrying: any plausible perturbation should be sufficient. Each evapotranspiration observation was multiplied by a perturbation drawn from a log-normal distribution, such that most observations were perturbed by no more than 10 %. Correlation between observations within 24 h was also included, so if a particular observation has a high perturbation, nearby ones will also. This is motivated by the daily period of the evapotranspiration time series.

Parameter perturbations are performed by multiplying each initial parameter by some random perturbation, with nearby multipliers being correlated. The size of the perturbations were chosen such that the parameters rarely changed by much more than 10 % over the course of a simulation. This creates collections of perturbations that cause the parameters to evolve slowly without sudden large changes and without a large change overall. The parameter perturbations have a significant effect on the output, but expert opinion about how these are likely to change over time and by how much is lacking. In principle, in such a situation one should make the correlation and the magnitude of the perturbations configurable parameters, so as to understand their influence. For this example, however, this complication is avoided. An example of the evolution of a particular choice of $x_{(1)}$ for a particular perturbation can be seen in Fig. 2.6.

Perturbing the rainfall also has a significant effect on the output. In this case, however, there is some more guidance on the perturbations required. Sources of

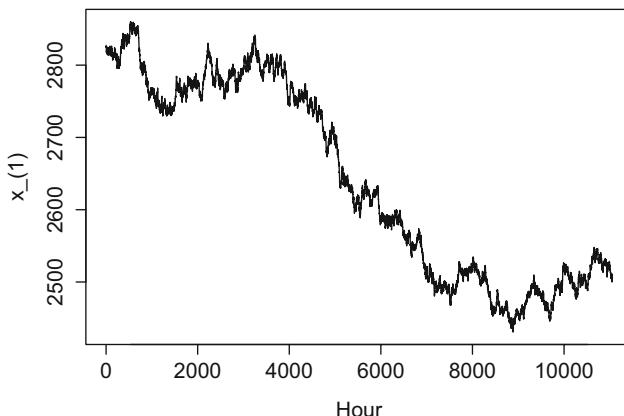

Fig. 2.6 The evolution of parameter $x_{(1)}$ for a particular parameter perturbation

uncertainty in the rainfall was attributed to three significant causes: the “local” gauge measurement error, the process of aggregating readings to the nearest hour, and the process of averaging over the catchment by kriging. Suitable perturbations from these errors were generated and combined.

The overall rainfall perturbations generated for this process typically display occasional noticeable differences but mostly small differences. This suggests that the rainfall error could contribute significantly to discrepancy for maximum stream flow, but not so much for discrepancy for average stream flow.

Abstract

In many practical situations, where one is interested in employing Bayesian inference methods to infer parameters of interest, a significant challenge is that actual data is not available. Rather, what is most commonly available in the literature are summary statistics on the data, on parameters of interest, or on functions thereof. In this chapter, we present a general framework relying on the maximum entropy principle, and employing approximate Bayesian computation methods, to infer a joint posterior density on parameters of interest given summary statistics, as well as other known details about the experiment or observational system behind the published statistics. By essentially redoing the experimental fitting using proposed data sets, the method ensures that the inferred joint posterior density on model parameters is consistent with the given statistics *and* with the model.

1 Introduction

Statistical inference methods are useful for estimation of uncertain model inputs and/or parameters based on experimental measurements of observable model outputs. Parameter estimation based on fitting to data can, of course, be done using least-squares fitting methods [4, 15, 20]. Further, this fitting can, under certain conditions such as Gaussian noise and model linearity in parameters, provide measures of uncertainty in fitted parameters. However, more generally, when these assumptions are relaxed, the most natural framework for uncertain parameter estimation based on data is a statistical framework [5].

Further, the Bayesian viewpoint on probability theory [2, 18], and associated statistical inference methods [6, 28], provide numerous advantages over alternate frequentist methods. Bayesian inference methods involve an in-built requirement for an explicit statement on prior knowledge. This requisite encapsulation of prior information in the fitting process is often necessary due to the need for regularization because of data sparsity, as is self-evident from the wide-scale use of regularization in deterministic optimization studies. The Bayesian framework incorporates regularization naturally through the prior [25, 31, 32]. Further, priors provide a basis for sequential learning and for learning from multiple experiments and heterogeneous data sources, among other uses. Bayesian methods also provide well-founded means for dealing with nuisance parameters, hypothesis testing, as well as model comparison/selection and averaging [9]. In the following, we place ourselves squarely within the Bayesian probabilistic framework and more particularly in the context of Bayesian inference for parameter estimation.

Given availability of measurement data on observable model outputs, there is a wealth of literature on the practical use of Bayesian inference methods for estimation of model inputs/parameters with quantified uncertainty [6, 28]. However, there are many practical situations where estimation of uncertain model parameters is necessary, but no data is actually available. Rather, what is typically available to the analyst is information in the form of data summaries. Our goal is to discuss the estimation of a joint probability density function (PDF) on the parameters in the absence of actual measurement data, but given such data summaries.

This is in fact a very typical scenario. A probabilistic characterization of uncertain model parameters is not typically available in the literature for a wide range of relevant models. Rather, one might find published information on nominal values and error bars on model parameters. Alternately, one might find similar

information, in terms of nominals and error bars, on specific functions of the parameters, e.g., fitted model output observables.

For example, consider a computational model $F(u, \lambda) = 0$, where u is a vector of observables and λ is a parameter vector. Estimation of uncertain predictions, namely, the PDF $p(u)$, requires knowledge of $p(\lambda)$. However, published literature, where λ is measured, does not report $p(\lambda)$. Rather, what is available is published information on nominals and error bars such as $\lambda = \mu_\lambda \pm \sigma_\lambda$, based on experimental measurements of λ . Alternately, what may be available, e.g., in an experiment where an observable $y = f(\lambda)$ was measured to estimate λ , are nominals and error bars on y , (μ_y, σ_y) . One can interpret $(\mu_\lambda, \sigma_\lambda)$ as specific moments of conditional or marginal densities on λ resulting from experimental fitting. Similarly, one might interpret (μ_y, σ_y) as similar moments of the pushed forward posterior density $p(y|D)$ or as statistics of the data distribution. The appropriate interpretation depends on the specific situation at hand. In general, such information can be viewed as providing summary statistics on the missing data D for the observable y . The core question one is faced with, then, is whether this information may be used in a statistical inference context to arrive at a meaningful density on λ .

This is, in fact, the typical situation in the context of computational modeling of chemical kinetic systems. Consider, for example, computations of a reacting hydrocarbon-air mixture. The governing equation system relies on a chemical source term for each species which involves contributions due to a number of elementary reaction steps. Considering a simple setting, the rate of progress of each reaction is determined by its stoichiometry, the participating species concentrations, and its reaction rate k , whose temperature dependence is commonly parameterized with the Arrhenius expression $k(T) = AT^n e^{-E/RT}$. The parameter vector $\lambda_i = (A_i, n_i, E_i)$ for each reaction i is typically measured using shock tube experiments and reported in different ways using nominals and error bars. One often finds reported best-fit values of (A, n, E) , with error bars only on $\ln A$, not on either of n or E . Alternately, in some cases, one finds published nominals and error bars on $\ln k(T)$ at a number of T -values. In neither case is the actual shock tube ignition data published along with the fitted parameters. Without the data, there is a need for an alternate procedure, aside from the direct application of Bayes' rule, to arrive at a meaningful joint density on the full set of parameters for all reactions. The limited amount of information available is not sufficient to arrive at a joint density exhibiting internal correlations among the Arrhenius rate parameters of each reaction, let alone correlations among parameters of different reactions.¹ Yet, a meaningful joint PDF on the input space is in principle necessary for reliable estimates of uncertainty in predictions with a chemical kinetic model. Again, the challenge is how to construct

¹It is worth noting that, presuming reported error bars in $\ln k(T)$ over a sufficient number of temperature points and considering a Gaussian parameter PDF, the joint correlation structure of $p(A, n, E)$ has been inferred through other means [23]. However, neither of these assumptions is required in the present approach.

a meaningful PDF on model parameters in the absence of actual data, but given some set of summary statistics based on a missing data set.

This problem is in fact solvable with recourse to the maximum entropy (MaxEnt) principle [7, 18]. In the absence of data, but given constraints on a distribution, the MaxEnt density is that density which maximizes relative entropy while satisfying the constraints. Maximizing entropy translates to maximizing uncertainty up to available information. The application of the MaxEnt principle relies on an explicit statement on the constraints in a partition function. This is not easily done given the above scenarios of interest because of the complex nature of the constraints. For example, we are not after a density that simply satisfies the stated nominals and bounds, but rather one that satisfies these *and* is consistent with the fitted model and the fitting that was done on the missing data to arrive at the given statistics. Rather, what is needed is a general computational procedure that allows the estimation of a joint density on parameters of interest given arbitrary and complex constraints ultimately stated as summary statistics. This is the procedure we outline in this chapter. The construction of this “data-free inference” (DFI) procedure is based on the MaxEnt principle, coupled with Approximate Bayesian Computation (ABC) methods. In the following, we outline the mathematical formulation of the method, followed by its general algorithmic structure. We then present illustrations of its use in simple problems as well as more complex problems of practical relevance.

2 Mathematical Setup

2.1 Bayesian Inference

In this section, we will provide the mathematical background for understanding the DFI procedure. We will start with a brief introduction to Bayesian inference and how it relates to entropic inference, i.e., MaxEnt.

For the examples in this chapter, it will be sufficient to only consider finite-dimensional random variables that live in a subset of Euclidean space. In general, however, let $(\Omega, \mathcal{A}, \mathbb{P})$ be the canonical probability triplet, where Ω is the sample space, \mathcal{A} the associated σ -algebra, and \mathbb{P} the probability measure on the σ -algebra \mathcal{A} . Let $X : \Omega \mapsto \mathbb{R}^d$ be a d -dimensional random variable which maps the event space into a subset of finite-dimensional Euclidean space. The random variable induces a probability triplet $(\mathbb{R}^d, \mathcal{B}, \mu)$, where \mathcal{B} is the Borel σ -algebra and $\mu \in \mathcal{P}(\mathbb{R}^d)$ is the measure induced by the random variable, where $\mathcal{P}(\mathbb{R}^d)$ is the space of all probability measures on \mathbb{R}^d . In particular, we have $\mu(B) = \mathbb{P}(\omega \in X^{-1}(B) : B \in \mathcal{B})$. When the probability measure μ is absolutely continuous w.r.t. the Lebesgue measure, we can write the density of the random variable as $\mu(x) \in \mathbb{R}$, $x \in \mathbb{R}^d$. From here on, we will assume that all measures introduced in this chapter are absolutely continuous w.r.t. the Lebesgue measure, which means that all probability measures will have an associated probability density function.

In the classical Bayesian inference procedure, consider a true model, f , which depends on an uncertain parameter $x \in \mathbb{R}^d$ and some auxiliary parameter t , which may represent some known quantities, e.g., time or temperature,

$$y_{\text{true}} = f(t; x), \quad (3.1)$$

where y_{true} represents the noiseless observation of the model. For example, $f(t; x)$ could be a linear function of x , e.g., $f(t; x) = t \cdot x$. Note that in many applications, one can make a reasonable assumption on the model form for $f(t; x)$ and the goal of the inference is then to determine the model parameters. To illustrate this point further, $f(t; x)$ may be a polynomial in t , and x represents the coefficients. Inferring x in this model is referred to as regression.

In the context of Bayesian inference, modeling x as a realization of the random variable $X \in \mathbb{R}^d$, the inference of x is the estimation of the posterior density on X given (typically noisy) observations of y_{true} . For the purposes of forward uncertainty quantification, one might also be interested in propagating the uncertain random variable X through the model $f(t; X)$, to obtain a distribution on the output. For the purposes of this work, we will focus on the Bayesian parameter estimation problem where the goal is to characterize the posterior density on X given observations of the model output.

As alluded to earlier, one does not directly observe measurements in the form of y_{true} . Instead, one observes the true model perturbed by some instrument error/noise. The Bayesian procedure now proceeds as follows. First, let $\beta(x) \in \mathcal{P}(\mathbb{R}^d)$ be a prior density on X , which represents our prior belief on the uncertain parameters [18]. Next, the likelihood or probability that the data came from a model y , not to be confused with y_{true} , with uncertain parameter $X = x$, will be denoted by $\gamma(y|x) \in \mathcal{P}(\mathbb{R}|\mathbb{R}^d)$ and is, not surprisingly, referred to as the likelihood density. Now, we have all the ingredients to apply Bayes' rule. The posterior density on the uncertain random variable X is given by the following ratio:

$$\nu(x|y) = \frac{\gamma(y|x)\beta(x)}{\int_{\mathbb{R}^d} \gamma(y|x)\beta(x)dx}. \quad (3.2)$$

The denominator is the “evidence,” or the marginal likelihood, being the integral of the likelihood over the prior-distributed parameters. For purposes of parameter estimation, it is sufficient to treat the evidence simply as a normalization constant. Thus, there is no need to evaluate the marginal likelihood integral.

For convenience, it is useful to consider the following observation model, where the noise is additive Gaussian. Thus, we write

$$y = f(t; x) + \sigma\eta \quad (3.3)$$

where $\eta \sim \mathcal{N}(0, 1)$ and σ is the standard deviation of the Gaussian noise. Generally, σ may be unknown, to be estimated from the data, and thus treated as

a hyperparameter in the Bayesian inference context. For the present discussion, we consider it known. Given this data model, the likelihood takes on the form

$$\gamma(y|x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{1}{2\sigma^2}\|y - f(t; x)\|^2\right). \quad (3.4)$$

Equation (3.2) provides a density for X given a single observation y . We now consider n observations, $\mathbf{y} = (y_1, \dots, y_n)$. Again, for convenience of illustration, we consider the case of *i.i.d* (independent and identically distributed) noise, such that $\gamma(\mathbf{y}|x) = \prod_{i=1}^n \gamma(y_i|x)$. The resulting posterior is then

$$\nu(x|\mathbf{y}) \propto \prod_{i=1}^n \gamma(y_i|x) \beta(x). \quad (3.5)$$

Now that we have a density for X , given by $\nu(x|\mathbf{y})$, let us assume we can obtain samples from this density, which is by no means a trivial task, but will help us illustrate the next point. If we propagate those samples through the data model in Eq. (3.3), we obtain the *posterior predictive* density $\rho_0(f(t, X) + \sigma\eta)$, where $X \sim \nu(x|\mathbf{y})$ and $\eta \sim \mathcal{N}(0, 1)$ [11, 22]. The posterior predictive is useful as a means of predicting the data and is often employed as a diagnostic to evaluate the quality of the inference. On the other hand, for prediction purposes, in order to estimate model predictions with quantified uncertainty, what is required is to push forward $\nu(x|\mathbf{y})$ through the predictive model. This can be done by propagating random samples of X through $f(t, x)$ alone, without the noise model. In this case, one obtains the *pushed forward posterior* density $\rho(f(t; X))$. Note the distinction between the pushed forward posterior and the posterior predictive. The posterior predictive propagates the uncertainty in X as well as the noise (and any associated uncertainty in noise model hyperparameters), through the data model. The pushed forward posterior, most commonly associated with forward uncertainty quantification, propagates the uncertainty in X through the predictive model $f(t, x)$. We will come back to these definitions after we discuss the idea of entropic inference and maximum entropy.

To motivate this transition, let us review the concept of Bayesian inference and how it relates to DFI. In the Bayesian procedure, one has the observation y^* and a likelihood function, $\gamma(y^*|x)$, which relates the data to the observation, measuring the likelihood of observing y^* given that the uncertain random variable is x . In the DFI context, we no longer observe y^* directly, but rather are given some function or summary statistic of y^* , call it $S(y^*)$, which may be a nonlinear, non-invertible mapping, e.g., $S(y^*)$ could be the variance of the observations y^* , or it could be the mean of the posterior distribution on $x \sim \nu(x|y^*)$. In this scenario, how do we calculate the likelihood for a particular realization y^* of the observed data if we only know $S(y^*)$? In other words, how do we calculate $\tilde{\nu}(S(y^*)|x)$, where $\tilde{\nu}$ does not necessarily have the same form as ν ? The hope is that the likelihood can be written explicitly as a function of $S(y)$, but this is rarely the case. Alternatively, for each

x , one could sample $S(y)$, fit a probability density, and measure the likelihood of $S(y^*)$, but this could be very costly. A less costly and more accurate procedure that integrates these two ideas is the following. The idea is to approximate the likelihood with

$$\tilde{v}(S(y)|x) \approx v(y|x)w(y), \quad (3.6)$$

where $w(y)$ is a probability density itself which weighs how close $S(y)$ is to the observed summary statistics. Essentially, this function holds information about the density of $S(y)$ w.r.t. the data space and is the work horse for this procedure. For example, $w(y) = \delta(S(y) - S(y^*))$, which means that $\tilde{v}(S(y)|x)$ is nonzero only when $y = y^*$ (assuming S is one-to-one). In the next section, we discuss how the Bayesian procedure can proceed with this new likelihood given that we only have $S(y^*)$ and not y^* directly.

2.2 Entropic Inference

In this section, we derive the Bayesian procedure from an entropic point of view [7], in which the DFI setting and the likelihood defined in Eq. (3.6) fit naturally. First, let $q(x)$ be a prior density on the parameters and $q(y|x)$ be the likelihood function relating the data and the parameters. Consider the joint density $q(y, x) = q(y|x)q(x)$ on both the data and parameters. Let $p(y, x)$ be some unknown joint density on the data and parameters, such that p is absolutely continuous w.r.t. q . The relative entropy between p and q is given by

$$\mathcal{E}(p, q) = -D_{\text{KL}}(p\|q) = -\int \log \frac{p(y, x)}{q(y, x)} p(y, x) dy dx, \quad (3.7)$$

where $D_{\text{KL}}(p\|q)$ is the Kullback-Leibler (KL) divergence from p to q [10]. D_{KL} is a pseudo-metric which enjoys some useful properties, such as convexity in both p and/or q , lower semi-continuity, and nonnegativity [10]. However, it should be noted that it is not symmetric nor does it satisfy the triangle inequality, which is why it is a *pseudo*-metric instead of complete metric. The idea of relative entropy originally came from Claude Shannon and was popularized by E.T. Jaynes [18, 26].

We now claim that the posterior density, $q(x|y)$, is a member of the class of densities that maximizes $\mathcal{E}(p, q)$ subject to a particular set of constraints. In the simplest case, where we have an observation y^* , the single constraint on the density is

$$p(y) = \delta(y - y^*), \quad (3.8)$$

so that the data is constrained to be the observation y^* , but in general, this need not be the case. In fact, in our construction, our constraint can be written more generally as

$$p(y) = \delta(S(y) - S(y^*)), \quad (3.9)$$

where $S(y)$ is again some statistic on the observation y .

Considering first the simple case with the constraint in Eq. (3.8), the feasible region for the relative entropy maximization problem is given by

$$\mathcal{P}_0 := \left\{ p(y, x) : p(y) = \delta(y - y^*), \int p(y, x) dy dx = 1 \right\}, \quad (3.10)$$

and this convex optimization problem can be written as

$$\max_{p \in \mathcal{P}_0} \mathcal{E}(p, q). \quad (3.11)$$

To summarize, the problem defined in Eq. (3.11) is to find the joint density $p(y, x) \in \mathcal{P}_0$ which maximizes $\mathcal{E}(p, q)$ or (equivalently) is *closest* to the joint prior $q(y, x)$ in terms of $D_{KL}(p \| q)$.

In order to solve this optimization problem, one can use the method of Lagrange multipliers. Note that since the constraint is a function, the Lagrange multiplier must be infinite-dimensional. Denote the Lagrange multiplier by $\lambda(y) \in \mathbb{R}$. The Lagrange function is given by

$$L(p, \alpha, \lambda) = \mathcal{E}(p, q) + \alpha \left[\int p(y, x) dy dx - 1 \right] + \int \lambda(y) [p(y) - \delta(y - y^*)] dy. \quad (3.12)$$

Differentiating and setting the roots to zero yield the solution

$$p(y, x) = q(y, x) \frac{e^{\lambda(y)}}{Z} \quad (3.13)$$

where Z is a normalization constant, to guarantee that $p(z, x)$ integrates to one, and $\lambda(x)$ is determined from the observation constraint (see [7] for a derivation). In order to satisfy the constraint, we must have $p(y) = \delta(y - y^*)$. Using Eq. (3.13), the marginal density on y is given by

$$p(y) = \int p(y, x) dx = \frac{e^{\lambda(y)}}{Z} q(y) \quad (3.14)$$

which must equal the integral constraint

$$\frac{e^{\lambda(y)}}{Z} q(y) = \delta(y - y^*). \quad (3.15)$$

Thus,

$$p(y, x) = q(x|y) q(y) \frac{e^{\lambda(y)}}{Z} = q(x|y) \delta(y - y^*). \quad (3.16)$$

Marginalizing over y finally shows that

$$p(x) = q(x|y^*) \quad (3.17)$$

which is Bayes' rule!

The entropic inference framework allows us to generalize Bayes' rule for the case when exact observations are not known, such as the case when only indirect functions of the observations, i.e., statistics, $S(y)$ are observed. In general, let $w(y)$ be a density describing the given data set, e.g., $w(y) = \delta(S(y) - S(y^*))$, as described in the previous section, and consider the modified class of feasible densities

$$\mathcal{P}_0 := \left\{ p(y, x) : p(y) = w(y), \int p(y, x) dy dx = 1 \right\}. \quad (3.18)$$

Thus, we are looking at joint densities for which $y \sim w(y)$, among the other constraints. Now, it can be shown (see [7]) that the joint density maximizing the entropy $\mathcal{E}(p\|q)$ is

$$p(y, x) = q(x|y)w(y). \quad (3.19)$$

Again, marginalizing over the data space gives

$$p(x) = \int q(x|y)w(y) dy = E_y[q(x|y)]. \quad (3.20)$$

Recall that marginalizing with the case $w(y) = \delta(y - y^*)$ brings us back to the original Bayes' rule, but in this case, since $w(y)$ may in general be any density, the analogous solution is computing the mean posterior density of x over $w(y)$. Now the DFI algorithm starts to take form. The idea is to first compute consistent data sets $y \sim w(y)$, and then, for each consistent data set, compute the posterior $q(x|y)$. Finally, to obtain samples from $p(x)$, we marginalize the joint samples over $y \sim w(y)$. This is also called linear average pooling. One disadvantage of linear pooling is that it is *not* externally Bayesian [3, 12], i.e., Bayesian updating and pooling do not commute, with the result that each consistent posterior has to be computed individually from each consistent data set, and saved, before proceeding to pooling. This can be quite inefficient. A more computationally efficient option is logarithmic pooling, which *is*, as discussed below, externally Bayesian. In this context, we average/pool the posterior densities as follows:

$$p(x) = \exp \left(\int \log(q(x|y)) w(y) dy \right). \quad (3.21)$$

Intuitively, linear pooling of densities is similar to taking the union of the densities, whereas logarithmic pooling of densities is similar to taking their intersection.

Logarithmic pooling can also be derived using an analogous maximum entropy procedure, but with the additional constraint that the joint density $p(x, y)$ can be written as $p(x)p(y)$. That is, the new feasible set is now

$$\mathcal{P}_2 = \left\{ p(y, x) : p(y) = w(y), \int p(y, x) dy dx = 1, p(y, x) = p(y)p(x) \right\}. \quad (3.22)$$

Then, it can be shown that the maximum entropy solution is Eqn. (3.21).

As already indicated, an important characteristic of logarithmic (or log for short) average pooling is that it is externally Bayesian [3, 12]. This means one can log pool the individual posteriors or, equivalently, calculate the posterior based on the log pooled likelihoods. More formally, suppose we have M samples from $w(y)$: y_1, \dots, y_M . Each data sample has a respective posterior density $q(x|y_i)$ for $i = 1, \dots, M$. We can write $q(x|y_i) = q(y_i|x)\pi(x)/q(y_i)$, where $q(y_i) = \int q(y_i, x) dx$ and $\pi(x)$ is a prior on the parameter space. For simplicity, let us assume that the prior for each posterior density is the same. If we let T denote the logarithmic average pooling operator of the M posterior densities, then it can be shown [12] that

$$T(q(x|y_1), \dots, q(x|y_M)) = T\left(\frac{q(y_1|x)\pi(x)}{q(y_1)}, \dots, \frac{q(y_M|x)\pi(x)}{q(y_M)}\right) \quad (3.23)$$

$$= \frac{T(q(y_1|x), \dots, q(y_M|x))\pi(x)}{T(q(y_1), \dots, q(y_M))}. \quad (3.24)$$

Thus, instead of parameterizing and saving M posteriors to be pooled, one can simply redo the inference one more time with the union of all consistent data sets and with the pooled likelihood.

2.3 Sufficient Statistics

Thus far, we have introduced a Bayesian procedure to infer our uncertain model parameters x where the likelihood as $\tilde{v}(S(y)|x)$ is approximated as $v(y|x)w(y)$, where S might be some mapping of some complicated statistic on the data. Ideally, one would like to observe y directly, since we have an analytic form for the data likelihood. So when is $\tilde{v}(S(y)|x)$ a good substitute for $v(y|x)$? The answer is when $S(y)$ is a *sufficient* statistic for the posterior density on x . In this case, any data set y that produces the same sufficient statistic, $S(y^*)$, as the true observed information will yield the same posterior density on x . In general, when using a likelihood-based inference, any two data sets with the same sufficient statistics, for the underlying model parameters, will yield the same inference on the posterior of those model parameters. This is due to the Fisher factorization theorem [21].

Let $p(y|x)$ be any likelihood function and let $S(y)$ be a sufficient statistic for the model parameter x . We will show that any set of data with the same value of $S(y)$ will yield the same inference, e.g., posterior, on x . By the Fisher factorization theorem, there exist nonnegative functions $p(S(y)|x)$ and $q(y)$ such that

$$p(y|x) = p(S(y)|x)q(y). \quad (3.25)$$

Next, with $\pi(x)$ as the prior on x , we have

$$p(x|y) = \frac{p(y|x)\pi(x)}{p(y)} = \frac{p(S(y)|x)q(y)\pi(x)}{p(y)} = \frac{p(S(y)|x)\pi(x)}{\tilde{p}(y)} = \tilde{p}(x|S(y)), \quad (3.26)$$

where the posterior distribution depends on the data only through the sufficient statistics, up to a normalization factor $q(y)$. Thus, any two data sets yielding the same sufficient statistics for x will yield the same posterior density. Further, it is important to be aware that sufficient statistics are not necessarily unique and multiple data sets could yield the same posterior distribution. Finally, we note that one can apply the DFI procedure irrespective of the sufficiency of the available statistics. Ideally one would indeed like to have sufficient statistics that fully capture the relevant information in the missing data. However, whether available statistics are sufficient or not, DFI seeks the posterior that satisfies them.

2.4 Consistent Data Sets and Approximate Bayesian Computation

Before we move on to the algorithm behind DFI, we need to spend some time discussing the work horse of the procedure, i.e., sampling consistent data sets $y \sim w(y)$. Recall that we need to do this in order to approximate the likelihood which relates the data y to the uncertain parameters x . Ideally, given an observed set of statistics $S(y^*)$, one would like to sample from $w(y) = \delta(S(y) - S(y^*))$, but this would be nearly impossible unless we can explicitly invert the operator S . However, in most cases, e.g., if S calculates the mean, this inverse problem is ill-posed and has infinitely many solutions. Instead, if we relax this constraint that $S(y)$ must exactly match $S(y^*)$, then the problem becomes well-posed again, although our likelihood becomes an approximation. This leads to Approximate Bayesian Computation (ABC) methods [1, 27].

With ABC methods, one has to derive a reasonable way to measure the discrepancy between the observed statistics, $S(y^*)$ and the sample statistic $S(y)$. For example, Berry *et al.* introduced a weight function [3] that penalized certain quantiles of the observed statistics, using the KL divergence pseudo-metric. We proceed in a similar manner. First, let us define the following subset of the data space:

$$\Delta_\varepsilon = \{y \in \mathbb{R}^n : d(S(w), S(y^*)) \leq \varepsilon\}, \quad (3.27)$$

where d is some metric or pseudo-metric that measures the discrepancy between the test statistic and the observed statistic. The subset Δ_ε represents the set of approximately consistent data. Note that as $\varepsilon \rightarrow 0$, the set Δ_ε becomes $\delta(S(y) - S(y^*))$. Next, we replace the likelihood function with the following approximate consistency function

$$w(y) \propto \mathbb{1}_{\Delta_\varepsilon}(y), \quad (3.28)$$

where the right-hand side is the indicator function. Alternatively, we can approximate the data likelihood directly using d , i.e.,

$$w(y) \propto d(S(y), S(y^*)) \quad (3.29)$$

where the right-hand side is at its maximum when $y = y^*$. We can also add a simulated annealing parameter $\delta \geq 1$ where

$$w(y) \propto d(S(y), S(y^*))^\delta. \quad (3.30)$$

In this case, larger δ corresponds to a likelihood which samples more frequently about the maximum. In fact, as $\delta \rightarrow \infty$, we obtain the maximum likelihood estimate. In the following sections, we will define the distance measure d and the observed statistics more precisely.

3 Algorithmic Structure

We describe in the following a specific algorithmic structure for the method. Alternate formulations can be explored of course, which can potentially be more computationally efficient; however, the present construction is both flexible and quite general. The construction relies on Markov chain Monte Carlo (MCMC) methods. It employs a nested pair of MCMC chains to explore the data and parameter spaces, arriving at a pooling of consistent data-marginalized posteriors on the parameters.

With unknown data y and parameters X and given some information I in terms of constraints on some functional of X , we are ultimately after the marginalized posterior

$$p(x|I) = \int p(x, y|I) dy = \int p(x|y) p(y|I) dy \quad (3.31)$$

where $p(x, y|I)$ is the MaxEnt joint posterior on data and parameters that satisfies given constraints. The DFI procedure provides means of estimation of this marginal

density without explicit estimation of the MaxEnt joint density. This is done by generating *consistent* data samples $\{y^1, y^2, \dots, y^M\}$ and *pooling* the resulting parametric posteriors $\{p_1, p_2, \dots, p_M\}$, where $p_i \equiv p(x|y_i)$ [3]. In this context, consistency is used to mean consistency with respect to the given information I , i.e., consistent data samples are samples from the data density $p(y|I)$. Further, as indicated above, pooling [3, 13] provides a means of combining information from different sources, in the form of consistent posteriors p_i , in a manner corresponding to the marginalization in Eq.(3.31), with optionally additional constraints. In particular, the above introduced linear average pooling providing the pooled posterior density as an arithmetic average

$$p_a = \frac{1}{M} \sum_i p_i \quad (3.32)$$

corresponds to the marginalization in Eq.(3.31). This linear pooling operation is *externally filtered*, such that it commutes with marginalization, while, as indicated above, it is not *externally Bayesian*, and therefore it does *not* commute with Bayesian updating [3, 12]. On the other hand, and as already stated, enforcing an additional requirement of independence of the data and parameters, via $p(x, y|I) = p(x|I)p(y|I)$, leads to logarithmic pooling, corresponding to a geometric average

$$p_g = \left[\prod_{i=1}^m p_i \right]^{1/M}, \quad (3.33)$$

an operation which is indeed externally Bayesian.

The key challenge in the algorithm is the generation of the consistent data sets. Once these are found, associated consistent Bayesian posteriors are easily found and pooled as desired. In principle, an MCMC procedure can be used to generate samples from $p(y|I)$, except that, in a computational setting, one does not have this density explicitly. Likelihood-free Approximate Bayesian Computation (ABC) methods have been used in this regard, employing a quasi-likelihood kernel density that enforces the requisite constraints by construction. An MCMC chain that uses this likelihood to judge acceptance of proposed data samples provides the means of generation of consistent data.

The overall algorithmic construction then looks as follows. We have an MCMC chain on data space whose objective is to generate consistent data samples $y \sim p(y|I)$. Generally, this chain can also include some hyperparameters θ that are involved in the formulation of the ABC likelihood, such that this “outer” chain is over the parameter vector $\zeta = (y, \theta)$. Bayes formula for the outer chain can be written as

$$p(\zeta|I) \propto p(I|\zeta)\pi(\zeta) \quad (3.34)$$

where $\pi(\zeta)$ is a requisite prior on ζ and $p(I|\zeta)$ is the ABC likelihood, which generally can combine K kernel densities, functions of associated statistics on ζ , in a manner that enforces requisite constraints. For example,

$$p(I|\zeta) = \prod_{k=1}^K F_k(S_k(\zeta)) \quad (3.35)$$

where $S_k(\zeta)$ is the k -th statistic on ζ and $F_k(\cdot)$ is the associated kernel density, e.g., of the form

$$F_k(S_k(\zeta)) = \frac{w_k}{\epsilon_k} F\left(\frac{\rho(S_k, S_k^*)}{\epsilon_k}\right) \quad (3.36)$$

where w_k and ϵ_k are scaling factors, $\rho(S_k, S_k^*)$ is a measure of distance between $S_k(\zeta)$ and the requisite value S_k^* of this statistic, and $F(\cdot)$ is the Gaussian kernel

$$F(z) = \frac{1}{\sqrt{2\pi}} e^{-\frac{z^2}{2}}. \quad (3.37)$$

An outer single-site MCMC chain on the data space can be written simply as shown in Algorithm 1. In this algorithm illustration, being with no loss of generality a single-site MCMC algorithm, s is the MCMC step index, ζ^s is the ζ at step s , \tilde{p}^s is the corresponding un-normalized posterior value, with

$$\tilde{p}(\zeta|I) \equiv p(I|\zeta)\pi(\zeta), \quad (3.38)$$

and v is a vector of variances for the normal proposal distribution used in the algorithm.

Algorithm 1 Outer chain single-site MCMC algorithm [17]

```

Input:  $\zeta^0 \in \mathbb{R}^N$ ,  $\tilde{p}^0 = \tilde{p}(\zeta^0|I)$ ,  $v \in \mathbb{R}_+^N$ 
Output: MCMC chain samples
foreach  $s = 1, \dots, M$  do
     $\zeta^s \leftarrow \zeta^{s-1}$ 
     $\tilde{p}^s \leftarrow \tilde{p}^{s-1}$ 
    foreach  $i = 1, \dots, N$  do
         $\delta\zeta_i \leftarrow \xi \sim N(0, v_i)$ 
         $\zeta^* \leftarrow (\zeta_1^s, \dots, \zeta_{i-1}^s, \zeta_i^s + \delta\zeta_i, \zeta_{i+1}^s, \dots, \zeta_N^s)$ 
         $\tilde{p}^* \leftarrow \tilde{p}(\zeta^*|I)$ 
         $\alpha \leftarrow \min(1, \frac{\tilde{p}^*}{\tilde{p}^s})$ 
        if  $u \sim U(0, 1) < \alpha$  then
             $\zeta^s \leftarrow \zeta^*$ 
             $\tilde{p}^s \leftarrow \tilde{p}^*$ 
        end
    end
end

```

At any step in the outer chain, given $\zeta^s = (y^s, \theta^s)$, we run an inner MCMC chain on the parameter space to evaluate the requisite statistics $S_k(\zeta^s)$, $k = 1, \dots, K$. In general, we define any statistic $S(\zeta)$ as a functional on the posterior density $p(\beta|y)$ of the model parameters β inferred given data y . Presuming some hyperparameters ϕ for the inner chain also, we define the state vector for the inner chain as $\lambda = (\beta, \phi)$ and write the inner chain posterior as

$$p(\lambda|y) \propto p(y|\lambda)\pi(\lambda) \quad (3.39)$$

where $\pi(\lambda)$ is the prior on λ , capturing prior belief on λ , and $p(y|\lambda)$ is the likelihood of data y given the fit model and λ . The formulation of the inner chain likelihood function depends on the presumed data model for the missing data from the experiment, involving both the fit model and a statistical model for the discrepancy between the model and the data. For example, presuming an additive zero-bias *i.i.d.* Gaussian noise model for the discrepancy, we have the data model

$$y = f(\beta) + \epsilon, \quad \epsilon \sim N(0, \sigma^2) \quad (3.40)$$

such that, with $\lambda = (\beta, \sigma)$, the likelihood based on data $y^s = (y_1^s, \dots, y_J^s)$ is given by

$$p(y^s|\lambda) \equiv L^s(\lambda) = \prod_{j=1}^J \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{(f(\beta) - y_j^s)^2}{2\sigma^2}\right). \quad (3.41)$$

With this likelihood, and the prior $\pi(\lambda)$, any suitable MCMC chain construction can be employed to generate samples from the posterior $p(\lambda|y^s)$. With these samples, requisite statistics $S_k(\zeta_s)$ can be evaluated. For example, statistics such as $E_{\lambda|y^s}[\beta]$, $\text{Var}_{\lambda|y^s}[\beta]$, $E_{\lambda|y^s}[f(\beta)]$, or $\text{Var}_{\lambda|y^s}[f(\beta)]$ can be easily evaluated and employed in the outer/data chain ABC likelihood to check consistency with associated given values.

With this, we have a number of consistent data sets y^s , and associated consistent posteriors $p(\lambda|y^s)$, for $s = 1, \dots, M$. A suitably pooled posterior can be estimated in a straightforward manner as outlined above, arriving at, e.g., an arithmetically or geometrically averaged posterior as in Eqs. (3.32) and (3.33). In particular, considering logarithmic pooling, which is externally Bayesian, one can, in order to avoid laborious parameterization of posterior densities, pool the data rather than explicitly pooling the posteriors. For example, for the above *i.i.d.* Gaussian likelihood in Eq. (3.41), we have

$$p_g = \left[\prod_{s=1}^M p(\lambda|y^s) \right]^{1/M} \propto \left[\prod_{s=1}^M p(y^s|\lambda) \right]^{1/M} \pi(\lambda) \quad (3.42)$$

$$\propto \left[\prod_{s=1}^M \prod_{j=1}^J \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{(f(\beta) - y_j^s)^2}{2\sigma^2}\right) \right]^{1/M} \pi(\lambda). \quad (3.43)$$

Thus, a single MCMC chain on the parameters, with the full data vector y^{pool} given by $\{y_j^s\}$, $s = 1, \dots, M$, $j = 1, \dots, J$, and with the modified likelihood

$$p(y^{\text{pool}}|\lambda) = L^{\text{pool}}(\lambda) = \left[\prod_{s=1}^M \prod_{j=1}^J \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{(f(\beta) - y_j^s)^2}{2\sigma^2}\right) \right]^{1/M} \quad (3.44)$$

provides the logarithmically pooled posterior.

Irrespective of the chosen pooling method, in the limit of sufficiently dense sampling of the data space, the resulting pooled posterior is the sought-after marginal MaxEnt density, being marginalized over the data. It is the density which is consistent with all given information on the model, the experiment, and summary statistics.

3.1 Remarks

The above DFI construction has been employed in a range of problems [3, 8, 24]. Before moving forward to a discussion of illustrative applications, we give in the following some general remarks regarding the algorithm.

1. One of the key challenges in the algorithm is the potential high dimensionality of the data space. Leaving aside any hyperparameters, with N data pairs (x_i, y_i) , the data chain is $2N$ -dimensional. It is quite feasible to imagine many practical problems with large N , with an associated high-dimensional MCMC chain on the data. In this context, it becomes crucial that numerous MCMC details be judiciously chosen to ensure accurate results with reasonable computational efficiency. This includes careful choices of the chain starting point, priors on data space, and the proposal distribution. We have found that data chain burn-in, in particular, can be a significant computational burden in high dimensions. Further, it is precisely because of the challenges in proposal distribution selection in high dimensions that our above-illustrated MCMC chain on the data space relies on single-site proposal structure.
2. The outer chain, by construction, is sampling along a manifold in data space, where the manifold is defined by the given constraints. While the chosen ABC kernel width adds a certain small width to the manifold, sampling along the manifold in data space does remain a challenge. While it remains to be shown, it is likely that geometric MCMC methods that take the geometry of the manifold into consideration in adapting the proposal distribution would be useful in this

regard. Further, in principle, any point on the manifold is equally good. As a result, while “good mixing” may be sought-after as regards jumps orthogonal to the manifold, it is in principle expected that the chain may wander aimlessly *along* the manifold. In order to get good statistics from the data chain, the key requirement is that it gets good “coverage” of the manifold. In order to ensure this, it is useful to run many data chains in parallel, with randomly chosen starting points, and to pool all the resulting consistent data sets. This strategy allows assessment of the convergence of the resulting statistics by estimating the fractional change in select metrics with the inclusion of additional chains.

3. The nested structure of the construction, while flexible and generally useful, is nonetheless a computational burden. It is clearly of interest to explore a single-chain version of the algorithm that employs joint sampling on both the data and parameter spaces.
4. The practical implementation of the algorithm does rely on knowing a number of necessary details about the study behind the reported statistics. For example, aside from knowing the details of the physical system, the details of the model that was fitted, and the operating conditions of the experiment, it is also necessary to know some aspects of the measurement process, for example, the noise structure of the instrument, e.g., the distribution of the noise, its correlation structure if any, and its dependence on operating conditions. Further, if the fitting done in the original experiment employed parameters from previous measurements, these need to be accounted for as nuisance parameters, with specified uncertainty. Moreover, the actual number of data points used in the experiment needs to be estimated. This can be difficult, depending on how much information is reported in the literature. In a case where this or other pertinent details are missing, one can assign a density that encapsulates what one *does* know about the relevant detail and to then marginalize the results over this distribution. For example, if N , the number of data points, is unknown, but can be confidently bounded from below and above, then a MaxEnt uniform probability mass function can be assigned to N in this range. Another important experimental detail that is frequently hard to assess is the precise meaning of error bars reported. This is a challenge in general, aside from the present purposes. Nonetheless, it is an issue in the present context, because everything depends on the meaning of the declared statistics. Frequently, a judicious assumption is necessary, declaring, for example, that the error bars refer to a specific multiple of the standard deviation, or specific quantiles, of the reported observable interpreted as a random variable.

4 Applications

4.1 Algebraic System

4.1.1 Setup

Consider a nonlinear model problem that involves the chemical decomposition of an unstable radical, with initial concentration c_0 at time $t = 0$. Synthetic data pairs

of time and concentration, (t_i, y_i) , are generated using a double exponential decay truth model $s(t)$, with a multiplicative data noise model.

$$s_i = 2e^{-2t_i} + \frac{1}{2}e^{-\frac{1}{2}t_i}, \quad (3.45)$$

$$\begin{aligned}\gamma_i &= \frac{1}{4}s_i + \frac{1}{20}, \\ y_i &= s_i + \gamma_i \varepsilon_i,\end{aligned}$$

where ε_i are i.i.d. $\mathcal{N}(0, 1)$ random variables and t_i are the time values in the set

$$\tau = \{i/2 \quad i = 1, \dots, 10\}, \quad (3.46)$$

with $t_i \in [0, 5]$. Also, at each time point, 10 data points are generated for a total of 100 data points, i.e., the experiment was performed ten times. Here, s_i is the true signal, ε_i is Gaussian white noise, and y_i 's are our observations.

A researcher observes these time-concentration data pairs and reports fitting a *single* exponential decay model to this data (not knowing the true underlying double exponential decay model). Furthermore, instead of publishing the data pairs, (t_i, y_i) , the researcher publishes summary statistics, namely, nominal values and error bars on the predicted concentration from the fitted single exponential decay model at a set of time instances [16]. This means that our $S(y)$ function will involve a complicated and potentially computationally expensive procedure, which will be outlined in the next two subsections.

As readers of this published report, we want to use the author's results and produce detailed predictions with associated uncertainty estimates, i.e., we want to know the full posterior distribution for the uncertain model parameters. We could easily do this if the observed data pairs were published, but in this case, we have no such luck. Thus, we need to infer consistent data sets w.r.t. the given summary statistics, then use those data pairs to perform our own model fitting, and pool those results to obtain an averaged posterior. Before we describe the procedure for generating consistent data sets, let us describe the single exponential decay model that the inference is based on. This will help determine the mapping $S(y)$. It should be emphasized that the fitted model and the procedure for obtaining the processed data products or summary statistics are presumably reported in the author's work.

4.1.2 Single Exponential Model Fit

Let us assume that the author fits a single exponential decay model with the observed, but unpublished, (synthetic) data pairs using a Bayesian procedure. The reported single exponential decay model is

$$\tilde{s}_i = ae^{-kt_i} \quad (3.47)$$

$$\tilde{\gamma}_i = \sigma_1 \tilde{s}_i + \sigma_2 \quad (3.48)$$

$$y_i = \tilde{s}_i + \tilde{\gamma}_i \varepsilon_i. \quad (3.49)$$

for $i = 1, \dots, N_t = 10$, where k is the decay rate parameter, a is the initial concentration, and σ_1, σ_2 are nuisance parameters. With N data points at each t_i , let $n = N \cdot N_t$ be the dimensionality of the observed data. Furthermore, let the t_i 's be known, deterministic variables, while the nuisance parameters, σ_1 and σ_2 , are not known. By assumption, the author infers and marginalizes over these parameters to obtain a distribution on the model parameters of interest, a and k .

The fitting is done using a Bayesian approach, which necessitates the need for a likelihood function for the model, as well as a choice of priors. Let $x = (a, k)$, $\sigma = (\sigma_1, \sigma_2)$, and define the data set $y = (y_1, \dots, y_n)$. Then, the likelihood is

$$p(y|x, \sigma) \propto \left(\prod_{i=1}^n (\sigma_1 a e^{-kt_i} + \sigma_2) \right)^{-1} \cdot \exp \left\{ -\frac{1}{2} \sum_{i=1}^n \left(\frac{y_i - ae^{-kt_i}}{\sigma_1 a e^{-kt_i} + \sigma_2} \right)^2 \right\}. \quad (3.50)$$

Using improper uniform priors on σ , the posterior on x and σ is then given by

$$p(x, \sigma|y) \propto p(y|x, \sigma). \quad (3.51)$$

This summarizes the Bayesian fitting procedure presumably reported to us in the author's work. We can now define the procedure that the author used to produce the summary statistics, which we denote by $S(y)$.

4.1.3 Summary Statistics for Processed Data Products

We presume that the author reported error bars on the predicted concentration at a set of time instances, using the fitted model. More specifically, say the author reported summary statistics in the form of means and 2σ quantiles (equivalently, 95% confidence interval) on the pushed forward posterior at particular time instances.² These types of summary statistics will also be referred to as processed data products (PDPs). Figure 3.1 shows the published summary statistics. From this figure, we will attempt to infer the original data used to create it. To do this, we assume that we know how the summary statistics were computed (without actually knowing the data used to create them).

We now assume that the processed data products were computed by the following procedure. First, given the raw data y^* , we presume that the author determined the posterior distribution $X \sim p(x|y^*)$ on the model parameters and computed mean and quantiles (twice the standard deviation) for $f(t; x)$ where $x \sim p(x|y)$ (this represents the pushed forward posterior) for each t_i . This is summarized by the mapping $S : y \in \mathbb{R}^n \mapsto \mathbb{R}^{2N_t}$ defined as

$$S : y \in \mathbb{R}^n \mapsto x \sim p(x|y) \mapsto (\mu_{f_1}(y), \dots, \mu_{f_{N_t}}(y), \sigma_{f_1}(y), \dots, \sigma_{f_{N_t}}(y)), \quad (3.52)$$

²We will assume that the author had an assumption of normality, hence their interpretation as 95% quantiles.

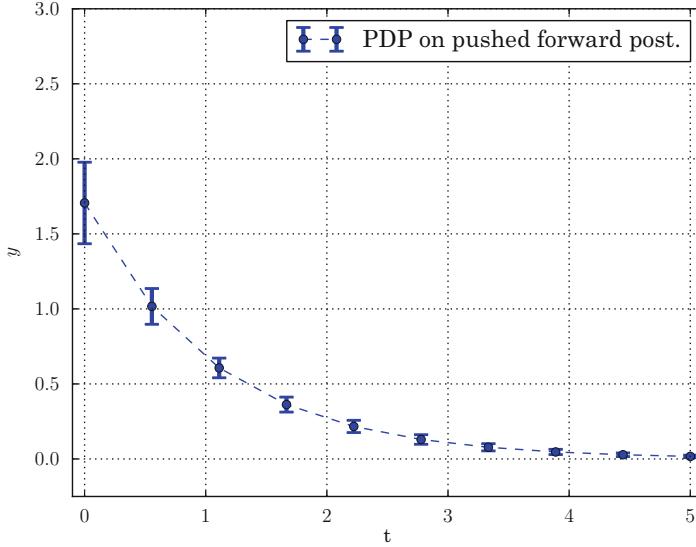

Fig. 3.1 Summary statistics or processed data products provided in the published report. These are error bars on the pushed forward posterior through the single exponential decay model [30]

where

$$\mu_{f_i}(y) = \mathbb{E}_{p(X|y)}[f(t_i; X)] = \int_{\mathbb{R}^d} f(x; t_i) p(x|y) dx, \quad (3.53)$$

$$\sigma_{f_i}^2(y) = \mathbb{E}_{p(X|y)}[(f(t_i; X) - \mu_{f_i})^2] = \int_{\mathbb{R}^d} [f(t_i; x) - \mu_{f_i}]^2 p(x|y) dx. \quad (3.54)$$

It is important to note that the mapping S requires the posterior to be computed, which makes S computationally expensive.

At this point, we, the readers of the published report, only have access to the fitting procedure and the PDPs $S(y^*)$ and *not* the actual observed data y^* . Our goal is to produce a set of data that is consistent with the given summary statistics. In other words, we want to choose the data y s.t. $S(y)$ is *close* to the given $S(y^*)$. The next section details a possible definition for such a discrepancy measure, which we denote as $w(y)$.

4.1.4 PDP Pseudo-metric

Let $y^* \in \mathbb{R}^n$, denote the unpublished, hidden data used to produce the PDP $S(y^*)$. In order to obtain an appropriate pseudo-metric, $w(y)$, for these types of processed data products, it is useful to think of $w(y)$ as a way to penalize the data y for being inconsistent with the given processed data products, i.e., not having $S(y)$ close, in some sense, to $S(y^*)$. We will derive w in two parts. For convenience, let us write

$$w(y) = w^{(1)}(y) \times w^{(2)}(y). \quad (3.55)$$

The first term $w^{(1)}$ will try to force consistency between the data sets and the given pushed forward posterior means (contained in $S(y^*)$). Likewise, the second term $w^{(2)}(y)$ will try to force consistency between the data sets and the pushed forward posterior quantiles (interpreted as $\mu_{f_i}(y) \pm 2\sigma_{f_i}(y)$, also contained in $S(y^*)$).

In order to check consistency between the data sets and the pushed forward posterior mean, we define the function $w^{(1)}(y) : \mathbb{R}^n \mapsto \mathbb{R}$ as follows:

$$w^{(1)}(y) = \prod_{i=1}^{N_t} \exp(-\delta_1(\mu_{f_i}(y) - \mu_{f_i}(y^*))^2) \quad (3.56)$$

where δ_1 is a tunable parameter, i.e., the annealing parameter [14, §12.4]. If we assume that the sampled pushed forward posterior means $\mu_{f_i}(y)$ are distributed normally, i.e., $\mu_{f_i}(y) \sim \mathcal{N}(\mu_{f_i}(y^*), \delta_1^{-2})$, we may interpret $1/\delta_1^2$ as the variance for this sample mean. In practice, because we have to perform sampling to approximate $\mu_{f_i}(y)$, we can justify this approximation from a central limit type argument, where δ_1 is proportional to the square root of the number of sample points. Alternatively, if we substitute the definition of $\mu_{f_i}(y)$ into Eq. (3.56), we get

$$w^{(1)}(y) = \prod_{i=1}^{N_t} \exp \left(-\delta_1 \left(\int_{\mathbb{R}^d} [f(x; t_i) - \mu_{f_i}(y^*)] p(x|y) dx \right)^2 \right). \quad (3.57)$$

It is clear that this weight function is enforcing the mean of the pushed forward posterior.

To enforce the variance or quantiles of the pushed forward posterior on model outputs, one can take a similar approach to (3.56) and simply replace $\mu_{f_i}(y)$ with $\sigma_{f_i}(y)$. However, we choose a more robust approach outlined in [3], which performs a trinomial quantile check. Instead of comparing means and variances directly, which can be highly sensitive to sampling noise, i.e., via Monte Carlo estimation, we sample the pushed forward posterior of a sample data set y and bin the samples according to the 2.5 % – 95 % – 2.5 % quantiles according to the given summary statistics. This binning produces a trinomial density for the sample data set y . Ideally, the trinomial density will have 2.5 % – 95 % – 2.5 % probability masses in each bin. To check consistency, we use relative entropy/KL divergence to compare the sample trinomial density, computed from the pushed forward posterior based on y , with the ideal trinomial density, with probability masses 2.5 % – 95 % – 2.5 %.

In order to properly define this pseudo-metric, we must first make an assumption that the data provided for the standard deviation can be equivalently interpreted as quantiles. That is, if we are given the mean and standard deviation μ and σ , we can equivalently say that 95 % of the data falls within $[\mu - 2\sigma, \mu + 2\sigma]$ and 2.5 % of the data falls below $\mu - 2\sigma$ and above $\mu + 2\sigma$. If the underlying distribution is normal, this assumption is justified. If this assumption cannot be justified, then using (3.56)

with σ_{f_i} instead of μ_{f_i} will suffice. In the case that the processed data products are provided in the form of quantiles, we do not need to make any assumption at all, and the following approach is justified.

That being said, let us assume that the quantiles for the pushed forward posterior, $f(x; t_i)$, are given to us in the form of $[\mu_{f_i}(y^*) - 2\sigma_{f_i}(y^*), \mu_{f_i}(y^*) + 2\sigma_{f_i}(y^*)]$ for $i = 1, \dots, N_t$. We introduce a function $g_i(y)$ which measures the mismatch between the pushed forward samples and the summary statistics. This measure essentially checks that 2.5, 95, and 2.5 percent of the pushed forward posterior samples fall within the bins

$$\begin{aligned} & [-\infty, \mu_{f_i}(y^*) - 2\sigma_{f_i}(y^*)] \\ & [\mu_{f_i}(y^*) - 2\sigma_{f_i}(y^*), \mu_{f_i}(y^*) + 2\sigma_{f_i}(y^*)] \\ & [\mu_{f_i}(y^*) + 2\sigma_{f_i}(y^*), \infty], \end{aligned} \quad (3.58)$$

respectively. In other words, $g_i(y)$ measures the likelihood that the correct binning is achieved. To measure the mismatch, we use the KL density [3, 10]. In order to define $g_i(y)$, let us introduce the following probabilities. Let $p_{f(t_i; x)}(y)$ be the pushed forward posterior density at t_i . Then, define

$$\begin{aligned} p_i(y) &:= \int_{y < \mu_{f_i}(y^*) - 2\sigma_{f_i}(y^*)} p_{f(t_i; x)}(y) dy \\ q_i(y) &:= \int_{y > \mu_{f_i}(y^*) + 2\sigma_{f_i}(y^*)} p_{f(t_i; x)}(y) dy, \\ r_i(y) &:= 1 - p_i(y) - q_i(y). \end{aligned} \quad (3.59)$$

Let $P_i(y) = [p_i, r_i, q_i](y)$ represent a probability density, with $p_i + q_i + r_i = 1$, which represents the percent of samples that fall within the 2.5%–95%–2.5% bins defined in (3.58). Ideally, we would like this density to be $Q = [0.025, 0.95, 0.025]$ for $i = 1, \dots, N_t$. Using the KL density to compare measures, one obtains

$$g_i(y) \propto \exp(-\delta_2 D_{\text{KL}}(P_i(y) \| Q)) \quad (3.60)$$

where increasing $\delta_2 > 0$ acts to improve the match between P_i and Q , by increasing the severity of the application of the constraint. Finally, we want this to hold true for $i = 1, \dots, N_t$ which gives us the corresponding weight

$$w^{(2)}(y) \propto \prod_{i=1}^{N_t} g_i(y) = \prod_{i=1}^{N_t} \exp(-\delta_2 D_{\text{KL}}(P_i(y) \| Q)). \quad (3.61)$$

Combining weights $w_2^{(1)}$ and $w^{(2)}$ gives

$$w(y) \propto \left[\prod_{i=1}^{N_t} \exp(-\delta_1(\mu_{f_i}(y) - \mu_{f_i}(y^*))^2) \right] \times \left[\prod_{i=1}^{N_t} \exp(-\delta_2 D_{\text{KL}}(P_i(y) \| Q)) \right]. \quad (3.62)$$

As we will see in the examples, it may be desirable to only match or penalize a subset of the provided quantiles. That is, let $B \subset \{1, \dots, N_t\}$ and consider the reduced weight function

$$\tilde{w}(y) \propto \left[\prod_{i \in B} \exp(-\delta_1(\mu_{f_i}(y) - \mu_{f_i}(y^*))^2) \right] \times \left[\prod_{i \in B} \exp(-\delta_2 D_{\text{KL}}(P_i(y) \| Q)) \right]. \quad (3.63)$$

Note that \tilde{w} does not enforce a matching between all N_t means and quantiles, but rather a smaller subset B of those same means and quantiles. We now explain in the following how we employ these constraints to generate consistent data sets and arrive at the pooled posterior of interest.

4.1.5 Generating Consistent Data and Pooling the Posterior

With $w(y)$ properly defined, let us utilize Algorithm 1 to generate replica data sets from these processed data products, consistent with the given summary statistics. Note that in Algorithm 1, we do not consider N a random variable. Instead, we fix N at an arbitrarily chosen value.³ Once these data sets have been generated, we then produce a posterior on the model parameters for each consistent data set and pool these distributions. We detail the application of this approach below.

We are given a total of ten error bars at ten different time points, i.e., $N_t = 10$. Using the means and quantiles from the error bars, we generate consistent data using Algorithm 1. For convenience, we will fix N to be 5, which means we have underestimated the dimensionality of the data set (since the original data set contains $N = 10$ observations for each time point). We use Algorithm 1 with $\delta_1 = \delta_2 = 300$. Each run of the algorithm generates 3000 samples. To obtain a sizable number of consistent data sets, we employ MCMC runs for 50 different random seeds to obtain a total of 150,000 data sets. Additionally, as done above, and for the same reasons, instead of matching the full set of 10 quantiles for $t \in \tau$, we ran Algorithm 1 with a smaller subset of error bars, i.e., $B = \{1, 3, 5, 8\}$.

Figure 3.2 shows the quantiles of each data set versus the given quantiles from the PDP. This figure shows how well the algorithm produced consistent data.

After generating consistent data sets, we want to be able to infer the posterior on the model parameters of the original data set. Figures 3.3 and 3.4 show the posterior

³Again, we do this to reduce the computational cost of generating data sets over multiple dimensions. Although we do not marginalize over the dimensionality, we show that for a reasonable choice of the dimension parameter $N = 5$, we can still recover consistent data sets.

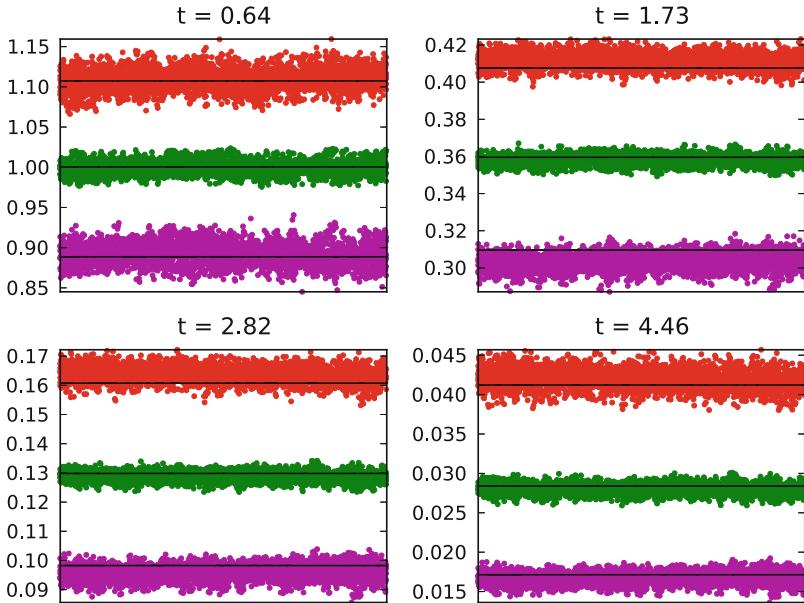

Fig. 3.2 The *black lines* denote the true quantiles (means and 2.5 % and 97.5 % quantiles) based on the original raw data set (hidden from us, but displayed here for comparison purposes) at four different times. The *green dots* represent the means for each consistent data set generated using Algorithm 1 with $\delta_{1,2} = 300$. Likewise, the *red* and *magenta dots* represent the upper and lower quantiles, respectively, for each consistent data [30]

means and covariance of each individual sample versus the original posterior, similar to what is displayed in Figure 3.2. Figure 3.5 displays the log and linear pooled posterior from all 150,000 samples, superposed on the true posterior. In this case, both pooled posteriors are very similar, since the generated data does not exhibit much sample-to-sample variance in the posterior. More importantly, they both agree very well with the true posterior, given (a) the correct interpretation of the error bars in this case, and (b) the evident near sufficiency of the given statistics.

We also show, in Fig. 3.6, quantiles for consistent data when $\delta_2 = 150$ instead of $\delta_2 = 300$. As expected, the quantiles are less tightly consistent, but in fact still within an acceptable amount.

We also repeated the experiment with the dimensionality $N = 10$ to simulate the true dimension of the data set. We found that the results were very similar to $N = 5$ so we omit the results.

4.2 Chemical System

We now present an illustration of the method as applied in the context of parameter estimation in a chemical system. We consider a realistic scenario where we are

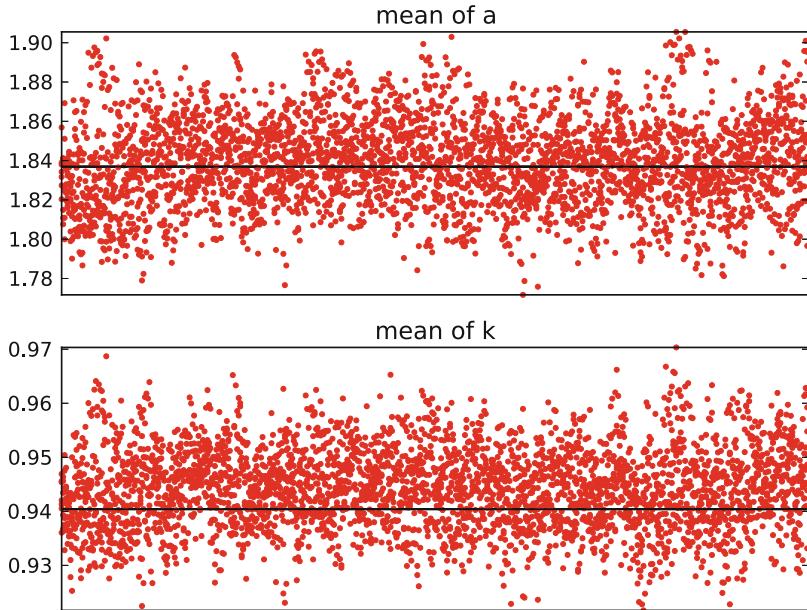

Fig. 3.3 The black lines denote the true posterior means from the raw data set, unbeknown to us. The red dots represent the means for the model fit parameter after each consistent data set, generated using Algorithm 1, is fit to the single exponential decay model via a Bayesian approach [30]

given summary statistics on Arrhenius reaction rate coefficients of a global methane-oxidation reaction based on some missing chemical ignition data set. We consider these statistics to be based on a joint posterior density on the parameters that is not reported and use them to infer a marginal MaxEnt posterior that is consistent with the given information.

More specifically, and in order to enable an examination of the effectiveness of the approach, we consider a synthetic data context, where we first generate methane-air ignition data with a detailed chemical mechanism, namely, GRIMech3.0 [29], over a range of initial temperature, and corrupt it with multiplicative *i.i.d.* Gaussian noise. We then use this data in a Bayesian inference context to calibrate a single-step global methane-oxidation model, arriving at a joint posterior on its two parameters of interest (A, E), being the pre-exponential and activation energy. Evaluating and retaining nominal values and marginal posterior 5 % and 95 % quantiles on each of the two parameters, we next discard the data, use the DFI algorithm to discover the marginal MaxEnt posterior, and compare it to the known “true” posterior based on the original data set.

The data D is a collection of 11 pairs of ignition time and initial temperature [24]. The synthetic data from the detailed model before and after corruption by multiplicative *i.i.d.* Gaussian noise is shown in Fig. 3.7. With this data, and

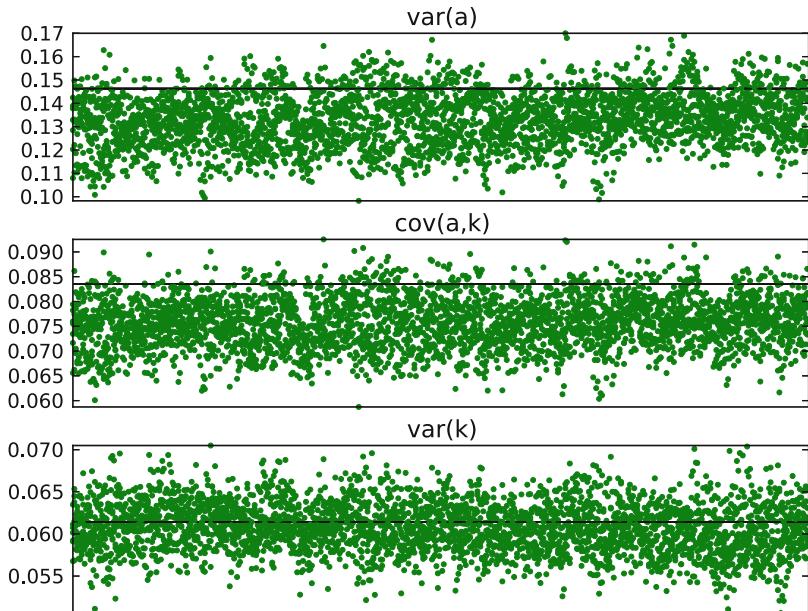

Fig. 3.4 The *black lines* denote the true posterior covariance from the original (synthetic) data set, unbeknown to us. The *green dots* represent the covariance for the model fit parameter after each consistent data set, generated using Algorithm 1, is fit to the single exponential decay model via a Bayesian approach [30]

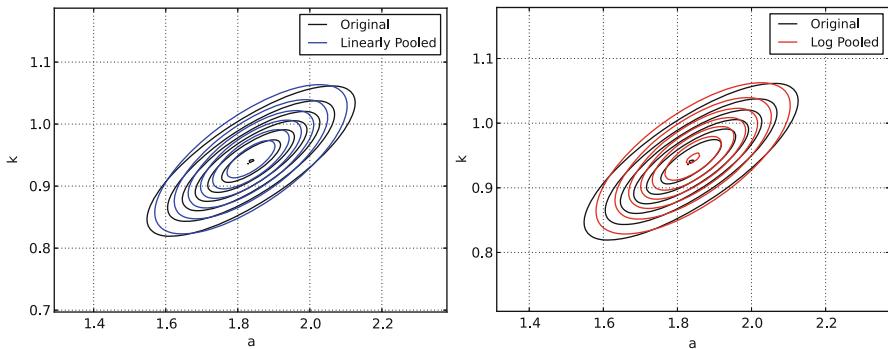

Fig. 3.5 The true posterior, based on the original (synthetic) data set, is shown in *black* contours. The linear and log pooled covariance is shown in the *left* and *right* images, respectively, using Algorithm 1 when we have error bars on the pushed forward posterior [30]

employing a corresponding data model, we use Bayesian inference [24] to arrive at the posterior density on the two parameters of interest $p(\ln A, \ln E | D)$, shown in Fig. 3.8. Extracting the nominal values, as well as the 5 % and 95 % quantiles,

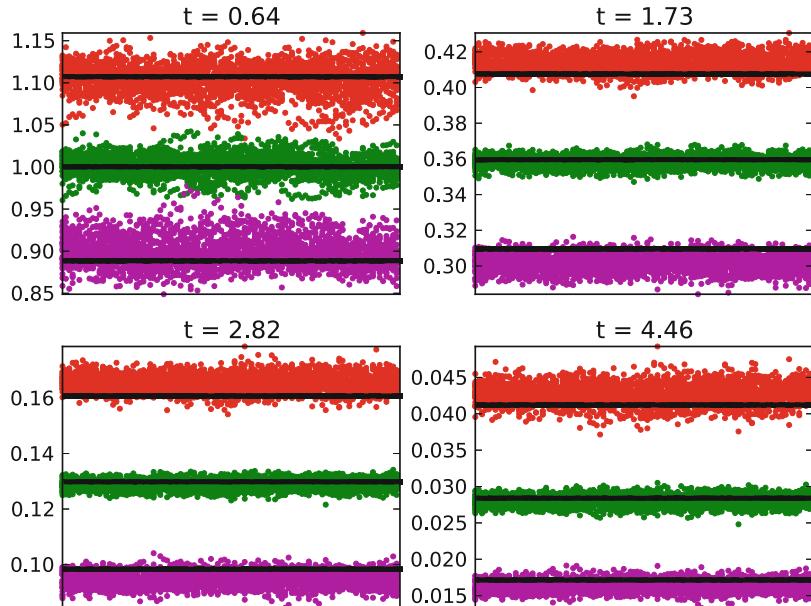

Fig. 3.6 The *black lines* denote the true quantiles (means and 2.5 % and 97.5 % quantiles) based on the original, raw synthetic data set (hidden from us, but displayed here for comparison purposes) at four different times. The *green dots* represent the means for each consistent data set generated using Algorithm 1 with $\delta_{1,2} = 150$. Likewise, the *red* and *magenta dots* represent the upper and lower quantiles, respectively, for each consistent data [30]

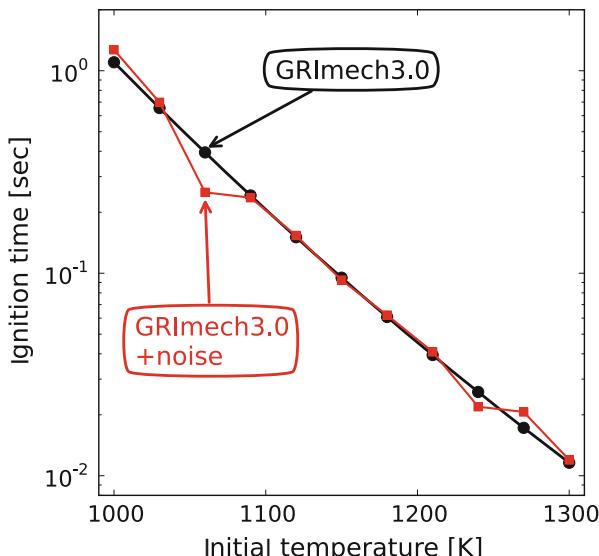

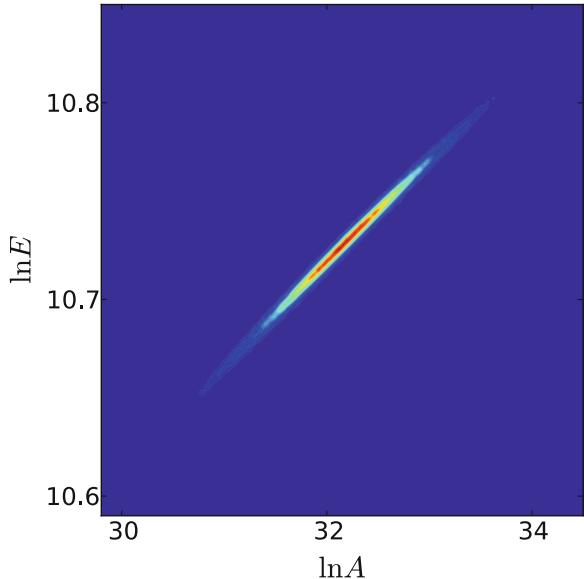

Fig. 3.7 Ignition time computed with GRImech3.0 over a range of variation of initial temperature, including also the corresponding noisy synthetic data points used for inference [17]

Fig. 3.8 Joint 2D marginal posterior on $(\ln A, \ln E)$ [17]

from the marginal parameter posteriors, we then proceed to the application of DFI, forgetting for the moment both the data and the true posterior structure.

For the application of DFI, we presume 8 data pairs, as opposed to the true original number of 11, for illustration. We do this in order to accentuate the point that in an actual application with experimental data that is not reported, the number of missing data points may not necessarily be known. As we indicated earlier, one in principle can propose a density that encapsulates knowledge of the number of points. Here, we simply posit a number, that is different from the truth. An analysis of the impact of different choices for the number of points, not reported here, suggests a small effect on the result of inference in this particular situation.

The construction of the data chain likelihood relies on kernel densities that enforce the nominal values of $(\ln A, \ln E)$ and their 5 %/95 % quantiles. With the data chain state $\zeta = (z, \ln \sigma_d)$, where z is the vector of 8 data pairs and σ_d is the standard deviation of the noise, we define the data chain likelihood as

$$p(I|\zeta) = w_\delta(z, \ln \sigma_d) = F_\delta(z) \frac{p(z, \ln \sigma_d | \beta_0)}{\max_{\beta, \sigma} [p(z, \ln \sigma | \beta)]}. \quad (3.64)$$

where $\beta \equiv (\ln A, \ln E)$, β_0 is the nominal value of β , and $p(z, \ln \sigma_d | \beta_0)$ is evaluated from the likelihood function of the inner chain. Specifically, we have

$$p(z, \ln \sigma | \beta) = p(z | \beta) p(\ln \sigma | \beta) = p(z | \beta, \ln \sigma) \pi(\beta, \ln \sigma) / \pi(\beta) \quad (3.65)$$

where $\pi(\beta, \ln \sigma)$, $\pi(\beta)$ are priors on $(\beta, \ln \sigma)$ and β , respectively, and $p(z | \beta, \ln \sigma)$ is the inner chain likelihood. This likelihood is based on the model prediction of ignition time $\tau^m(T^o, \beta)$ for any initial temperature T^o and parameter vector $\beta = (\ln A, \ln E)$, on the multiplicative *i.i.d.* Gaussian noise data model $\tau = \tau^m(1 + \sigma\epsilon)$, and on the data set $\{(T_i^o, \tau_i^d)\}_{i=1}^N$ for the given data chain step, here with $N = 8$. Specifically, we have

$$p(z | \beta, \ln \sigma) \propto \frac{1}{(2\pi\sigma^2)^{N/2}} \frac{1}{\prod_{i=1}^N \tau^m(T_i^o, \beta)} \exp \left\{ -\frac{1}{2\sigma^2} \sum_{i=1}^N \left[\frac{\tau_i^d}{\tau^m(T_i^o, \beta)} - 1 \right]^2 \right\}. \quad (3.66)$$

Thus, the ratio term on the right-hand side of Eq. (3.64) enforces consistency with the nominal parameter values, as $p(z, \ln \sigma_d | \beta_0)$ measures the likelihood of the proposed outer chain state for the *nominal* value of β . Further, the normalization by the denominator shown in Eq. (3.64) ensures that the ratio is in $[0, 1]$.

The $F_\delta(z)$ term, with $\delta > 0$, is constructed to enforce consistency with the quantiles. Specifically, we use

$$F_\delta(z) \propto \prod_{i=1}^2 f_\delta \left([p_i(z), 1 - p_i(z) - q_i(z), q_i(z)] \mid [0.05, 0.90, 0.05] \right) \quad (3.67)$$

where,

$$p_1(z) = \int_{\ln A < (\ln A)_5} p(\beta | z) d\beta, \quad q_1(z) = \int_{\ln A > (\ln A)_{95}} p(\beta | z) d\beta, \quad (3.68)$$

$$p_2(z) = \int_{\ln E < (\ln E)_5} p(\beta | z) d\beta, \quad q_2(z) = \int_{\ln E > (\ln E)_{95}} p(\beta | z) d\beta, \quad (3.69)$$

where $p(\beta | z)$ is the marginal inner chain posterior on the parameters β , $\{(\ln A)_5, (\ln E)_5\}$ are the specified 5% quantiles and $\{(\ln A)_{95}, (\ln E)_{95}\}$ the specified 95% quantiles on $(\ln A, \ln E)$, and the trinomial density with probabilities $p + r + q = 1$ is denoted $[p, r, q]$. Further, f_δ is defined as [3]

$$f_\delta([p, r, q] | [0.05, 0.90, 0.05]) = \exp \left\{ -\delta \left(p \ln \frac{p}{0.05} + r \ln \frac{r}{0.90} + q \ln \frac{q}{0.05} \right) \right\}, \quad (3.70)$$

being the KL density [3] formed of the KL divergence from the density $[p, r, q]$ to $[0.05, 0.90, 0.05]$, where, for two measures (μ, ν) with ν absolutely continuous w.r.t. μ , we have

$$f_\delta(\mu | \nu) \propto \exp(-\delta \cdot D_{\text{KL}}(\mu \| \nu)) \quad (3.71)$$

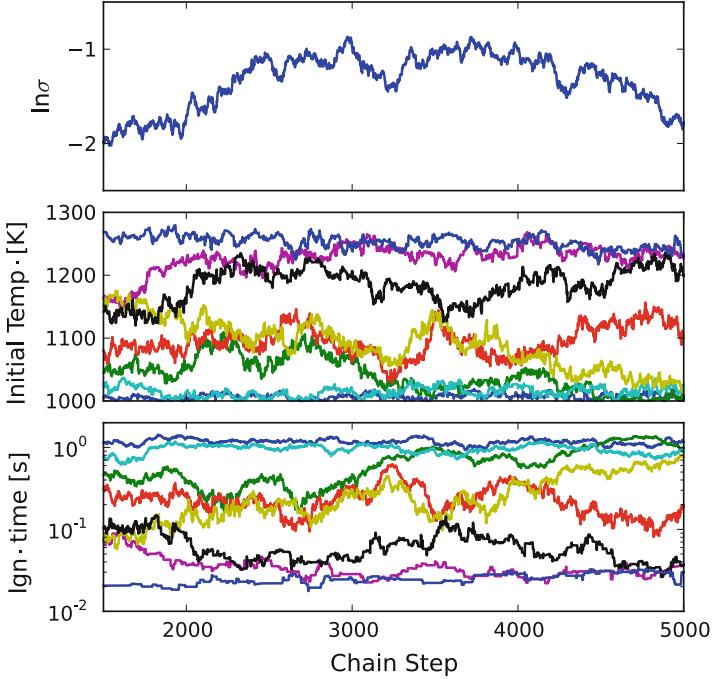

Fig. 3.9 A segment of the DFI data chain, showing the MCMC sampled values of the data vector. In the *bottom* two frames, each line corresponds to the sampled value of each data point, (T_i^o, τ_i) , $i = 1, \dots, 8$ [17]

and $D_{\text{KL}}(\mu \| \nu) \geq 0$ is the KL divergence from μ to ν . The choice of δ provides a control on the sharpness of the density f_δ , with larger values of δ leading to sharper f_δ , being also by construction in $[0, 1]$.

A segment of the data chain is shown in Fig. 3.9. Each state of the chain is composed of ignition time τ_i and initial temperature T_i^o , for $i = 1, \dots, 8$, and the standard deviation of the noise σ . The consistency of data chain samples from 50 independent outer chains is illustrated in Figure 3.10, where the scatter of summary statistics from accepted chain samples is shown on top of the enforced values for both $\ln A$ and $\ln E$. As already indicated, the δ -factor in the outer chain likelihood controls the tightness of the bounds consistency check and therefore the scatter in the quantiles observed in the figure. Further, the consistency of the data samples from the 50 chains, relative to the actual data behind the statistics, is illustrated in Fig. 3.11. Clearly, satisfying the requisite statistics, as fitted using ignition with the global chemistry model, generates data sets that are close to the original data set.

The resulting marginal logarithmically pooled posterior on $(\ln A, \ln E)$, based on the 50 chains, is shown in Fig. 3.12. The figure indicates the near congruence between the DFI posterior and the reference posterior. We note, however, that this agreement between the two posteriors is not necessarily expected. It clearly has to

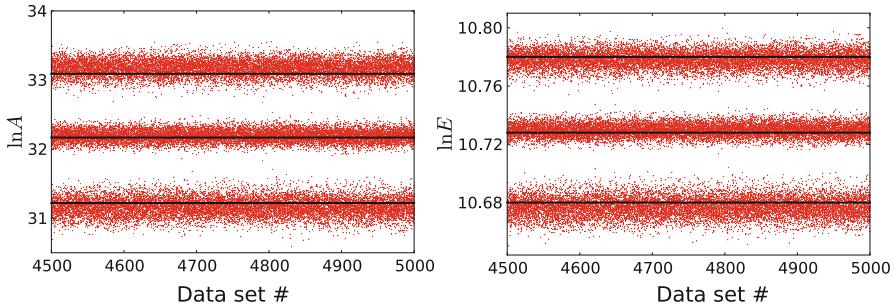

Fig. 3.10 A plot of the means, as well as the 5 % and 95 % quantiles from the parameter posteriors from each data chain step, for all 50 chains, and for the last 500 steps from each chain. The *left frame* shows those for $\ln A$, while the *right frame* shows those for $\ln E$. The *solid lines* indicate the corresponding values from the reference posterior [17]

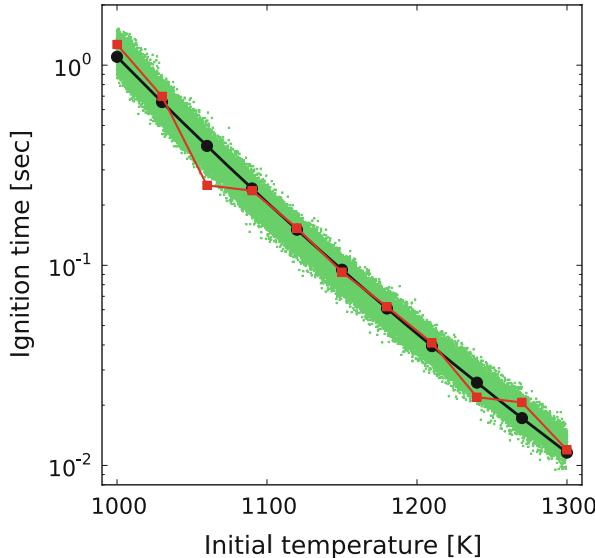

Fig. 3.11 Scatter plot of 50 chains, with the first 1500 burn-in states removed from each chain. Only every 25th chain state is plotted for convenience [17]

do with the amount of given information, the nature of the summary statistics, and the structure of the model. In this case, evidently, posteriors consistent with all this given information are essentially equivalent to the missing posterior. In other words, the available information constitutes a nearly sufficient statistic [6].

Finally, the statistical convergence of the algorithm is highlighted in Fig. 3.13. Here, the convergence of the KL divergence between successive pooled posteriors, with increasing data volume, is illustrated. The abscissa k is the number of

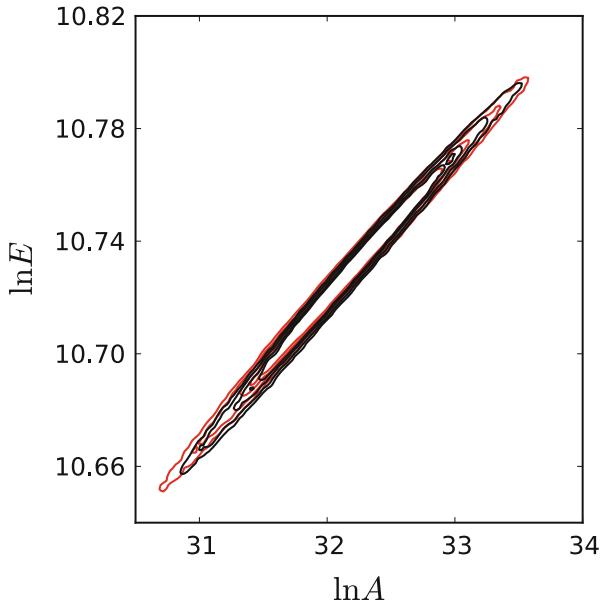

Fig. 3.12 Two-dimensional marginal parameter posteriors on $(\ln A, \ln E)$ resulting from pooling 50 chains of data (red), compared with the reference known posterior (black) [17]

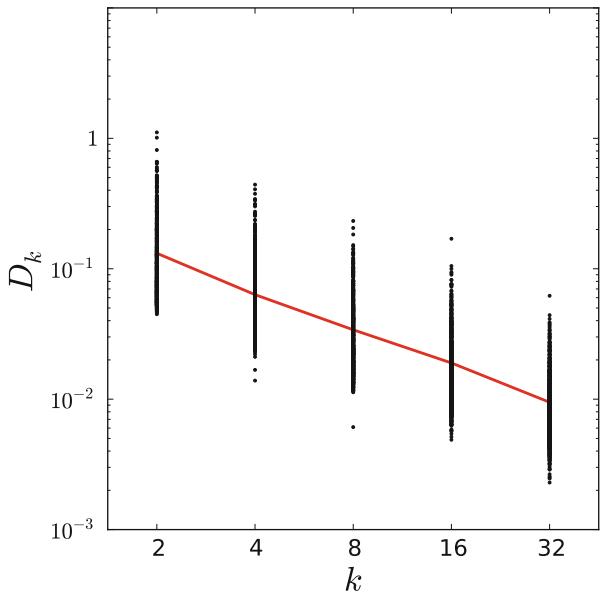

Fig. 3.13 Plot showing the statistical convergence of the algorithm in terms of the KL divergence (KLdiv) between successive pooled posteriors. Also shown is the scatter in each of the KLdiv values. The red line indicates the evolution of the mean with increased number of chains [17]

(equal-length) chains. Thus, if the pooled posterior with k -chains is p_k , we define the KL divergence D_k as

$$D_k = D_{KL}(p_{k/2} || p_k) \equiv \int p_{k/2} \ln \frac{p_{k/2}}{p_k} d\ln A d\ln E d\ln \sigma. \quad (3.72)$$

The results highlight the scatter of D_k , for any given k , resulting from 1024 combinatorial choices of k -chains out of 50. The average divergence, however, exhibits a roughly inverse linear dependence on k , such that $\bar{D}_k \propto 1/k$. Thus, with additional data, we have an associated linear convergence of the pooled posterior.

5 Conclusion

This chapter has focused on the context of Bayesian learning from summary statistics based on missing data. We motivated this focus with practical challenges faced in forward UQ given probabilistically incomplete published information on uncertain model parameters, this being most commonly in the form of summary statistics. We outlined a maximum entropy framework within which the problem can be posed in general and discussed the relationship between the maximum entropy and Bayesian data analysis frameworks. We also outlined a general algorithm, relying on the use of Approximate Bayesian Computation methods for solving the MaxEnt problem, providing sampling from the MaxEnt posterior on the joint data-parametric space, and pooling/marginalizing over the data space to arrive at the marginal posterior density on parameters of interest. Finally, we illustrated the application of this algorithm, with synthetic data, on an algebraic model problem as well as the practical context of estimation of Arrhenius reaction rate coefficients for a global chemical model of methane-air oxidation, based on reported summary statistics on these parameters.

Aside from these applications, the method has been used for estimation of rate constants for an elementary H_2/O_2 reaction, namely, $H + O_2 = OH + O$, based on reported processed data summaries from a shock tube experiment [19]. In this application in particular, the practical utility of having a meaningful joint density on model parameters, rather than the default of ignoring such un-reported correlations, has been illustrated in terms of associated impact on uncertainties in predicted model observables. Similarly, the utility of the method in allowing the handling of other previously measured uncertain model parameters as nuisance parameters, and exploring the correlation among these and the parameters of interest, has been studied.

In closing, it is useful to emphasize that, given the legacy of published literature on physical models in general, where partial information is provided on uncertain model inputs, largely composed of nominal values and error bars on each parameter, with hardly ever any other information on correlations among parameters, let alone the joint PDF on all parameters, there is a significant need for further development and demonstration of statistical methods, such as the above DFI algorithm, that

allow adequate handling of such partial information to build meaningful joint densities on model parameters and enable accurate estimation of uncertainty in computational predictions.

Multi-response Approach to Improving Identifiability in Model Calibration

4

Zhen Jiang, Paul D. Arendt, Daniel W. Apley, and Wei Chen

Abstract

In physics-based engineering modeling, two primary sources of model uncertainty that account for the differences between computer models and physical experiments are parameter uncertainty and model discrepancy. One of the main challenges in model updating results from the difficulty in distinguishing between the effects of calibration parameters versus model discrepancy. In this chapter, this identifiability problem is illustrated with several examples that explain the mechanisms behind it and that attempt to shed light on when a system may or may not be identifiable. For situations in which identifiability cannot be achieved using only a single response, an approach is developed to improve identifiability by using multiple responses that share a mutual dependence on the calibration parameters. Furthermore, prior to conducting physical experiments but after conducting computer simulations, in order to address the issue of how to select the most appropriate set of responses to measure experimentally to best enhance identifiability, a preposterior analysis approach is presented to predict the degree of identifiability that will result from using different sets of responses to measure experimentally. To handle the computational challenges of the preposterior analysis, we also present a surrogate preposterior analysis based on the Fisher information of the calibration parameters.

1 Introduction

Computer simulations have been widely used for design and optimization in many fields of science and engineering, as they are often much less expensive than physical experiments in analyzing complex systems. However, computer simulations never agree completely with experiments, because no computer model is perfect. Several sources of uncertainty accounting for the differences between computer simulations and physical experiments have been reported in the literature [1, 2]. *Parameter uncertainty* and *model discrepancy* are typically the two main

sources; the former is due to the lack of knowledge of physical parameters (e.g., friction coefficient in a finite element analysis) that are naturally fixed but unknown and cannot be directly observed in physical experiments, while the latter is associated with the lack of knowledge of the underlying true physics and is represented by a discrepancy function. Other sources of uncertainty may include *numerical uncertainty* due to numerical errors in implementing computer models, *experimental uncertainty* due to random observational error when taking experimental measurements, and uncertainty due to randomly varying physical parameters. To analyze the differences between computer simulations and physical experiments and to adjust simulation models to better reflect the reality, several model uncertainty quantification methodologies [1–5] have been developed for learning these uncertainties via combining simulation data with physical experimental data. Adjusting predictive models based on identifying the unknown physical parameters and the model discrepancy are referred to as *calibration* [1] and *bias correction* [6–8], respectively.

When there is no discrepancy function, calibration is typically a straightforward, statistically identifiable problem [9–11]. However, it is well known [12–15] that, when a discrepancy function is present, the estimation problem is often poorly identifiable, in the sense that it is difficult to distinguish the effects of calibration parameter uncertainty from the discrepancy function or to estimate these quantities individually. Much of the prior calibration work that has considered a discrepancy function, including work on experimental design for calibrating computer models [1, 2, 4, 16, 17], focused on the more easily attainable objective of good response prediction with the calibrated computer model, even if one is unable to accurately identify the calibration parameters and distinguish their effects from the discrepancy function.

Higdon et al. [2], Loeppky et al. [12], and Han et al. [13] distinguished between two different types of parameters – tuning parameters and calibration parameters – that can serve as input variables in a computer model. Tuning parameters have no meaning in the physical experiment, whereas calibration parameters do have concrete physical meaning but are unknown in reality. Examples of tuning parameters [18] are mesh density in a finite element simulation or some constant in an empirically postulated material flow law (e.g., [19]). Han et al. [13] and the references therein provide a number of examples of calibration parameters that have concrete physical meaning, such as the friction between bone and prosthesis in a prosthetic knee simulation, and they discuss the importance of identifying the true values of the calibration parameters. In this chapter, the situation is considered in which there are unknown calibration parameters that have physical meaning but are unmeasurable, and it is desired to estimate their true values and distinguish their effects from the effects of the discrepancy function.

Recent studies [12, 14, 15] indicate that calibration is usually difficult and that existing methodologies often fail at distinguishing between the effects of parameter uncertainty and model discrepancy and even between the effects of different model parameters. This issue is referred to as (non)*identifiability*. Loosely speaking, identifiability problems occur when different but equally likely combinations of the

calibration parameters and the discrepancy function result in equally good agreement with the observed data. Most of the existing model uncertainty quantification techniques [1, 2, 4, 20] treat the process as a black-box and have the objective of improving the experimental response prediction but with little regard to identifying the true model calibration parameters and model discrepancy. Loepky et al. [12] explored the identifiability issue and concluded that accurate prediction of the experimental response is often possible, even if the individual calibration parameters and discrepancy function are not identified precisely. Furthermore, they concluded that the true values of the calibration parameters are only attainable when the model discrepancy between simulation and reality is neither present nor included in the model updating formulation. Higdon et al. [2] found that in some simple cases the calibration parameters and discrepancy function can be accurately identified, but in other cases their effects cannot be distinguished even though the response predictions may be reasonable.

A broader view should be taken that good identifiability is often critically important for many reasons: (1) Learning the calibration parameters may in itself be a primary goal with broad-reaching implications for product/process improvement (e.g., if these calibration parameters are needed for a system-level simulation or if the calibration parameters themselves reflect the performance of interest but cannot be observed directly). (2) Knowledge of the model discrepancy improves the understanding of the deficiencies of the computer model for improving future generations. (3) It results in more accurate prediction over a broader set of input regions, because the model adjustment from learning the calibration parameters is more global than the adjustment from learning the model discrepancy. In the context of using predictive modeling for engineering design, adjusting the calibration parameters changes the prediction of the experimental response for a wide range of values for the design variables, whereas adjusting the discrepancy function tends to change the prediction of the experimental response predominantly within some neighborhood of the specific design variable settings that were used in the experiments.

In many engineering applications, good identifiability is virtually impossible if considering a single experimental response. In this chapter, we aim to provide a better understanding of the issue of identifiability and offer feasible treatments to predict and to enhance identifiability via a multi-response approach. The remainder of the chapter is organized as follows: Sect. 2 investigates the issue of identifiability using a simply supported beam example. Whereas the example and discussion in Sects. 2.1 and 2.2 convey the conclusion that identifiability is often very difficult, or impossible, in typical implementations, Sect. 2.3 discusses situations in which it is reasonable to expect that good identifiability can be achieved. Section 3 further investigates the identifiability issue and demonstrates that incorporating multiple experimental responses that share a mutual dependence on a common set of calibration parameters can substantially improve identifiability. Section 4 provides a detailed description of a preposterior analysis, in conjunction with the multi-response uncertainty quantification approach, for predicting identifiability prior to conducting physical experiments. Furthermore, to handle computational challenges

in the preposterior analysis, a surrogate preposterior analysis is presented based on the Fisher information of the calibration parameters. The methods are applied to the same simply supported beam example to enhance identifiability. The results of the preposterior and surrogate preposterior analyses are compared to the results of the posterior analysis (after observing the experimental data) to demonstrate the effectiveness of the methods. Conclusions are made in Sect. 5.

2 Identifiability Challenge in Model Calibration

2.1 Overview of Lack of Identifiability

Following the seminal work of Kennedy and O'Hagan [1], the model uncertainty quantification formulation that incorporates the various uncertainties is [1, 2, 4, 21]:

$$y^e(\mathbf{x}) = y^m(\mathbf{x}, \boldsymbol{\theta}^*) + \delta(\mathbf{x}) + \varepsilon, \quad (4.1)$$

where the controllable inputs (aka design variables) are denoted by the vector $\mathbf{x} = [x_1, \dots, x_d]^T$ and the calibration parameters, which are unknown model parameters, are denoted by the vector $\boldsymbol{\theta} = [\theta_1, \dots, \theta_r]^T$. A calibration parameter is defined as any physical parameter that can be specified as an input to the computer model and that is unknown or not measurable when conducting the physical experiments [1]. $\boldsymbol{\theta}^*$ (an $r \times 1$ vector of constants) denotes the true values of the unknown calibration parameters over the course of the physical experiments. $y^e(\mathbf{x})$ is the experimental response, $y^m(\mathbf{x}, \boldsymbol{\theta})$ is the computer model response as a function of \mathbf{x} and $\boldsymbol{\theta}$, $\delta(\mathbf{x})$ is the additive discrepancy function that represents the difference between the model response (using the true $\boldsymbol{\theta}^*$) and the experimental response, and ε accounts for the experimental uncertainty. Experimental uncertainty is typically assumed to follow a normal distribution with mean 0 and variance λ , denoted $\varepsilon \sim \mathcal{N}(0, \lambda)$.

Parameter uncertainty has two forms. A parameter $\boldsymbol{\theta}$ may be constant but unknown and its uncertainty represented via a probability distribution. Alternatively, a parameter \mathbf{x} may vary randomly (from run to run over the physical experiments and/or over any future instances for which the model is used to predict reality) according to some probability distribution. An example of the latter could be the blank thicknesses in a sheet metal stamping operation that vary randomly from blank to blank due to manufacturing variation. Calibration generally refers to the former form of parameter uncertainty, with the goal of identifying the true values of the constant parameters. "Constant" parameters refer to those that do not change over the duration of the physical experiments. Accordingly, in this chapter, only this form of parameter uncertainty is considered. Calibration in the case of parameters that vary randomly throughout the physical experiment would be far more challenging. One might assume some distribution for the randomly varying parameters and define the "calibration" goal as to identify the statistical parameters of the distribution (e.g., the mean and variance of a normal distribution) [20]. However, this would require

far more experimental observations than are needed for the goal in this chapter of identifying constant physical parameters.

The formulation in Eq. (4.1) is comprehensive in that it accounts for parameter uncertainty, model discrepancy, experimental uncertainty, and interpolation uncertainty. To quantify uncertainty in the calibration parameters and discrepancy function, the modular Bayesian approach presented in [1] is used to calculate their posterior distributions. Notice that the discrepancy function in Eq. (4.1) is not directly observable from the collected data, since the true value of θ is unknown. Notation-wise two Gaussian process (GP) models are used to infer the computer model response and the discrepancy function such that:

$$y^m(\cdot, \cdot) \sim \mathcal{GP}(\mathbf{h}^m(\cdot, \cdot)\boldsymbol{\beta}^m, \sigma_m^2 R^m((\cdot, \cdot), (\cdot, \cdot))), \quad (4.2)$$

$$\delta(\cdot) \sim \mathcal{GP}(\mathbf{h}^\delta(\cdot)\boldsymbol{\beta}^\delta, \sigma_\delta^2 R^\delta(\cdot, \cdot)). \quad (4.3)$$

The prior mean function of the computer model response is comprised of the unknown regression coefficients $\boldsymbol{\beta}^m$ and the known regression functions $\mathbf{h}^m(\mathbf{x}, \theta)$. The prior covariance function is the product of an unknown constant σ_m^2 and a correlation function $R^m((\mathbf{x}, \theta), (\mathbf{x}', \theta'))$, where (\mathbf{x}, θ) and (\mathbf{x}', θ') denote two sets of computer model inputs. The notations for the discrepancy function are similarly defined. $R^m((\mathbf{x}, \theta), (\mathbf{x}', \theta'))$ and $R^\delta(\mathbf{x}, \mathbf{x}')$ are parameterized by a $(d+r) \times 1$ vector $\boldsymbol{\omega}^m$ and a $d \times 1$ vector $\boldsymbol{\omega}^\delta$ such that:

$$R^m((\mathbf{x}, \theta), (\mathbf{x}', \theta')) = \exp \left\{ - \sum_{k=1}^d \omega_k^m (x_k - x'_k)^2 - \sum_{k=d+1}^{d+r} \omega_k^m (\theta_k - \theta'_k)^2 \right\}, \quad (4.4)$$

$$R^\delta(\mathbf{x}, \mathbf{x}') = \exp \left\{ - \sum_{k=1}^d \omega_k^\delta (x_k - x'_k)^2 \right\}. \quad (4.5)$$

The modular Bayesian approach incorporates the prior knowledge of calibration parameters θ , estimates the *hyperparameters* of the GP models $\phi = [\boldsymbol{\beta}^m, \sigma_m^2, \boldsymbol{\omega}^m, \boldsymbol{\beta}^\delta, \sigma_\delta^2, \boldsymbol{\omega}^\delta, \lambda]$, and evaluates the posterior distribution of θ . Because Eq. (4.1) accounts for several different forms of uncertainty and also includes \mathbf{x} , it is viewed as providing a comprehensive and widely applicable model updating formulation for design under uncertainty. However, one limitation is that for some systems it is very difficult to distinguish between the effects of parameter uncertainty and model discrepancy. More specifically, the same predicted experimental response can result from many different but equally likely combinations of the calibration parameters and the discrepancy function. This constitutes a lack of identifiability [12, 22] of the calibration parameters and discrepancy function, even though the experimental response still may be accurately predicted.

Figure 4.1 illustrates this with an example having a scalar input $x(d = 1)$ and a scalar calibration parameter $\theta(r = 1)$. $\hat{\theta}^{(1)}$, $\hat{\theta}^{(2)}$, and $\hat{\theta}^{(3)}$ denote three possible estimates of the calibration parameter θ ; $y^m(x, \hat{\theta}^{(1)})$, $y^m(x, \hat{\theta}^{(2)})$, and $y^m(x, \hat{\theta}^{(3)})$ are the computer simulation models corresponding to the three different values of θ .

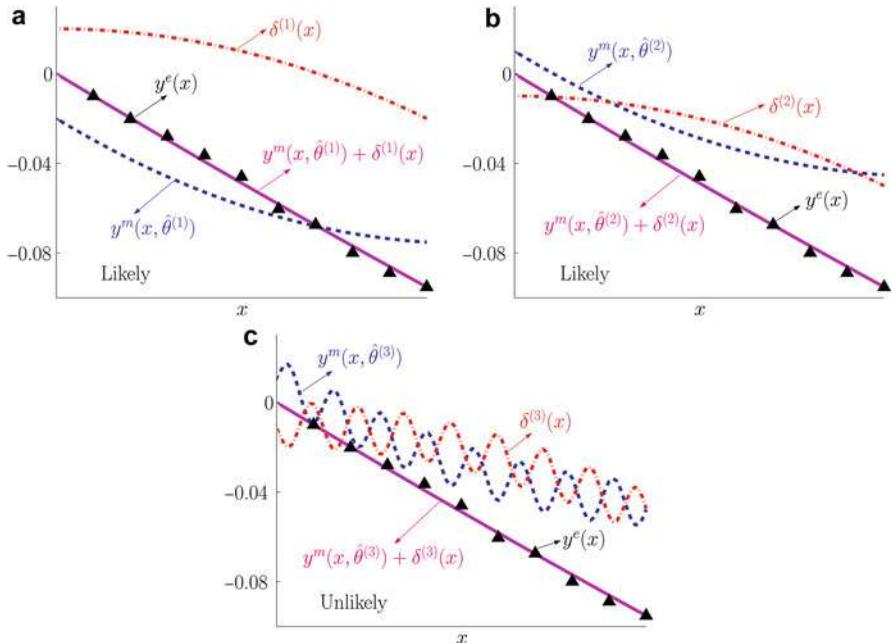

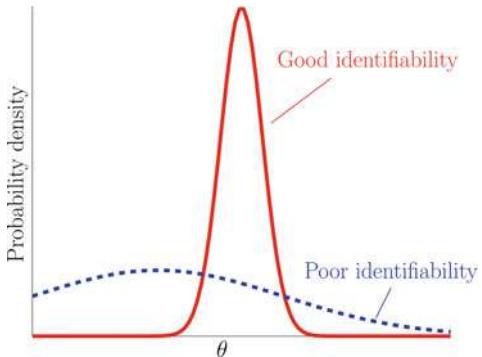

Fig. 4.1 An illustration of identifiability. While it is easy to tell that (c) is the least likely estimate of θ , it may be impossible to identify which of (a) and (b) is better

For each simulation realization $y^m(x, \hat{\theta}^{(i)})$ ($i = 1, \dots, 3$), an estimated discrepancy function $\delta^{(i)}(x)$ ($i = 1, \dots, 3$) can be found so that the resulting experimental response predictions $y^m(x, \hat{\theta}^{(1)}) + \delta^{(1)}(x)$, $y^m(x, \hat{\theta}^{(2)}) + \delta^{(2)}(x)$, and $y^m(x, \hat{\theta}^{(3)}) + \delta^{(3)}(x)$ are quite similar and in equally good agreement with the experimental data within the experimental region. Intuitively from the smoothness of the observed experimental data, the combination of $\hat{\theta}^{(3)}$ and $\delta^{(3)}(x)$ seems less likely than the other two combinations to be the true parameter value and true discrepancy function as the simulation is highly nonlinear. Rigorous calculation can show that its posterior probability density $p(\hat{\theta}^{(3)}|y^m, y^e)$ has a smaller value than $p(\hat{\theta}^{(1)}|y^m, y^e)$ and $p(\hat{\theta}^{(2)}|y^m, y^e)$. However, it may be virtually and computationally impossible to identify which of $\hat{\theta}^{(1)}$ and $\hat{\theta}^{(2)}$ is a better estimate of θ , since in both cases (Fig. 4.1a, b) the computer simulations are consistent with the experiments to a similar degree, and the values of $p(\hat{\theta}^{(1)}|y^m, y^e)$ and $p(\hat{\theta}^{(2)}|y^m, y^e)$ are close.

Figure 4.2 depicts how the posterior distribution of θ can be used to assess the level of identifiability for a hypothetical single-parameter example. A tight posterior distribution of θ with a clear mode indicates good identifiability. In sharp contrast, with a widely dispersed posterior distribution, the identifiability is poor. As in much of the prior work that assessed calibration identifiability (e.g., [4, 12, 13]), identifiability can be quantified via the posterior covariance matrix of the set of calibration parameters (posterior to observing the physical experimental

Fig. 4.2 Posterior distribution of calibration parameter as a demonstration of identifiability for the single-parameter case

data, in addition to the simulation data). One might also consider using the posterior covariance function of the discrepancy function as a measure of identifiability; however, this is infinite dimensional and cumbersome. Moreover, the posterior covariance of the discrepancy function is closely related to the posterior covariance of the calibration parameters, in the sense that precisely estimated calibration parameters generally imply a precisely estimated discrepancy function (which is somewhat obvious from Eq. (4.1)). Consequently, the posterior covariance matrix of the calibration parameters is more manageable to work with. Here, the term “identifiability” is used rather informally to refer to whether one can expect to achieve reasonable and useful estimation of the calibration parameters with typical finite sample sizes (which is sometimes possible), as opposed to whether estimators are consistent and guaranteed to asymptotically converge to the true values when sample sizes approach infinity in some sense (which is perhaps never possible under realistic assumptions).

2.2 Case Study: An Illustrative Simply Supported Beam Example

To further illustrate this identifiability problem, an example using a simply supported beam [14] is presented in Fig. 4.3. The beam has length of 2 m and a rectangular cross-section with a height of 52.5 mm and width of 20 mm. One end of the beam is fixed (no vertical or horizontal displacement permitted), while the other end of the beam is supported by a roller (no vertical displacement permitted). A static force is applied to the midpoint of the beam to induce various responses (e.g., stress and displacement). In this example, the magnitude of the applied force is chosen as the design variable x . Refer to Table 4.1 for the notation of this example.

The computer model response $y^m(x, \theta)$ (angle of deflection at the end of the beam in radians) is obtained from a finite element analysis (FEA) model representing a simply supported beam (using Abaqus 6.9) with a simplified (perfectly plastic) material law. For illustrative purposes, the “experimental response” $y^e(x)$ (angle of deflection at the end of the beam in radians) is taken to be the response from a FEA model using a more elaborate material law (a power law for the plastic region with

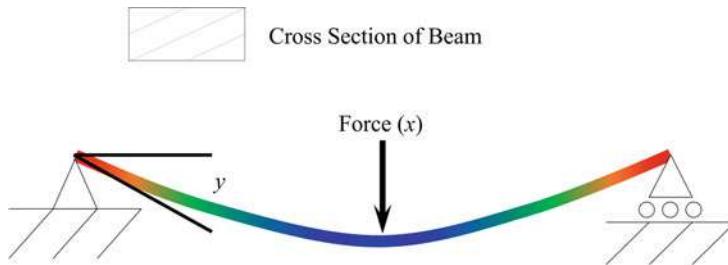

Fig. 4.3 Schematic of the simply supported beam

Table 4.1 Notation for the simply supported beam example

Variable	Description
x	Static force (N) applied to the midpoint of the beam (on the range [1300 2300] N)
θ	Young's modulus (GPa), on which both the simulation model and physical reality depend (on the range [150 300] GPa), $\theta^* = 206.8$ GPa is the true value
y	The angle of deflection (radians) at the end of the beam
$y^m(x, \theta)$	y calculated via a finite element analysis (FEA) with a simplified material model
$y^e(x)$	"Experimentally measured" y (for illustrative purposes, calculated from a FEA model with a more elaborate material model assuming $\theta = \theta^*$)
$\delta(x)$	Discrepancy function
ε	Random error, assumed 0 in this example

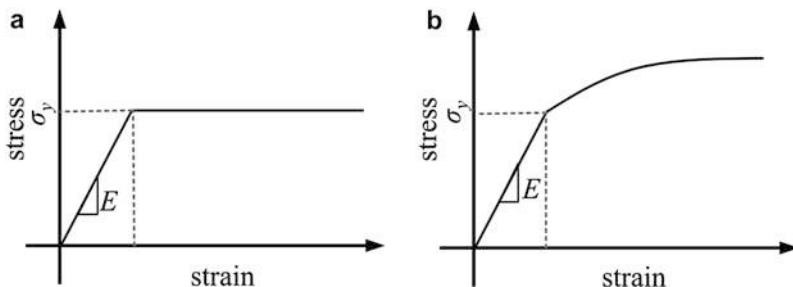

Fig. 4.4 Material stress-strain curves for (a) the computer model and (b) the "physical experiments." E is Young's modulus and the calibration parameter. σ_y is the yield stress (225 MPa)

constant stress $C = 2068$ MPa and strain-hardening exponent $n = 0.5$) [23]. These material laws are in part governed by Young's modulus, E , which is treated as the unknown calibration parameter θ (Fig. 4.4). For the "physical experiments," the true value of the calibration parameter is set to $\theta^* = 206.8$ GPa but is treated as unknown during the analysis and assigned a uniform prior over the range $150 \leq \theta \leq 300$ GPa. The prior distribution was chosen to be relatively wide in order to minimize the effect of the prior on the posterior distributions and to avoid choosing a prior that does not contain any support at the true value θ^* (in which case the posterior will

not contain any support at θ^* either). In practice, it is recommended choosing a conservatively wide prior in order to ensure that there is some support at the true value of the parameters.

The goal is to use the observed simulation and experimental data to infer the calibration parameter and the discrepancy function of the model updating formulation of Eq. (4.1). It should be noted that this example is intended only to illustrate the modular Bayesian approach and the identifiability challenges. There are many standard experimental methods to determine Young's modulus using specimens of the material.

To infer the calibration parameter and the discrepancy function, the modular Bayesian approach discussed in [1] is applied to this example. We begin by fitting a GP model of the computer model using a 4 by 4 grid over the input space ($1300 \leq x \leq 2300$ N and $150 \leq \theta \leq 300$ GPa). The experimental data \mathbf{y}^e is observed at $\mathbf{X}^e = [1300, 1400, 1500, \dots, 2300]^T$ and indicated in Fig. 4.5a by the black dots. The experimental data, together with the uniform prior for θ and the hyperparameter MLEs, are used to estimate the hyperparameters of the GP model for the discrepancy function. Finally, the posterior distributions for the discrepancy function and the calibration parameter are calculated via Legendre-Gauss quadrature. The posterior distributions are shown in Fig. 4.5. From Fig. 4.5a, the posterior distribution of the experimental response is very accurate and precise, because there was a relatively

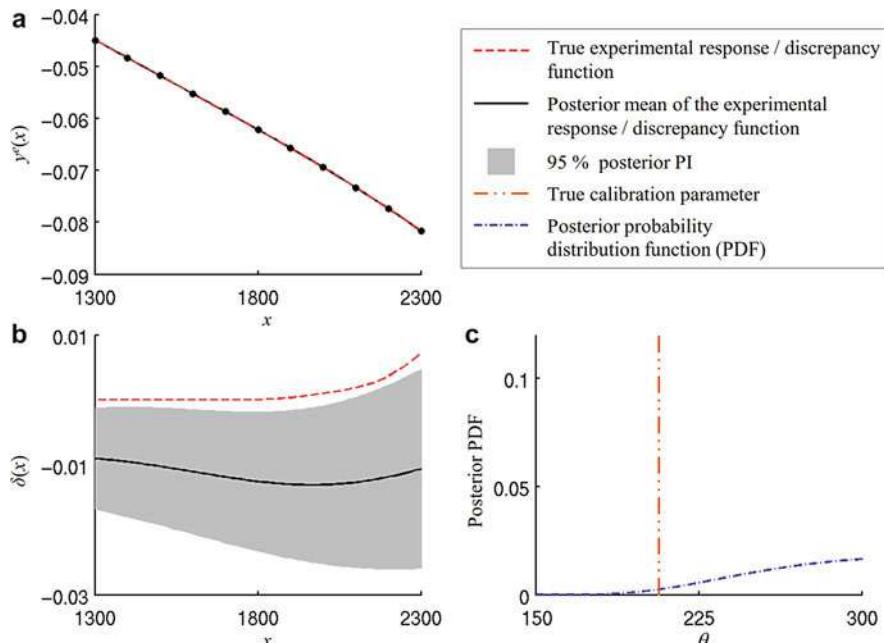

Fig. 4.5 The posterior distributions for (a) the experimental response, (b) the discrepancy function, and (c) the calibration parameter showing a lack of identifiability

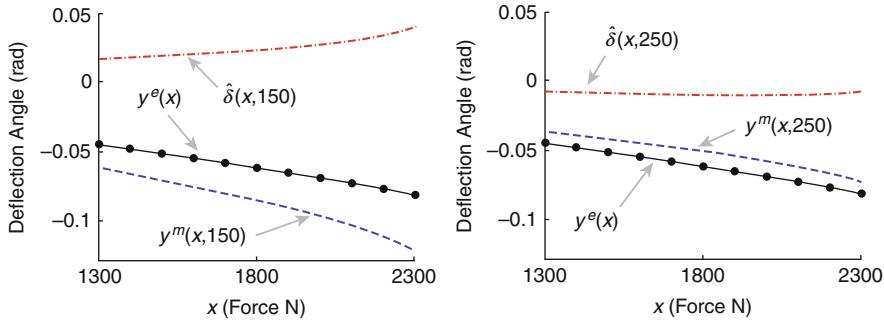

Fig. 4.6 The computer response $y^m(x, \theta)$, the experimental response $y^e(x)$ (bullets indicate experimental data), and the estimated discrepancy function $\hat{\delta}(x, \theta) = y^e(x) - y^m(x, \theta)$ for (a) $\theta = 150$ GPa and (b) $\theta = 250$ GPa

large amount of experimental data and no experimental error ε . In spite of this, the calibration parameter and the discrepancy function are not identifiable as illustrated below.

To assess identifiability, the posterior distributions of the calibration parameter (Fig. 4.5c) and the discrepancy function (Fig. 4.5b) are used. The large posterior variance of the calibration parameter and the large width of the prediction intervals for the discrepancy function indicate the poor identifiability of the calibration parameter and discrepancy function. Indeed, several different combinations of these are approximately equally probable and give approximately the same (quite accurate and precise) predicted response in Fig. 4.6a. It is also worth noting neither posterior reflects the true values of the calibration parameter and the discrepancy function. Because of the high uncertainty reflected by the posterior distributions, the system is not identifiable, even with the relatively dense spacing of the experimental data. Moreover, collecting additional experimental observations would help little.

To understand how the large uncertainty and the inaccuracy of the posterior distributions lead to a lack of identifiability, consider the estimated discrepancy function $\hat{\delta}(x, \theta) = y^e(x) - y^m(x, \theta)$ shown in Fig. 4.6 for two different values of θ . For θ underestimated at 150 GPa in Fig. 4.6a (the true $\theta^* = 206.8$ GPa) and for θ overestimated at 250 GPa in Fig. 4.6b, neither θ nor the resulting estimated discrepancy function are inconsistent with their priors or in disagreement with the data. They both result in very similar, and quite accurate, prediction of the experimental response. Consequently, without additional information, it is virtually impossible to distinguish between the effects of θ and $\delta(x)$ and accurately identify each in this example.

To improve identifiability, previous literature [4, 24] recommended using informative (i.e., low variance or tightly dispersed) prior distributions for the calibration parameters, the discrepancy function, or both. However, specifying informative priors for the discrepancy function (e.g., a linear or quadratic functional form [20, 25]) is often difficult because one rarely has significant prior knowledge.

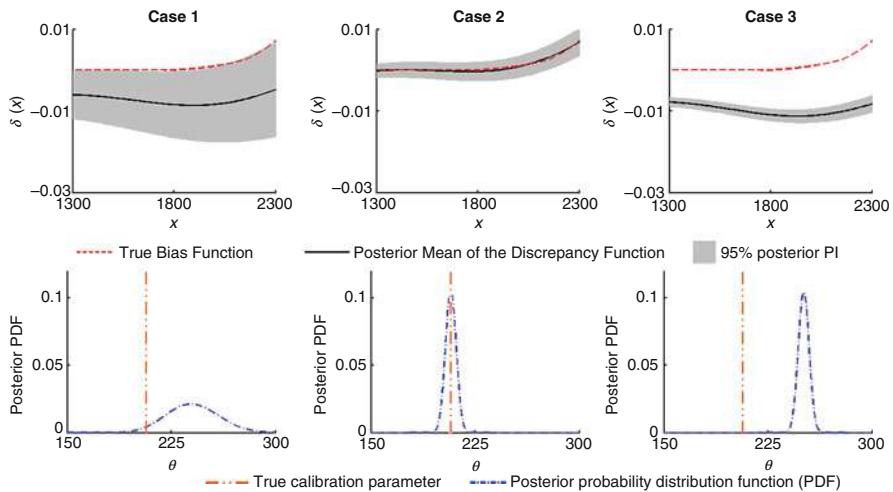

Fig. 4.7 Posterior distributions for the discrepancy function and the calibration parameter for the three prior distributions in Table 4.2

Table 4.2 Prior distribution (normal) and posterior distribution means and standard deviations for the calibration parameter

	Case 1	Case 2	Case 3
Prior mean	225.00	206.80	250.00
Prior std. dev.	22.36	3.87	3.87
Post mean	240.63	207.43	250.68
Post std. dev.	18.68	3.84	3.83

Likewise, one does not have such prior information on the calibration parameters (otherwise, they would be viewed as known parameters and not considered calibration parameters). However, to illustrate how this would improve identifiability, three versions of the preceding beam example are considered using three different normal prior distributions for θ , each with different means and/or variances. The resulting posterior distributions for θ and the discrepancy function are shown in Fig. 4.7 and Table 4.2.

Case 1 assumes a less informative (larger standard deviation) prior distribution centered about the midpoint of the calibration parameter range (mean of 225 GPa). In this case, the posterior distribution for the calibration parameter and the discrepancy function were neither accurate nor precise, which indicates a lack of identifiability. In Case 2, an informative prior (small standard deviation) with a mean equal to the true θ results in an identifiable system, which is evident by the accurate and precise posterior distributions. In contrast, Case 3 shows the inherent danger of using an informative prior that is inaccurate albeit precise. In this case, the posterior for the discrepancy function has a small prediction interval and the posterior of the calibration parameter has a small variance, which would lead one to believe that they are precisely estimated. However, the results of posteriors are inaccurate and do not reflect the true discrepancy function and θ .

In conclusion, since one rarely has such accurate and informative prior knowledge about the sources of uncertainty present in the engineering system, assuming informative priors for the calibration parameters or the discrepancy function is not a satisfying solution to the identifiability problem.

2.3 When Is Calibration Identifiability Possible?

The simply supported beam represents a system for which we cannot accurately and precisely identify both the calibration parameters and the discrepancy function (e.g., via their posterior distributions). This leads one to question whether identifiability is ever possible, given the nature of the model in Eq. (4.1). This section demonstrates that the answer is yes, but under certain assumptions. This is illustrated with a simple example in which the requisite assumptions are that the discrepancy function is reasonably smooth and can be represented by a smooth GP model (i.e., a GP with small roughness parameters, ω). Loosely speaking, “smooth” means that the function does not change abruptly for small changes in the design variables. In the context of our GP-based modeling, smooth means that the function is consistent with a GP model having relatively small roughness parameters (ω), as discussed later at the end of this section.

As evident from the posterior distributions of Fig. 4.5, the simply supported beam is not identifiable. The conceptual explanation (see the discussion surrounding Fig. 4.6) is that, for many different values of θ , the estimated discrepancy function is smooth and consistent with a GP model. In contrast, an example is considered next in which the estimated discrepancy function has behavior that is inconsistent with a GP model when $\theta \neq \theta^*$, but consistent when $\theta = \theta^*$. It will be shown that this is the essential ingredient for good identifiability [14]. Consider the following step function as the computer model

$$y^m(x, \theta) = \begin{cases} 1 - \theta & x < 2 \\ 1 + \theta & x \geq 2 \end{cases}, \quad (4.6)$$

with $1 \leq x \leq 3$ and $0.5 \leq \theta \leq 3$. Notice that the magnitude of the step is dictated by the calibration parameter θ . Plots of $y^m(x, \theta)$ for $\theta = 1.0$ and 3.0 , respectively, are shown in Fig. 4.8a, c. The physical experimental responses were generated according to Eq. (4.1) with the true calibration parameter $\theta^* = 2.5$, experimental error $\varepsilon = 0$, and the true discrepancy function $\delta(x)$ generated as one random realization of a smooth GP with a prior mean of 0 and a Gaussian covariance function with $\omega^\delta = \sigma_\delta = 1$.

To quantitatively assess identifiability, again, the modular Bayesian approach is used. A GP model for the computer model (the step function of Eq. (4.6)) was created using a total of 168 simulation runs, as shown in Fig. 4.9. 144 runs were observed on a 12 by 12 grid. Additionally, to accurately capture the step behavior of the computer model, 24 additional runs were conducted at $x = 1.99$ and 2.01 , for 12 evenly spaced values of θ . The GP model of the computer model

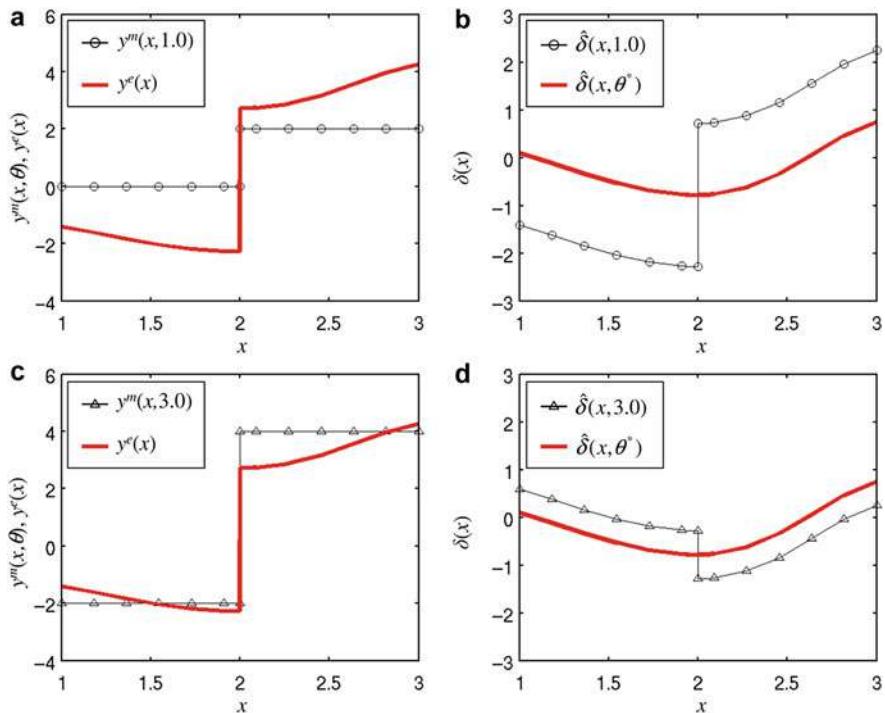

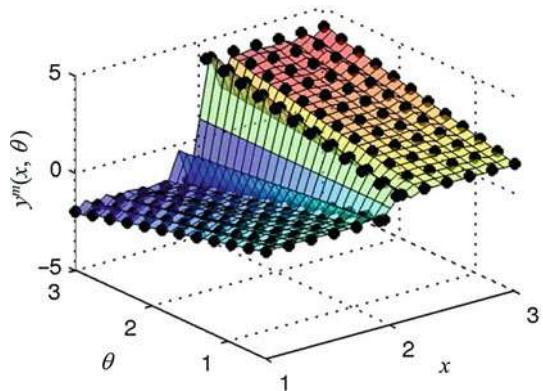

Fig. 4.8 Computer model and experimental response for Eqs. (4.6) and (??) with (a) $\theta = 1.0$ and (c) $\theta = 3.0$. Corresponding estimated discrepancy function $\hat{\delta}(x, \theta)$ for (b) $\theta = 1.0$ and (d) $\theta = 3.0$

Fig. 4.9 Fitted GP model of the computer model of Eq. (4.6) based on 168 simulation runs, y^m (black dots)

was difficult to fit using the 168 simulations, due to the discontinuity at $x = 2$. Typically, a GP model with a Gaussian correlation function is not a good choice to model a step function because of its inherent smoothness (see Ref. [26, p. 123] and subsequent discussion). However, Fig. 4.9 shows that, with the large amount of

data and allowing large roughness parameters (the MLEs of the hyperparameters are $\omega^m = [\omega^x, \omega^\theta]^T$, where $\omega^x = 377.52$ and $\omega^\theta = 50$, and ω^θ fell at the upper boundary of what is allowed in the MLE algorithm for numerical purposes), a fairly accurate GP metamodel results. Although the fitted GP metamodel is somewhat rough and interpolates less accurately near the discontinuity, it serves to illustrate when identifiability is achievable.

After creating the GP model for the computer model, the modular Bayesian approach estimates the hyperparameters for the GP model representing the discrepancy function. 14 experimental data points were collected at $\mathbf{X}^e = [1, 1.167, 1.333, \dots, 3, 1.99, 2.01]^T$ (the black dots in Fig. 4.10a). The same x locations were chosen for the simulation and experimental runs in order to focus on identifiability rather than interpolation performance. Finally, the posterior distributions for the calibration parameters, the experimental response, and the discrepancy function are calculated. 10 shows the resulting posterior distributions.

The accurate and precise (low posterior standard deviation) posterior distributions for the discrepancy function in Fig. 4.10b and the calibration parameter in Fig. 4.10c demonstrates that good identifiability is achievable for this example.

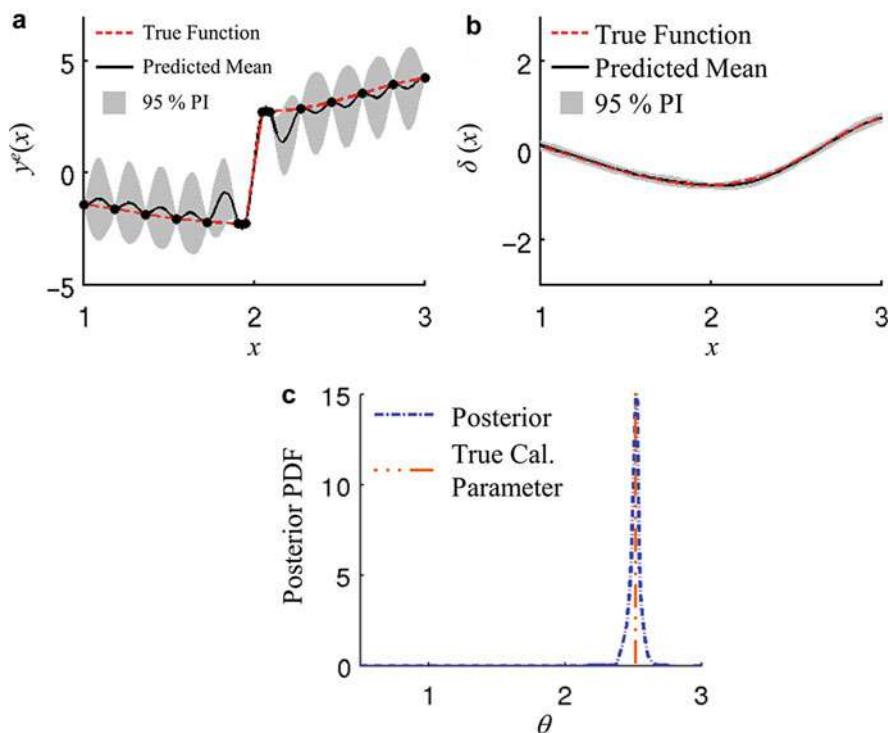

Fig. 4.10 Posterior distributions for (a) the experimental response (black dots indicate experimentally observed response values), (b) the discrepancy function, and (c) the calibration parameter θ

Notice that the posterior mean of the experimental response in Fig. 4.10a is a less accurate and precise predictor near the step discontinuity. In spite of this, reasonable identifiability of the calibration parameter was achieved, which was the objective of this analysis.

To understand why the system is identifiable in this example, consider the estimated discrepancy functions $\hat{\delta}(x, \theta)$ for two incorrect values of θ shown in Fig. 4.8b ($\theta = 1.0$) and Fig. 4.8d ($\theta = 3.0$). For reference, the estimated discrepancy function $\hat{\delta}(x, \theta^*)$ for the true $\theta^* = 2.5$ is shown in both figures. The salient feature is that $\hat{\delta}(x, \theta)$ for the incorrect values of θ have discontinuities that are inconsistent with a smooth GP model for the discrepancy function. The only value of θ that results in a $\hat{\delta}(x, \theta)$ consistent with model is the true value $\theta^* = 2.5$. By a $\hat{\delta}(x, \theta)$ “inconsistent” with the model, it means that, when that value of θ and its corresponding $\hat{\delta}(x, \theta)$ are plugged into the likelihood function, the resulting likelihood is exceptionally low. Because the estimated discrepancy function entails a high likelihood only when θ is close to θ^* , and the likelihood drops off abruptly as θ deviates from θ^* , the second derivative of the likelihood function (with respect to θ) is quite large. This translates to a large observed Fisher information, which results in a tight posterior distribution for θ . This is, in essence, the definition of identifiability. The preceding example illustrates that identifiability is possible when small changes in the calibration parameters about their true values result in an estimated discrepancy function (which reflects the differences between the observed experimental data and the simulation model) that is inconsistent with the GP model of the discrepancy function.

The identifiability issues in the preceding discussion can also be viewed in a slightly different light. In essence, the approach evaluates identifiability by considering the simulation data, considering the experimental data, and then assessing the likelihood that the observed differences between the simulation and experimental data are explained by the discrepancy function, by an adjustment of the calibration parameters, or by various combinations thereof. Hypothetically, if there is roughly equal likelihood that the differences between the simulation and experimental data are explained by two (or more) different combinations of a discrepancy function and an adjustment in the calibration parameters, then identifiability would be poor in this case. On the other hand, if the likelihood is high that one particular combination of discrepancy function and adjustment in the calibration parameters accounts for the differences between the simulation and experimental data, then identifiability would be good in this case.

In either case, the likelihood must be evaluated with respect to the assumed prior distribution for the discrepancy function. And in this sense, identifiability is possible only by making certain assumptions on the prior distribution model for the discrepancy function. Although identifiability is achieved in the step example via certain assumptions on the prior distributions, this is quite different than assuming a tight, informative prior distribution for the calibration parameters. The latter would also generally result in identifiability (i.e., a tight posterior), but it would be an artificial identifiability in that one would have to begin with precise knowledge of

the parameters via a tight prior. In all of the examples of this section, only relatively non-informative prior distributions have been used for the calibration parameters. Note that, in the preceding, the term “likelihood” is used, but it is technically a Bayesian posterior probability, which considers both the likelihood and the prior distributions for all parameters and hyperparameters.

3 Improving Identifiability in Model Calibration Using Multiple Responses

In engineering systems where there is a lack of identifiability with a single response, this section introduces the use of multiple responses as additional information to improve identifiability. Multiple responses are considered to be a collection of single responses of different quantities (e.g., load force, displacement, stress, etc.), each of which can also be measured over time and/or space. When the multiple responses are mutually dependent on the same set of calibration parameters, the information obtained from them can be combined to better infer the true value of the calibration parameters. Note that multiple responses usually can be “measured” for free in computer simulations, as they are automatically calculated in the simulation. Hence, the added cost of observing multiple responses is that associated with their measurement in the physical experiments.

To quantify the uncertainty that results from having to interpolate the responses between discrete input sites at which they are observed in expensive computer simulations or physical experiments, multi-response surrogate models are necessary. One existing body of work uses a multi-response Gaussian process (MRGP) model, which is defined by its mean and covariance functions, as a surrogate model representing only the computer model. Most existing work uses the same mathematical structure for the mean function. However, for the covariance function, two different mathematical structures are common. References [27–30] assign an indexing variable to each response, which is treated as an additional input over which the covariance function is defined. This is only applicable if the multiple responses are inherently ordered in a manner that permits such an indexing.

More recently, Conti et al. [31, 32] defined a covariance function that is the combination of a spatial correlation function and a discrete covariance matrix, the latter representing the covariance between responses. This covariance parameterization is relatively simple yet flexible, and the resulting MRGP model is a straightforward extension of the well-established single-response Gaussian process model [32]. Therefore, this covariance function is adopted here to construct the MRGP model for both the computer model and the discrepancy functions.

Although using multiple responses to quantify computer model uncertainty based on experimental data has been considered in previous literature, the “multiple responses” were restricted to a single response measured at multiple spatial and/or temporal locations [33–36]. Furthermore, the prior work focuses solely on predicting the experimental response and not on identifiability of the calibration parameters

and the discrepancy functions. As demonstrated in Sect. 2.2, different combinations of the calibration parameters and the discrepancy functions can often result in the same experimental response prediction, which is the root of the identifiability problem.

The previous section shed light on the challenging problem of identifying the calibration parameters and the discrepancy function when combining single-response data from a computer model and physical experiments. The main objective of this section is to show that identifiability can be improved by including multiple responses in the model updating formulation. A multi-response modular Bayesian approach is developed in [15] to extend the single-response modular Bayesian approach [1], which is used to calculate the posterior distributions of the calibration parameters and the discrepancy functions. Subsequently, the multi-response modular Bayesian approach is applied to the same simply supported beam example introduced in Sect. 2.2. Whereas identifiability was not achievable using only a single response in Sect. 2.2, it will be shown here that identifiability can be substantially enhanced using certain combinations of multiple responses.

3.1 Multi-response Modular Bayesian Approach

The single-response modular Bayesian approach [1] calculates the posterior distributions, which quantify the posterior uncertainty of the calibration parameters and the discrepancy function, by integrating data from both simulations and experiments. In this section, the modular Bayesian approach is extended to incorporate multiple responses [15]. To do this, the model updating formulation of Kennedy and O'Hagan [1] is reformulated as [15, 34]:

$$y_i^e(\mathbf{x}) = y_i^m(\mathbf{x}, \boldsymbol{\theta}^*) + \delta_i(\mathbf{x}) + \varepsilon_i, \quad (4.7)$$

for $i = 1, \dots, q$, where q denotes the number of response variables. The vector $\mathbf{x} = [x_1, \dots, x_d]^T$ denotes the design variables (aka controllable inputs) and $\boldsymbol{\theta} = [\theta_1, \dots, \theta_r]^T$ denotes a vector of calibration parameters with $\boldsymbol{\theta}^*$ denoting their true physical values, which are unknown to the user. $y_i^m(\mathbf{x}, \boldsymbol{\theta})$ ($i = 1, \dots, q$) denotes the i th response from the computer model as a function of \mathbf{x} and $\boldsymbol{\theta}$, and $y_i^e(\mathbf{x})$ denotes the corresponding experimentally observed response.

Note that all of the responses from the computer model mutually depend on the same set of calibration parameters $\boldsymbol{\theta}$, and the experimental responses depend on the same true calibration parameter value $\boldsymbol{\theta}^*$. $\delta_i(\mathbf{x})$ denotes the i th discrepancy function, which represents the difference between the computer model (with input $\boldsymbol{\theta}^*$) and the physical experiments. Finally, ε_i is independent random experimental error (e.g., observation error), which is assumed normal with mean 0 and variance λ_i .

Similar to the procedure for implementing the single-response modular Bayesian approach as briefly mentioned in Sect. 2.1, the multi-response modular Bayesian approach fits a MRGP model to the computer model and the discrepancy functions

in two separate modules (Modules 1 and 2). After fitting each MRGP model, one calculates the posterior distributions of the calibration parameters, the discrepancy functions, and the experimental responses (Modules 3 and 4). Details of each module in the multi-response modular Bayesian approach are provided in the following.

3.1.1 Multi-response Gaussian Process Model for the Computer Model (Module 1)

In Module 1, a MRGP model is fit to the computer responses and used to infer their values at input sites other than those that were simulated. Following Conti et al. [31, 32], the prior for the MRGP model is:

$$\mathbf{y}^m(\cdot, \cdot) \sim \mathcal{GP}(\mathbf{h}^m(\cdot, \cdot)\mathbf{B}^m, \boldsymbol{\Sigma}^m R^m((\cdot, \cdot), (\cdot, \cdot))), \quad (4.8)$$

where $\mathbf{y}^m(\mathbf{x}, \boldsymbol{\theta}) = [y_1^m(\mathbf{x}, \boldsymbol{\theta}), \dots, y_q^m(\mathbf{x}, \boldsymbol{\theta})]$ denotes the multiple responses from the computer model. The prior mean function is comprised of an arbitrary vector of specified regression functions $\mathbf{h}^m(\mathbf{x}, \boldsymbol{\theta}) = [h_1^m(\mathbf{x}, \boldsymbol{\theta}), \dots, h_p^m(\mathbf{x}, \boldsymbol{\theta})]$ and a matrix of unknown regression coefficients $\mathbf{B}^m = [\beta_1^m, \dots, \beta_q^m]$, where $\beta_i^m = [\beta_{1,i}^m, \dots, \beta_{p,i}^m]^T$. A frequently used regression function is $\mathbf{h}^m(\mathbf{x}, \boldsymbol{\theta}) = 1$, which corresponds to a constant prior mean. The prior covariance function is the product of an unknown nonspatial $q \times q$ covariance matrix $\boldsymbol{\Sigma}^m$ and a spatial correlation function $R^m((\mathbf{x}, \boldsymbol{\theta}), (\mathbf{x}', \boldsymbol{\theta}'))$, where $(\mathbf{x}, \boldsymbol{\theta})$ and $(\mathbf{x}', \boldsymbol{\theta}')$ denote two sets of computer model inputs. This prior covariance function can be rewritten as $\text{Cov}[y_i^m(\mathbf{x}, \boldsymbol{\theta}), y_j^m(\mathbf{x}', \boldsymbol{\theta}')] = \boldsymbol{\Sigma}_{ij}^m R^m((\mathbf{x}, \boldsymbol{\theta}), (\mathbf{x}', \boldsymbol{\theta}'))$ where $\boldsymbol{\Sigma}_{ij}^m$ is the covariance between the i th and j th computer model responses at the same input values. Further, this covariance structure reduces to the covariance function for a single-response Gaussian process model when $q = 1$. A Gaussian correlation function is used:

$$R^m((\mathbf{x}, \boldsymbol{\theta}), (\mathbf{x}', \boldsymbol{\theta}')) = \exp \left\{ -\sum_{k=1}^d \omega_k^m (x_k - x'_k)^2 \right\} \exp \left\{ -\sum_{k=1}^r \omega_{d+k}^m (\theta_k - \theta'_k)^2 \right\}, \quad (4.9)$$

parameterized by the $(d+r) \times 1$ vector of roughness parameters $\boldsymbol{\omega}^m$, which represent the rate at which the correlation between $y_i^m(\mathbf{x}, \boldsymbol{\theta})$ and $y_i^m(\mathbf{x}', \boldsymbol{\theta}')$ decays to zero as $(\mathbf{x}, \boldsymbol{\theta})$ and $(\mathbf{x}', \boldsymbol{\theta}')$ diverge. Lower values of $\boldsymbol{\omega}^m$ indicate a smoother MRGP model for the response $y_i^m(\mathbf{x}, \boldsymbol{\theta})$.

Reference [31] provides some justification, beyond the relatively simple parameterization that results in tractable computations, for using the covariance structure in Eq. (4.9). In particular, if multiple responses mutually depend on the same set of inputs (both design variables and calibration parameters), then one might expect the responses to be correlated and to share a similar spatial correlation structure or smoothness. The formulation of Eq. (4.9) assumes such a shared spatial correlation structure. On the other hand, if the responses are weakly correlated with different

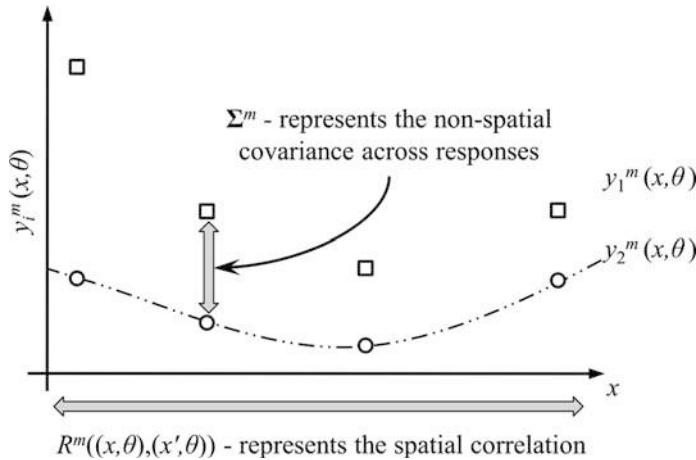

Fig. 4.11 Schematic showing the MRGP model's covariance function represented by spatial correlation and nonspatial covariance for a fixed θ

spatial correlations, then one can model each response independently, allowing each to have a different spatial correlation function [31].

Figure 4.11 illustrates the separation of the covariance function into spatial and nonspatial portions for the case of two responses. The gray arrow below the x -axis of Fig. 4.11 signifies the spatial correlation portion of the covariance function, which is represented by $R^m((x, \theta), (x', \theta))$ for computer model inputs x and x' with fixed θ . Alternatively, the nonspatial covariance matrix portion of the covariance function, Σ^m , represents the covariance across response functions, as signified in Fig. 4.11 by the gray arrow between the responses. Whereas the spatial correlation function dictates the smoothness of both responses, the nonspatial covariance matrix dictates the similarity between any trends or fluctuations (not represented by the prior mean function) in the two responses.

To obtain maximum likelihood estimates (MLEs) of the hyperparameters $\phi^m = \{\mathbf{B}^m, \Sigma^m, \omega^m\}$ for the computer model MRGP, the multivariate normal log-likelihood function based on the simulation data $\mathbf{Y}^m = [\mathbf{y}_1^m, \dots, \mathbf{y}_q^m]$ is maximized, where $\mathbf{y}_i^m = [y_i^m(\mathbf{x}_1^m, \theta_1^m), \dots, y_i^m(\mathbf{x}_{N_m}^m, \theta_{N_m}^m)]^T$, collected at N_m input sites $\mathbf{X}^m = [\mathbf{x}_1^m, \dots, \mathbf{x}_{N_m}^m]^T$ and $\boldsymbol{\Theta}^m = [\boldsymbol{\theta}_1^m, \dots, \boldsymbol{\theta}_{N_m}^m]^T$. Previous literature [37, 38] suggest a space-filling experimental design for the input settings of \mathbf{X}^m and $\boldsymbol{\Theta}^m$. Furthermore, to improve the numerical stability of the MLE algorithm, the inputs \mathbf{X}^m and $\boldsymbol{\Theta}^m$ can be transformed to the range of 0 to 1, and the simulation data can be standardized to have a sample mean of 0 and a sample standard deviation of 1 [39]. Details of the MLE algorithm can be found in Appendix A.

Inference of the computer model response $y_i^m(\mathbf{x}, \theta)$ at any \mathbf{x} and θ , can be determined by inserting the MLEs of the hyperparameters into the MRGP model posterior mean and covariance equations, Eqs. (4.22) and (4.23) of Appendix B. After obtaining the MLEs of the hyperparameters, the next step is to estimate the

hyperparameters of the MRGP model representing the discrepancy functions, as follows.

3.1.2 Multi-response Gaussian Process Model for the Discrepancy Functions (Module 2)

The MRGP model of the experimental response is the sum of two MRGP models representing both the computer model $y_i^m(\mathbf{x}, \boldsymbol{\theta})$ and the discrepancy functions $\delta_i(\mathbf{x})$. This MRGP model will then infer the experimental response $y_i^e(\mathbf{x})$ at any point \mathbf{x} .

To define the MRGP model for the experimental response, the MRGP model for the discrepancy functions needs to be defined first, which is the focus of Module 2. The prior of the MRGP model for the discrepancy functions is

$$\boldsymbol{\delta}(\cdot) \sim \mathcal{GP}\left(\mathbf{h}^\delta(\cdot)\mathbf{B}^\delta, \boldsymbol{\Sigma}^\delta R^\delta(\cdot, \cdot)\right), \quad (4.10)$$

where $\boldsymbol{\delta}(\mathbf{x}) = [\delta_1(\mathbf{x}), \dots, \delta_q(\mathbf{x})]$ denotes the multiple discrepancy functions. The mean function is comprised of a vector of specified regression functions $\mathbf{h}^\delta(\mathbf{x}) = [h_1^\delta(\mathbf{x}), \dots, h_s^\delta(\mathbf{x})]^T$ and a matrix of unknown regression coefficients $\mathbf{B}^\delta = [\boldsymbol{\beta}_1^\delta, \dots, \boldsymbol{\beta}_q^\delta]$, where $\boldsymbol{\beta}_i^\delta = [\beta_{1,i}^\delta, \dots, \beta_{s,i}^\delta]^T$. The prior covariance function of this MRGP model is the product of an unknown nonspatial covariance matrix $\boldsymbol{\Sigma}^\delta$ and a spatial correlation function $R^\delta(\mathbf{x}, \mathbf{x}')$, which is a Gaussian correlation function (similar to Eq. (4.9) but without the $\boldsymbol{\theta}$ inputs) parameterized by the $d \times 1$ vector of roughness parameters $\boldsymbol{\omega}^\delta$. This prior covariance function can be rewritten as $\text{Cov}[\delta_i(\mathbf{x}), \delta_j(\mathbf{x}')] = \boldsymbol{\Sigma}_{ij}^\delta R^\delta(\mathbf{x}, \mathbf{x}')$, where $\boldsymbol{\Sigma}_{ij}^\delta$ is the covariance between the i th and j th discrepancy functions at the same input values. Following the work of Kennedy and O'Hagan [1], the computer model, the discrepancy functions, and the experimental uncertainty are assumed a priori statistically independent (i.e., $\text{Cov}[y_i^m(\mathbf{x}, \boldsymbol{\theta}), \delta_j(\mathbf{x}')] = 0$, $\text{Cov}[y_i^m(\mathbf{x}, \boldsymbol{\theta}), \varepsilon_j] = 0$, and $\text{Cov}[\delta_i(\mathbf{x}), \varepsilon_j] = 0$ for $i, j \in \{1, \dots, q\}$ and all \mathbf{x} , \mathbf{x}' , and $\boldsymbol{\theta}$). These assumptions of a priori independence simplify many of the calculations required in the multi-response modular Bayesian approach. It should be noted that the posterior distributions for these quantities are generally highly correlated, even though their prior distributions are independent.

The priors for the computer model MRGP model [Eq. (4.8)] and the discrepancy functions MRGP model [Eq. (4.10)] are combined via Eq. (4.7) to form the prior for the experimental responses MRGP model:

$$\begin{aligned} \mathbf{y}^e(\cdot) | (\boldsymbol{\theta} = \boldsymbol{\theta}^*) &\sim \mathcal{GP}(m^e(\cdot, \boldsymbol{\theta}^*), V^e((\cdot, \boldsymbol{\theta}^*), (\cdot, \boldsymbol{\theta}^*))), \\ m^e(\mathbf{x}, \boldsymbol{\theta}) &= \mathbf{h}^m(\mathbf{x}, \boldsymbol{\theta})\mathbf{B}^m + \mathbf{h}^\delta(\mathbf{x})\mathbf{B}^\delta, \\ V^e((\mathbf{x}, \boldsymbol{\theta}), (\mathbf{x}', \boldsymbol{\theta})) &= \boldsymbol{\Sigma}^m R^m((\mathbf{x}, \boldsymbol{\theta}), (\mathbf{x}', \boldsymbol{\theta})) + \boldsymbol{\Sigma}^\delta R^\delta(\mathbf{x}, \mathbf{x}') + \boldsymbol{\lambda}, \end{aligned} \quad (4.11)$$

where $\mathbf{y}^e(\mathbf{x}) = [y_1^e(\mathbf{x}), \dots, y_q^e(\mathbf{x})]$ denote the multiple experimental responses. The $q \times q$ diagonal covariance matrix $\boldsymbol{\lambda}$ with diagonal entries $\lambda_1, \dots, \lambda_q$ represents the experimental uncertainty, i.e., $\varepsilon_i \sim \mathcal{N}(0, \lambda_i)$. Since Eq. (4.11) depends on the true calibration parameters $\boldsymbol{\theta}^*$, the objective is now to estimate the hyperparameters of

the MRGP model for the discrepancy functions without knowing the true value of θ^* .

Kennedy and O'Hagan [1] developed a procedure to obtain estimates of the hyperparameters of a single discrepancy function using the prior distribution of the calibration parameters. Specifically, this procedure constructs a likelihood function, marginalized with respect to the prior distribution of the calibration parameters, from the simulation and experimental data and using the MLEs of the computer model hyperparameters from Module 1. The experimental data consists of experimental response observations at N_e input sites, $\mathbf{X}^e = [\mathbf{x}_1^e, \dots, \mathbf{x}_{N_e}^e]^T$ (transformed to the range [0, 1]) with responses $\mathbf{Y}^e = [\mathbf{y}_1^e, \dots, \mathbf{y}_q^e]$, where $\mathbf{y}_i^e = [y_i^e(\mathbf{x}_1^e), \dots, y_i^e(\mathbf{x}_{N_e}^e)]^T$ (standardized). Then the MLE estimates of the hyperparameters $\hat{\phi}^\delta = \{\mathbf{B}^\delta, \Sigma^\delta, \omega^\delta, \lambda\}$ occur at the location of the maximum of the likelihood function (marginalized with respect to the priors of the calibration parameters). Appendix C contains a detailed description of this procedure. After estimating the hyperparameters of the two MRGP models in Modules 1 and 2, Bayes theorem is used to calculate the posterior distribution of θ , as follows.

3.1.3 Posterior of the Calibration Parameters (Module 3)

Module 3 calculates the posterior of the calibration parameters using the MLEs of the hyperparameters from Modules 1 and 2, the simulation data, and the experimental data. The posterior of the calibration parameters is:

$$p(\theta|\mathbf{d}, \hat{\phi}) = \frac{p(\mathbf{d}|\theta, \hat{\phi})p(\theta)}{p(\mathbf{d}|\hat{\phi})}, \quad (4.12)$$

where $\hat{\phi}$ are the MLEs of $\phi = \{\phi^m, \phi^\delta\}$, $\mathbf{d} = [vec(\mathbf{Y}^m)^T \ vec(\mathbf{Y}^e)^T]^T$ is the complete response data, and $p(\theta)$ is the prior of the calibration parameters (e.g., a uniform distribution defined a priori). The likelihood function $p(\mathbf{d}|\theta, \hat{\phi})$ is a multivariate normal distribution whose mean and covariance are determined by the two MRGP models for the computer model [Eq. (4.8)] and the experimental responses [Eq. (4.11)]. The denominator $p(\mathbf{d}|\hat{\phi})$ of Eq. (4.12) is the marginal distribution of the data [40], which does not depend upon θ (i.e., the denominator is a normalizing constant). Appendix D details the equations for calculating the posterior distribution in Eq. (4.12). The posterior distribution of the calibration parameters and the MLEs of the hyperparameters from Modules 1 and 2 influence the prediction of the experimental responses in the next and final module.

3.1.4 Prediction of the Experimental Responses and Discrepancy Function (Module 4)

After estimating the hyperparameters in Modules 1 and 2 and collecting the simulation and experimental data, the conditional (given a specific value of θ) posterior distribution for the experimental responses can be calculated at any point \mathbf{x} . The unconditional posterior distribution is then obtained by marginalizing the conditional posterior distribution with respect to the posterior of the calibration

parameters calculated in Module 3, as discussed in Appendix E. Therefore, the marginalized posterior distribution of the multiple experimental responses accounts for parameter uncertainty, model discrepancy, interpolation uncertainty, and experimental uncertainty. Since the discrepancy functions are also represented by a MRGP model, their posterior distributions can be calculated in a similar manner. One should note that the MRGP model prediction of the discrepancy functions will depend on the value of the calibration parameters. Therefore, similar to the prediction of the physical experiments, the prediction of the discrepancy functions is marginalized with respect to the posterior distribution of the calibration parameters.

3.2 Applying the Multi-response Approach to the Simply Supported Beam

This section revisits the simply supported beam example, introduced in Sect. 2.2, to show how using multiple responses can improve the identifiability of the calibration parameters and the discrepancy functions. Briefly (refer to Sect. 2.2 for details), the simply supported beam is fixed at one end and supported by a roller on the other end. A static force is applied to the midpoint of the beam to induce various responses, e.g., deflection and stress. The magnitude of this force was chosen as the design variable x , while Young's modulus was treated as the calibration parameter θ . For generating the “physical experiment” (which is taken to be the same computer simulations but with a more sophisticated material law) data, the true value of the calibration parameter is set to $\theta^* = 206.8 \text{ GPa}$. However, θ^* is treated as unknown during the analysis and we use a uniform prior distribution over the range $150 \leq \theta \leq 300 \text{ GPa}$. The experimental uncertainty was set to zero (i.e., $\lambda_i = 0$).

3.2.1 Identifiability with Single Responses

Before using multiple responses for the simply supported beam, the resulting identifiability from using only single responses is first examined. Table 4.3 shows the six responses measured from the beam (for both the computer model y_i^m and the physical experiments y_i^e). The simulation data for each response \mathbf{y}_i^m was

Table 4.3 Responses measured in the simply supported beam example

Response	Description
y_1	Strain at the midpoint of the beam (mm)
y_2	Plastic strain at the midpoint of the beam (mm)
y_3	Angle of deflection at the end of the beam (radians) (y of Sect. 2.2)
y_4	Internal energy of the beam (Joules)
y_5	Displacement at the middle of the beam (m)
y_6	Plastic dissipation energy (Joules)

collected using a 4 by 4 grid over the input space ($1300 \leq x \leq 2300$ N and $150 \leq \theta \leq 300$ GPa). The experimental data \mathbf{y}_e^e was collected at $\mathbf{X}^e = [1300, 1400, 1500, \dots, 2300]^T$ ($N_e = 11$). For each single response, the modular Bayesian approach was used to calculate the posterior distributions of the calibration parameter, the discrepancy function, and the experimental response.

Because of the relatively large amount of experimental data and no experimental uncertainty, the posterior distribution of the experimental response for each single response was accurate and precise (see Fig. 4.5a in Sect. 2.2 for y_3 of Table 4.3). Even so, the calibration parameter and the discrepancy function are not identifiable as evident from the high uncertainty reflected by their posterior distributions, as shown in Fig. 4.12 for responses 1 through 4 (similar results were obtained for y_5 and y_6 but are not shown due to space). Table 4.4 shows the resulting posterior mean and standard deviation of the calibration parameter for each single response. The large posterior standard deviations in Table 4.4 again indicate a lack of identifiability. Since the experimental data are already relatively dense, additional

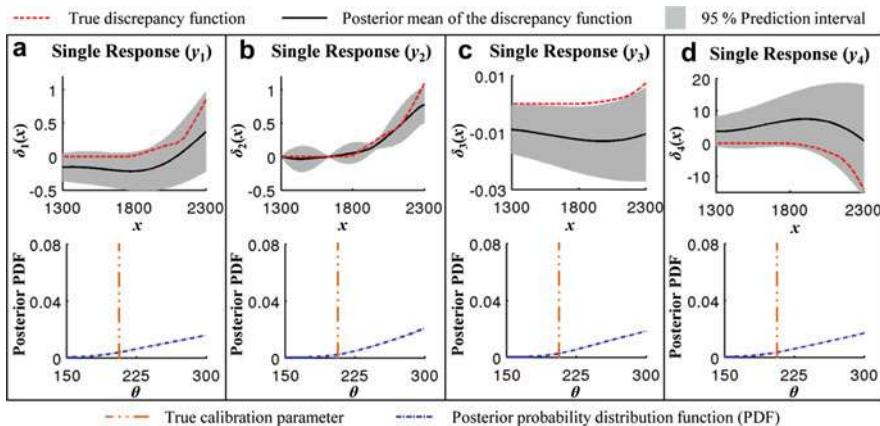

Fig. 4.12 Posterior distributions of the discrepancy function and the calibration parameter using a single response for (a) y_1 , (b) y_2 , (c) y_3 , and (d) y_4

Table 4.4 Single-response (SR) posterior mean ($\mu_{i,post}^{SR}$ in GPa) and standard deviation ($\sigma_{i,post}^{SR}$ in GPa) of the calibration parameter θ

Response	SR posterior distribution of θ	
y_i	$\mu_{i,post}^{SR}$	$\sigma_{i,post}^{SR}$
y_1	256.74	31.68
y_2	264.70	27.15
y_3	262.18	26.67
y_4	261.79	26.92
y_5	261.15	27.84
y_6	254.48	33.30

data will not improve identifiability when using only a single response. Instead, in the remainder of this section, the use of multiple responses is explored to enhance identifiability.

3.2.2 Identifiability with Multiple Responses

With the goal of enhancing identifiability, the procedure described in Sect. 2 combines information from multiple responses. In general, there will often be many responses that are automatically calculated in the computer model and that could potentially be measured experimentally. Ideally, one might like to include all of the responses in the model updating formulation, but this is not practical for a number of reasons. First, it can become more computationally expensive to implement the modular Bayesian approach with additional responses and including too many responses may result in numerical instabilities. Furthermore, some responses may be largely redundant, containing nearly the same information as other responses, which will not improve identifiability. As seen below, different combinations of responses result in drastically different identifiability. Third, although multiple responses are available for free in the computer simulation, their experimental measurement may involve prohibitive costs.

For ease of illustration and computational reasons, the multiple responses considered are various pairs of responses. To explore how different pairs of responses affect identifiability in the simply supported beam example, the relevant posterior distributions for the 15 pairs of responses from Table 4.3 are calculated. Specifically, for each pair of responses, the multi-response modular Bayesian approach discussed in Sect. 3.1 is used to calculate the posterior distributions of the calibration parameter, the discrepancy functions, and the experimental responses. The modular Bayesian approach begins with Module 1, which creates a MRGP model of the computer model using the simulation data \mathbf{y}_i^m (observed at the same input settings \mathbf{X}^m as in Sect. 3.2.1). In Module 2, the hyperparameters of the MRGP model for the discrepancy functions are estimated from the experimental data \mathbf{y}_i^e (observed at the same input settings \mathbf{X}^e as in Sect. 3.2.1), the prior distribution of the calibration parameter, and the hyperparameter MLEs from Module 1. Finally, Modules 3 and 4 calculate the posterior distributions for the calibration parameter, the discrepancy functions, and the experimental responses. As with the single responses in Sect. 3.2.1, the posterior of the experimental responses was extremely accurate and precise, although the identifiability of the calibration parameters varied widely from pair to pair of responses.

Table 4.5 shows the resulting posterior mean and standard deviation of the calibration parameter for each set of responses. In cases where the posterior distribution is not normal, as in Fig. 4.12, the standard deviation can be an oversimplification of the dispersion of the posterior distribution, but it is still perhaps the most relevant single measure of identifiability. To quantify identifiability improvement, the multi-response posterior standard deviation $\sigma_{ij,post}^{MR}$ is compared to the best single-response posterior standard deviation of the pair (i.e., the smaller of the two single-response posterior standard deviations $\sigma_{ij,min}^{SR} = \min(\sigma_{i,post}^{SR}, \sigma_{j,post}^{SR})$). The

Table 4.5 Multi-response posterior mean $\mu_{ij,post}^{MR}$ (in GPa) and standard deviation $\sigma_{ij,post}^{MR}$ (in GPa) of the calibration parameter θ and identifiability improvement compared to the single response

Responses			MR posterior distribution of θ		$\sigma_{ij,min}^{SR}$	Std. dev. improvement
y_i	y_j		$\mu_{ij,post}^{MR}$	$\sigma_{ij,post}^{MR}$		
y_1	y_2	(1)	259.81	27.37	31.68	14%
y_1	y_3		213.70	10.13	26.67	62%
y_1	y_4		215.00	9.29	26.92	65%
y_1	y_5		219.83	15.57	27.84	44%
y_1	y_6		247.33	24.08	31.68	24%
y_2	y_3		218.82	10.96	26.67	59%
y_2	y_4		228.28	18.35	26.92	32%
y_2	y_5		224.50	15.42	27.84	45%
y_2	y_6		265.96	26.46	33.30	21%
y_3	y_4	(3)	209.23	5.49	26.67	79%
y_3	y_5		210.39	6.27	26.67	76%
y_3	y_6		210.30	4.86	26.67	82%
y_4	y_5		213.23	3.63	26.92	87%
y_4	y_6		211.91	3.90	26.92	86%
y_5	y_6		210.35	4.67	27.84	83%

posterior standard deviation improvement, “std. dev. improvement” in Table 4.5, is defined as $(\sigma_{ij,min}^{SR} - \sigma_{ij,post}^{MR}) / \sigma_{ij,min}^{SR}$.

To better visualize improved identifiability, Fig. 4.13 shows the posterior distributions of the calibration parameter and the discrepancy functions for three sets of multiple responses with different degrees of identifiability improvement. The sets of responses shown in Fig. 4.13a, b, and c will from hereon be referred to as Case 1, 2, and 3, respectively, and are labeled in Table 4.5.

As can be seen in Table 4.5 and Fig. 4.13, the extent of the identifiability improvement varies widely from pair to pair. In Case 1, the combination of the strain y_1 and the plastic strain y_2 enhances identifiability little beyond that of a single response, and the resulting posterior distributions in Fig. 4.12a, b for the single responses are similar to those in Fig. 4.13a for the pair of responses (a 14% improvement, from Table 4.5). In contrast, in Case 2, the combination of the plastic strain y_2 and the angle of deflection y_3 resulted in a much more substantial improvement in identifiability. Specifically, the posterior distributions shown in Fig. 4.13b represent a 59% improvement in posterior standard deviation (see Table 4.5).

In Case 3, the combination of the angle of deflection y_3 and the internal energy y_4 resulted in even more substantially enhanced identifiability. The corresponding posterior distribution in Fig. 4.13c is much more narrowly dispersed (a 79% improvement, from Table 4.5) than for the single-response cases. Additionally, the posterior mean of the calibration parameter is quite close to the true value of

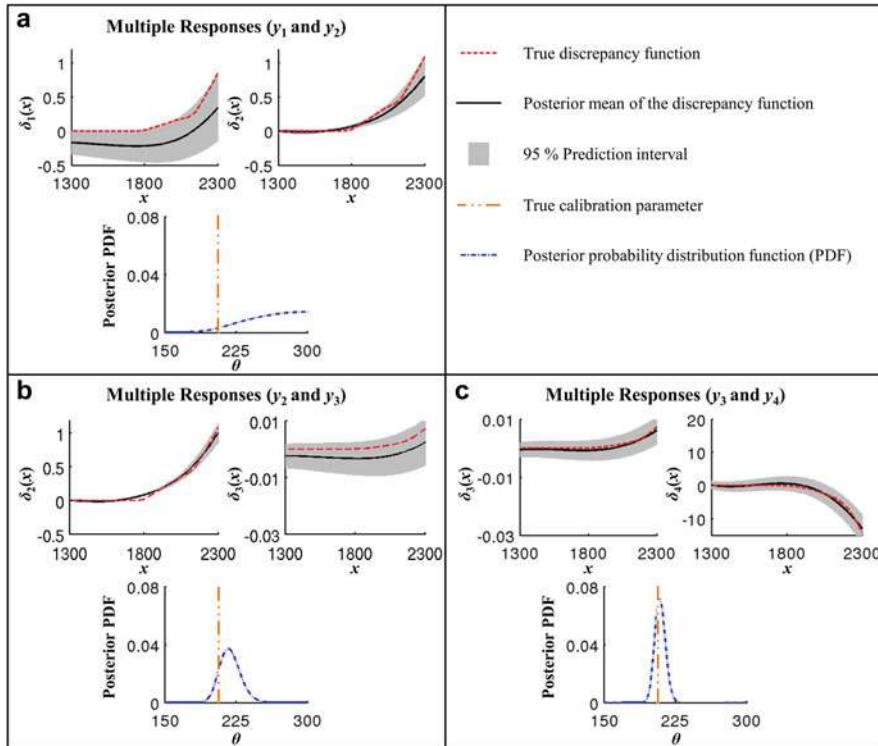

Fig. 4.13 Posterior distributions of the discrepancy functions and the calibration parameter using multiple responses for (a) y_1 and y_2 , (b) y_2 and y_3 , and (c) y_3 and y_4

$\theta^* = 206.8$ (marked by the vertical line in Fig. 4.13c). Moreover, the posteriors of the discrepancy functions $\delta_3(x)$ and $\delta_4(x)$ capture the true functions with relatively small uncertainty. These three cases are representative of the varied improvements in identifiability for all pairs of responses listed in Table 4.5.

In the simply supported beam example, 12 out of the 15 pairs of responses resulted in an identifiability improvement of 25% or more. The degree of improvement varied from little (e.g., 14%), to moderate (e.g., 24% and 32%), to substantial (e.g., 87%). This example illustrates that, if identifiability cannot be obtained using a single response, multiple responses may be used to achieve improved identifiability.

3.3 Remarks on the Multi-response Modular Bayesian Approach

In this section, it has been shown that identifiability can be enhanced by using multiple responses in model updating. The approach is most beneficial when data from a single response results in a lack of identifiability. The existing

single-response modular Bayesian approach was extended to multiple responses, and this extension required the use of multi-response Gaussian process (MRGP) models to represent the multiple computer simulation responses and the multiple discrepancy functions. The multi-response modular Bayesian approach allows one to calculate the posterior distributions of the calibration parameters upon which the multiple responses share a mutual dependence, the posterior distributions of the discrepancy functions of each response, and the predictions of multiple experimental responses.

By applying the multi-response modular Bayesian approach to the simply supported beam example, it was shown that including multiple responses can improve identifiability. In this example, the majority of paired responses resulted in an identifiability improvement of over 50%, and some pairs resulted in an improvement of over 85%. Across all pairs, the resulting improvement in identifiability varied from 14% to 87%. Overall, the simply supported beam example illustrates the effectiveness of using additional information from multiple responses to improve identifiability, when identifiability cannot be achieved using a single response.

As with the single-response modular Bayesian approach, one limitation of the proposed multi-response modular Bayesian approach is the computational cost, which is predominantly affected by the number of observations. Using additional responses also increases the computational cost, but not as significantly as adding observed data. For example, when using two responses, 17 s (on a single Intel 2.66 GHz processor) of computation time was required to calculate the posterior distributions of the simply supported beam example; whereas, when using a single response, only 10 s of computation time was required. The increase in computation time was a result of calculating the posterior distributions for two experimental responses and two discrepancy functions in Module 4. Also, one should notice that the increase in computational cost was due to the Bayesian computations, and not the computer simulations, because no additional computer simulations were run.

Another limitation of the multi-response approach is that considering additional responses can result in numerical instabilities. Theoretically, using additional responses should potentially improve, and never worsen, identifiability. However, additional responses can also introduce numerical conditioning problems. For example, when using more than two responses in the simply supported beam example, estimation of Σ^δ for the discrepancy functions in Module 2 became problematic. Due to the high correlations between the responses, the estimate of Σ^δ was close to singular, which caused numerical instability in the subsequent calculations.

Although in the examples the number of calibration parameters was less than or equal to the number of responses, this is not a requirement for identifiability (much like how regression modeling with a single-response variable can be used to fit a model with multiple parameters). Of course, using more responses will generally improve identifiability, but this improvement will depend on the specifics of the system (including the form of the computer model, the physical experiments, and the discrepancy functions), the multiple responses being measured (as seen in Figs. 4.12 and 4.13), and the location of the measurements in \mathbf{x} . In light of this, it is difficult to

generalize how many responses are necessary to achieve identifiability based on the number of calibration parameters.

Together, this section and the previous section (Sect. 2) shed light on the challenging problem of identifying calibration parameters and discrepancy functions when combining data from a computer model and physical experiments. They demonstrate that identifiability is often possible and can be reasonably achieved with proper analyses in certain engineering systems.

4 Preposterior Analyses for Predicting Identifiability in Model Calibration

It was shown in Sect. 2.3 that the degree of identifiability depends strongly on the nature of the computer model response as a function of the input variables and the calibration parameters, as well as on the prior assumptions regarding the discrepancy function (e.g., the smoothness of the discrepancy function). Computer simulations are inherently multi-response, as there are many intermediate and final response variables at many different spatial and temporal locations that are automatically calculated during the course of the simulation. Section 3.2 showed that, for systems with poor identifiability based on a single measured physical experimental response, identifiability may be improved by measuring multiple physical responses. In all situations, identifiability obviously depends on the design of the physical experiment, i.e., the number of experimental runs and the input settings for each run.

The same can be said when estimating the parameters of any parametric model based on physical experimental data, and standard criteria for designing such physical experiments are often based on measures related to parameter identifiability. However, calibration of computer simulation models involves a fundamental distinction: Prior to designing the physical experiment, one can learn via simulation a great deal about the nature of the functional dependence of the response(s) on the input variables and on the calibration parameters, and this knowledge can be exploited when designing the physical experiment to provide better identifiability. Indeed, because of the cost and difficulty in developing and placing apparatus for measuring certain responses, it is generally not feasible to measure experimentally all of the great many responses that are automatically calculated in the simulations. Moreover, it is generally not necessary, because measuring only a subset of the responses may result in acceptable identifiability. It is preferable to select a relatively small but most appropriate subset of responses to measure experimentally, to best enhance identifiability.

In order to accomplish this, one needs to predict or approximate the degree of identifiability prior to conducting the physical experiments, but after conducting the computer simulations. The primary purpose of this section is to introduce a preposterior analysis developed in [41–43] and investigate the use of the preposterior covariance matrix [44, 45] of the calibration parameters for this purpose and to demonstrate that it provides a reasonable prediction of the actual posterior

covariance, at least for the examples that are considered. Consequently, the preposterior covariance matrix can serve as a reasonable criterion for designing physical experiments in order to achieve good identifiability when calibrating computer simulation models.

It is worth noting that a preposterior analysis cannot improve one's knowledge of the calibration parameters, because it is conducted prior to observing any physical experimental data. However, it can provide a reasonable quantification of the uncertainty of the calibration parameters that one expects will result after observing the experimental data. This is analogous to what occurs in standard optimal design of experiments [46,47] for fitting a response surface via linear regression. Given the design matrix and the standard deviation of the random observation error, one can calculate the covariance matrix of the estimated parameters prior to conducting the experiment and use this as the experimental design criterion. Of course, one cannot estimate the parameters until the experimental data are collected.

The format of the remainder of the section is as follows. Section 4.1 presents the approach to calculate the preposterior covariance matrix of the calibration parameters. Section 4.2 discusses a modification of the preposterior analysis that provides insight into the behavior of the preposterior covariance as a means of predicting the posterior covariance. Section 4.3 provides a detailed description of the surrogate preposterior analysis, in conjunction with the multi-response modular Bayesian approach, for substantially reducing the computational cost in the preposterior analysis. Sections 4.4, 4.5, and 4.6 illustrates the effectiveness of the preposterior analysis in predicting identifiability prior to conducting physical experiments by using a number of examples and discusses the issue of identifiability of the calibration parameters. Remarks are made in Sect. 4.7.

4.1 Preposterior Analysis

The preposterior analysis framework [41–43] for selecting the experimentally measured responses is shown in Fig. 4.14. After conducting the simulations but before conducting the experiments, the user first defines a number of candidate subsets of responses for preposterior analysis. This could be accomplished based on some heuristics (e.g., one that will be discussed in Sect. 4.3) and/or on which responses are deemed inexpensive to measure. If there are N_c candidate subsets of responses, the analysis evaluates the degree of identifiability for each via the preposterior covariance.

We next provide an overview of the algorithm for calculating the preposterior covariance matrix. Following this, detailed descriptions of each step are given in the algorithm. The algorithm begins by fitting the Gaussian process model for $\mathbf{y}^m(\mathbf{x}, \boldsymbol{\theta})$ based on the computer simulation data (Step 1a). The user then specifies the physical experimental input settings and assigns priors for the GP model of $\delta(\mathbf{x})$, for the calibration parameters, and for $\boldsymbol{\epsilon}$ (Steps 1b and 1c). Because the preposterior analysis is conducted prior to observing actual experimental data, the main body of the algorithm is a Monte Carlo (MC) simulation (Step 2) in which, on each

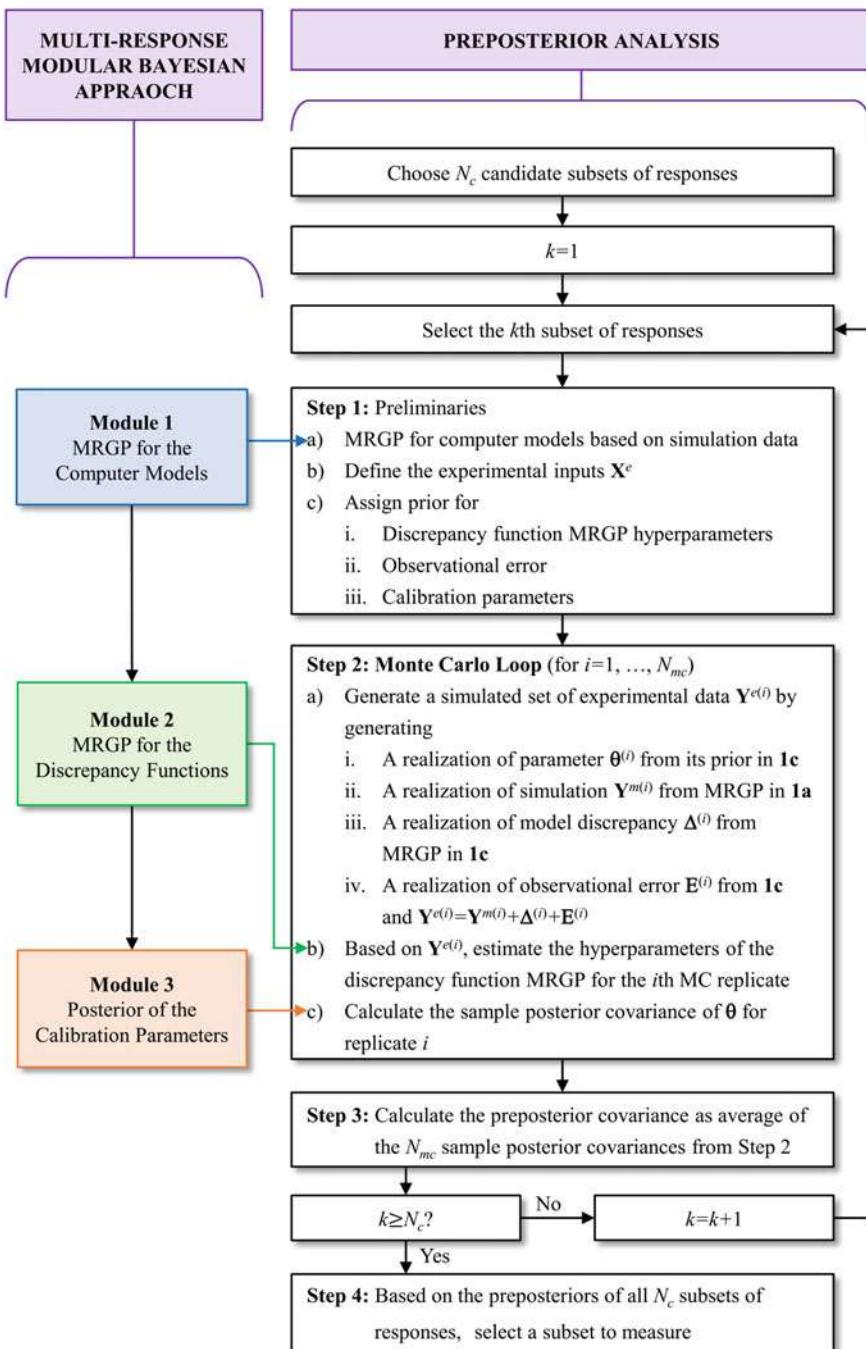

Fig. 4.14 Flowchart of the preposterior analysis for selecting experiment responses

MC replicate, a hypothetical set of physical experimental response observations is generated (Step 2a) at the specified input settings based on the knowledge of $\mathbf{y}^m(\mathbf{x}, \boldsymbol{\theta})$ from the computer simulation data and the relevant prior distributions for $\delta(\mathbf{x}), \boldsymbol{\theta}$, and $\boldsymbol{\varepsilon}$. Then Step 2b and 2c calculate a posterior covariance matrix for $\boldsymbol{\theta}$ for the experimental response observations generated in that MC replicate. The preposterior covariance matrix for $\boldsymbol{\theta}$ is taken to be (Step 3) the average of the posterior covariance matrices over all MC replicates. Within Step 2, Modules 2 and 3 of the standard modular Bayesian approach are used. The subset of responses that yields the tightest preposterior distribution (cost/difficulty of measurement can also be taken into consideration) would be deemed the most likely to achieve good identifiability.

Each step of the preposterior analysis is described in detail as follows. The algorithm is presented in a multi-response context; however one should note that it can be easily “degenerated” to a single-response version, by replacing relevant multi-response vectors/matrices (e.g., $\mathbf{y}^m(\mathbf{x}, \boldsymbol{\theta})$, $\delta(\mathbf{x})$, Σ^m , Σ^δ) by their single-response scalar counterparts (e.g., $y^m(\mathbf{x}, \boldsymbol{\theta})$, $\delta(\mathbf{x})$, σ_m^2 , σ_δ^2).

4.1.1 Step 1: Preliminaries

In this step, an MRGP model is fit to the simulation data, and several quantities needed in the subsequent steps are defined. First, Module 1 of the multi-response modular Bayesian approach described in Sect. 3.1.1 is implemented to construct the MRGP model for the computer simulations based on the simulation data $\mathbf{Y}^m = [\mathbf{y}_1^m, \dots, \mathbf{y}_q^m]$, where $\mathbf{y}_i^m = [y_i^m(\mathbf{x}_1^m, \boldsymbol{\theta}_1^m), \dots, y_i^m(\mathbf{x}_{N_m}^m, \boldsymbol{\theta}_{N_m}^m)]^T$, collected at N_m input sites $\mathbf{X}^m = [\mathbf{x}_1^m, \dots, \mathbf{x}_{N_m}^m]^T$ and $\boldsymbol{\Theta}^m = [\boldsymbol{\theta}_1^m, \dots, \boldsymbol{\theta}_{N_m}^m]^T$. The maximum likelihood estimation (MLE) method estimates the hyperparameters $\boldsymbol{\phi}^m = \{\mathbf{B}^m, \Sigma^m, \boldsymbol{\omega}^m\}$ of the computer simulations, from which expressions for the posterior distribution of $\mathbf{y}^m(\mathbf{x}, \boldsymbol{\theta})$ are obtained. In the MRGP model, \mathbf{Y}^m has mean vector $\mathbf{H}^m \mathbf{B}^m$, where $\mathbf{H}^m = [\mathbf{h}^m(\mathbf{x}_1^m)^T, \dots, \mathbf{h}^m(\mathbf{x}_{N_m}^m)^T]^T$ with each $\mathbf{h}^m(\mathbf{x})$ a specified regression basis function and \mathbf{B}^m a matrix of coefficients; and \mathbf{Y}^m has covariance matrix $\Sigma^m \otimes \mathbf{R}^m$, where \mathbf{R}^m is the $N_m \times N_m$ matrix with k th-row, j th-column entry equal to the prior correlation $R^m((\mathbf{x}_j^m, \boldsymbol{\theta}_j^m), (\mathbf{x}_k^m, \boldsymbol{\theta}_k^m))$ between $\mathbf{y}^m(\mathbf{x}_j^m, \boldsymbol{\theta}_j^m)$ and $\mathbf{y}^m(\mathbf{x}_k^m, \boldsymbol{\theta}_k^m)$. For all examples in this chapter, a constant prior mean function of unknown magnitude (i.e., $\mathbf{h}^m(\mathbf{x}) = 1$ and \mathbf{B}^m a $1 \times q$ vector hyperparameter to be estimated) and a Gaussian correlation function R^m were used. For numerical stability of the MLE algorithm, \mathbf{X}^m and $\boldsymbol{\Theta}^m$ are transformed to the range $[0, 1]$, and each \mathbf{y}_i^m is standardized to have a sample mean of 0 and a sample standard deviation of 1 [39].

In subsequent steps, the MRGP model is used to infer the simulation response at input settings within the design domain where no simulations are conducted. A multivariate normal random number generator will be used with mean and covariance taken to be the posterior mean and covariance of the MRGP model of $\mathbf{y}^m(\mathbf{x}, \boldsymbol{\theta})$ from Step 1a. The posterior mean and covariance are calculated using results from APPENDIX B. Here plug-in MLEs for Σ^m and $\boldsymbol{\omega}^m$ with a

non-informative prior for \mathbf{B}^m are used. Over the remainder of the preposterior analysis, the MRGP model of $\mathbf{y}^m(\mathbf{x}, \boldsymbol{\theta})$ is not updated from that of Step 1a.

Next, a total of N_e experimental input settings $\mathbf{X}^e = [\mathbf{x}_1^e, \dots, \mathbf{x}_{N_e}^e]^T$ are defined, representing the input settings, i.e., the experimental design that one intends to use for the physical experiment (in the MC simulations of Step 2, simulated experimental response values will be generated at these input settings). Step 1c then assigns the prior distribution parameters for the priors of MRGP hyperparameters in the discrepancy function. The prior for discrepancy function MRGP hyperparameters $\boldsymbol{\phi}^\delta \setminus \lambda = \{\mathbf{B}^\delta, \boldsymbol{\Sigma}^\delta, \boldsymbol{\omega}^\delta\}$ [analogous to the hyperparameters $\boldsymbol{\phi}^m$ for the MRGP model of $\mathbf{y}^m(\mathbf{x}, \boldsymbol{\theta})$] captures the prior uncertainty and nonlinearity of the discrepancy functions; $\boldsymbol{\Sigma}^\delta$ in Eq. (4.10) controls the magnitude of uncertainty of the MRGP model, and $\boldsymbol{\omega}^\delta$ controls its roughness (rougher surfaces correspond to larger values of $\boldsymbol{\omega}^\delta$). This prior for $\boldsymbol{\phi}^\delta$ is used only in Step 2a-iii of the MC loop, in which values of $\boldsymbol{\phi}^\delta$ are sampled from the specified prior before generating a hypothetical discrepancy function. Because the modular Bayesian approach calculates MLEs of $\boldsymbol{\phi}^\delta$ in Step 2b, the prior for $\boldsymbol{\phi}^\delta$ is not incorporated via maximum a posteriori estimators, although one could modify the approach to do this if desired. For computational convenience, $\{\mathbf{B}^\delta, \boldsymbol{\Sigma}^\delta, \boldsymbol{\omega}^\delta\}$ can be assigned with point mass priors.

Additionally in Step 1c, the user specifies the prior distribution for the experimental error, which is assumed to be *i.i.d.* normal with mean 0 and a prior variance chosen based on prior knowledge of the level of measurement error. λ is treated in the same manner as $\boldsymbol{\phi}^\delta$. Its prior is used in Step 2a-iv when generating a random value for $\boldsymbol{\epsilon}$, but this prior is not used when calculating the MLE of λ in Step 2b.

Lastly in Step 1c, the user assigns a prior distribution $p(\boldsymbol{\theta})$ to the calibration parameters $\boldsymbol{\theta}$. The prior for calibration parameters $\boldsymbol{\theta}$ should have support spanning the entire range of possible values for $\boldsymbol{\theta}$; for a less informative prior, one can use a uniform distribution over a broad range, while a normal distribution with specified mean and variance can be used for a more informative prior. Since the uncertainty in the calibration parameters is of direct interest, Module 3 of the modular Bayesian approach in Step 2c calculates a full posterior distribution for $\boldsymbol{\theta}$ based on the specified prior, in contrast to the MLE-only estimation for $\boldsymbol{\phi}^m$ and $\boldsymbol{\phi}^\delta$ in Modules 1 and 2. Based on the posterior of $\boldsymbol{\theta}$, Module 3 also calculates the posterior covariance of $\boldsymbol{\theta}$ for each MC replicate.

4.1.2 Step 2: Monte Carlo (MC) Loop (for $i = 1, \dots, N_{mc}$)

In order to calculate the preposterior covariance, a Monte Carlo (MC) sampling strategy is applied to generate N_{mc} replicates of hypothetical experimental response data based on the information calculated or specified in Step 1. For each replicate, after generating the hypothetical experimental data, the multi-response modular Bayesian approach is applied to estimate the hyperparameters of the discrepancy function MRGP models and to calculate the hypothetical posterior covariance for this replicate. For the i th MC replicate, the following steps are involved. The superscript (i) added to a quantity indicates that it is for the i th MC replicate.

(a) Generate a simulated set of experimental data $\mathbf{Y}^{e(i)}$.

A realization $\boldsymbol{\theta}^{(i)}$ of the calibration parameters is first generated from its prior distribution specified in Step 1. The generated $\boldsymbol{\theta}^{(i)}$ will be treated as a “true” value for $\boldsymbol{\theta}$ when generating the hypothetical physical experimental response observations on the i th MC replicate.

Next, using the MRGP model for the computer simulation obtained in Step 1, a realization of the computer simulation response values is generated at parameter values $\boldsymbol{\theta}^{(i)}$ and input settings \mathbf{X}^e , denoted by $\mathbf{Y}^{m(i)} = \hat{\mathbf{y}}^m(\mathbf{X}^e, \boldsymbol{\theta}^{(i)}) = [\hat{y}_1^{m(i)}, \dots, \hat{y}_q^{m(i)}]$ where $\hat{y}_j^{m(i)} = [\hat{y}_j^{m(i)}(\mathbf{x}_1^e, \boldsymbol{\theta}^{(i)}), \dots, \hat{y}_j^{m(i)}(\mathbf{x}_{N_e}^e, \boldsymbol{\theta}^{(i)})]^T$ ($j = 1, \dots, q$). Here, $\mathbf{Y}^{m(i)}$ is generated from a multivariate normal distribution whose mean vector and covariance matrix are determined by the MRGP model. The hat notation “ $\hat{\cdot}$ ” over $\mathbf{y}^m(\mathbf{X}^e, \boldsymbol{\theta}^{(i)})$ denotes that we are drawing interpolated data from the MRGP model (instead of the original model) of \mathbf{y}^m .

Subsequently, using the priors for $\boldsymbol{\phi}^\delta \setminus \boldsymbol{\lambda} = \{\mathbf{B}^\delta, \boldsymbol{\Sigma}^\delta, \boldsymbol{\omega}^\delta\}$ specified in Step 1c and the MRGP model of Eq. (4.10), a realization for the discrepancy functions is generated at the design settings \mathbf{X}^e , denoted by $\boldsymbol{\Delta}^{(i)} = [\boldsymbol{\delta}_1^{(i)}, \dots, \boldsymbol{\delta}_q^{(i)}]$ where $\boldsymbol{\delta}_j^{(i)}$ ($j = 1, \dots, q$) represents the realization of discrepancy function for the i th response at \mathbf{X}^e . Similar to generating $\mathbf{Y}^{m(i)}$, a multivariate normal distribution is used to generate $\boldsymbol{\Delta}^{(i)}$, but with mean vector and covariance matrix determined by the MRGP model for the discrepancy functions. Specifically, the mean is $\mathbf{H}^\delta \mathbf{B}^{\delta(i)}$, where $\mathbf{H}^\delta = [\mathbf{h}^\delta(\mathbf{x}_1^e)^T, \dots, \mathbf{h}^\delta(\mathbf{x}_{N_e}^e)^T]^T$ with $\mathbf{h}^\delta(\mathbf{x})$ some specified regression basis functions (in the examples, constant $\mathbf{h}^\delta(\mathbf{x}) = 1$ will be used), and the covariance is the $\boldsymbol{\Sigma}^{\delta(i)} \otimes \mathbf{R}^\delta$, where \mathbf{R}^δ is the $N_e \times N_e$ matrix with k th-row, j th-column entry equal to the prior correlation between $\delta(\mathbf{x}_k^e)$ and $\delta(\mathbf{x}_j^e)$ using parameters $\boldsymbol{\omega}^{\delta(i)}$.

Finally, a realization $\mathbf{E}^{(i)}$ of the observation errors is generated at the design settings \mathbf{X}^e , assuming that the experimental error ε_j ($j = 1, \dots, q$) follows *i.i.d.* normal distributions with mean 0 and variance λ_j specified in Step 1c. $\mathbf{E}^{(i)}$ is an $N_e \times q$ matrix whose uth -row, vth -column entry is the realization of observation error for the v th response at the uth design setting \mathbf{x}_u^e . Based on Eq. (4.7), the realization $\mathbf{Y}^{e(i)}$ of the simulated experimental responses at the design settings \mathbf{X}^e is calculated via:

$$\mathbf{Y}^{e(i)} = \mathbf{Y}^{m(i)} + \boldsymbol{\Delta}^{(i)} + \mathbf{E}^{(i)}. \quad (4.13)$$

(b) Based on $\mathbf{Y}^{e(i)}$, estimate the hyperparameters of the discrepancy function MRGP $\boldsymbol{\delta}^{(i)}(\mathbf{x})$ for the i th MC replicate.

This is a direct application of Module 2 of the multi-response modular Bayesian approach described in Sect. 3.1.2, but with an actual set of experimental data \mathbf{Y}^e replaced by the hypothetical set $\mathbf{Y}^{e(i)}$ generated on the i th MC replicate. Specifically, Module 2 estimates the hyperparameters of the MRGP model for the discrepancy functions for the i th MC replicate using MLE methods based

on combining the simulation data \mathbf{Y}^m obtained in Step 1 and the hypothetical experimental data $\mathbf{Y}^{e(i)}$ generated in Step 2a for the i th MC replicate.

(c) Calculate the sample posterior covariance of $\boldsymbol{\theta}$ for replicate i .

This is also a direct application of Module 3 of the multi-response modular Bayesian approach described in Sect. 3.1.3, but with an actual set of experimental data \mathbf{Y}^e replaced by the hypothetical set $\mathbf{Y}^{e(i)}$ generated on the i th MC replicate. Specifically, Module 3 calculates the sample posterior covariance $\text{Cov}^{(i)}[\boldsymbol{\theta} | \mathbf{Y}^m, \mathbf{Y}^{e(i)}]$ of the posterior distribution of $\boldsymbol{\theta}$ in Eq. (4.12). For low-dimensional $\boldsymbol{\theta}$, Legendre-Gauss quadrature [48, 49] can be used to calculate the posterior covariance. For higher-dimensional $\boldsymbol{\theta}$, other numerical approaches such as Markov chain Monte Carlo (MCMC) [50] or sampling-resampling [51] methods can be used.

4.1.3 Step 3: Calculate the Preposterior Covariance as Average of the N_{mc} Posterior Covariances from Step 2

Iterating through the N_{mc} MC replicates in Step 2 produces $\{\text{Cov}^{(i)}[\boldsymbol{\theta} | \mathbf{Y}^m, \mathbf{Y}^{e(i)}] : i = 1, 2, \dots, N_{mc}\}$. The preposterior covariance matrix of the calibration parameters is defined as $\mathbb{E}[\text{Cov}^{(i)}[\boldsymbol{\theta} | \mathbf{Y}^m, \mathbf{Y}^e] | \mathbf{Y}^m]$, where the outer expectation is with respect to the actual, yet-to-be-observed experimental response data \mathbf{Y}^e , conditioned on the already-observed simulation data \mathbf{Y}^m . As an estimate of the preposterior covariance matrix, we use:

$$\tilde{\Sigma}_{\boldsymbol{\theta}} \text{ (or } \tilde{\sigma}_{\theta}^2 \text{ for a scalar } \theta\text{)} = \frac{1}{N_{mc}} \sum_{i=1}^{N_{mc}} \{\text{Cov}^{(i)}[\boldsymbol{\theta} | \mathbf{Y}^m, \mathbf{Y}^{e(i)}]\}. \quad (4.14)$$

4.1.4 Step 4: Based on the Preposterior Covariances of All Subsets of Responses, Select a Subset to Measure Experimentally

In Bayesian analyses, the posterior covariance constitutes a standard quantification of parameter identifiability [14, 15]. The preposterior covariance serves as a prediction of the posterior covariance that is expected to result after conducting the physical experiment based on the knowledge obtained from the observed simulation response surface. Consequently, the preposterior covariance is used to guide the selection of the subset of responses to measure experimentally that has the most potential to enhance identifiability. For a simple case with a single calibration parameter, the subset of responses that leads to the smallest preposterior variance (tightest preposterior distribution) would be deemed as the most likely to achieve good identifiability. For cases with multiple calibration parameters, scalar metrics of the preposterior covariance matrix, such as its trace, determinant, maximum eigenvalue, etc., can be used to determine which subset yields the tightest preposterior distribution and, subsequently, which subset of responses to measure experimentally.

4.2 A Modified Algorithm for Investigating the Behavior of the Preposterior Analysis

To investigate the behavior of the preposterior analysis, consider the following modification to the algorithm of Fig. 4.14 [41]: In Step 2a-i, instead of generating a different $\theta^{(i)}$ randomly from its prior distribution on each MC replicate, the same fixed value (denoted by θ^t , a value specified by the user outside the MC loop) is used for all replicates. This algorithm is referred to as the *fixed- θ preposterior analysis*, and the resulting estimate of the preposterior covariance matrix is denoted by $\tilde{\Sigma}_{\theta}(\theta^t)$. Recall that $\theta^{(i)}$ in the Fig. 4.14 algorithm is only used when generating the hypothetical experimental observations $\mathbf{Y}^{e(i)}$, for which $\theta^{(i)}$ is treated as the true values of the calibration parameters. In reality there is only a single true value θ^* that the laws of nature will dictate when generating the actual experimental data \mathbf{Y}^e , based on which the actual posterior covariance of θ will be calculated. In light of this, one might wonder how well the preposterior analysis of Fig. 4.14 [which has no knowledge of the true θ^* when generating $\mathbf{y}^{e(i)}$ and must, therefore, average the results over values of $\theta^{(i)}$ drawn from the prior $p(\theta)$] can predict the actual posterior covariance matrix. In the ideal situation that $\tilde{\Sigma}_{\theta}(\theta^t)$ does not depend on θ^t , we might expect the preposterior covariance to provide a good prediction of the posterior covariance. In Sects. 4.4, the fixed- θ preposterior analysis is used to investigate the extent to which $\tilde{\Sigma}_{\theta}(\theta^t)$ depends on θ^t in the examples considered.

Although it may seem counterintuitive that $\tilde{\Sigma}_{\theta}(\theta^t)$ might not depend (strongly) on θ^t , this is precisely the situation in the standard linear regression formulation $\mathbf{y} = \mathbf{X}\theta + \text{error}$, where \mathbf{X} is the design matrix, and \mathbf{y} is the observation vector. In the linear regression formulation, under mild assumptions, the covariance matrix of the regression estimate of θ is $[\mathbf{X}^T \mathbf{X}]^{-1}$ multiplied by the error variance, which is independent of the true θ . This characteristic allows one to design experiments, prior to observing \mathbf{y} , that are “optimal” regardless of the true θ . The situation is more complex for the calibration problem, in part because of the black-box, potentially nonlinear dependence of $y^m(\mathbf{x}, \theta)$ on θ . However, in the next section, it is demonstrated that the relative (when comparing different experimental designs) dependence of $\tilde{\Sigma}_{\theta}(\theta^t)$ on θ^t in the examples is mild enough that the preposterior covariance still allows one to distinguish good experimental designs from poor ones.

Notice that the fixed- θ preposterior covariance $\tilde{\Sigma}_{\theta}(\theta^t)$ is related to the preposterior covariance $\tilde{\Sigma}_{\theta}$ via:

$$\tilde{\Sigma}_{\theta} = \int \tilde{\Sigma}_{\theta}(\theta^t) p(\theta^t) d\theta^t, \quad (4.15)$$

where $p(\cdot)$ is the prior distribution of θ specified in Step 1c-iii. In other words, the preposterior covariance is the expected value of the fixed- θ preposterior covariance with respect to the prior of θ .

4.3 Fisher Information-Based Surrogate Preposterior Analysis

Clearly, the proposed multi-response preposterior analysis is very computationally intensive. For a system with N responses, there are $N(N - 1)/2$ combinations of two responses and 2^N total combinations of any subset of the N responses. Even for a single subset of responses, the computational cost can be substantial. The MC strategy requires a large number N_{mc} of replicates, and for each MC replicate, Modules 2 and 3 (which themselves involve a MC simulation or numerical integration) of the modular Bayesian approach must be implemented. Therefore, to make the preposterior analysis feasible for engineering applications with many system responses, a more computationally efficient surrogate preposterior analysis is developed in [42, 43] that can be used to eliminate the responses that are unlikely to lead to good identifiability, thereby substantially reducing the number of response combinations that must be included in the preposterior analysis.

For the r -dimensional calibration parameter vector θ , the *observed Fisher information* $\mathcal{I}(\theta)$ is a matrix whose uth -row, vth -column entry is the negative second-order derivative of the log-likelihood function:

$$[\mathcal{I}(\theta)]_{u,v} = -\frac{\partial^2}{\partial \theta_u \partial \theta_v} \log p(\mathbf{Y}^m, \mathbf{Y}^e | \theta, \hat{\phi}) \quad (u, v = 1, 2, \dots, r), \quad (4.16)$$

where $p(\mathbf{Y}^m, \mathbf{Y}^e | \theta, \hat{\phi})$ is the likelihood function for the simulation and experimental data together, as in Eq. (4.12), and θ represents the true parameters. It measures the amount of information that yet-to-be-collected experimental data \mathbf{Y}^e , together with the already-observed \mathbf{Y}^m , provides about calibration parameter θ . It should be noted that θ in Eq. (4.16) is meant to be the true values of the calibration parameters. Hence, in Eq. (4.16) the distribution of the computer response \mathbf{Y}^m (which is known by itself does not depend on θ). Only the distribution of \mathbf{Y}^e depends on θ .

The Fisher-like surrogate preposterior criterion that will be introduced shortly in this section, which is used only for reducing the number of response combination that must be considered, is a modified version of Eq. (4.16). To handle the complication that the yet-to-be-collected experimental data \mathbf{Y}^e are unknown in Eq. (4.16), the simple substitution $\hat{\mathbf{Y}}^m(\mathbf{X}^e, \theta)$ for \mathbf{Y}^e is made. Here, $\hat{\mathbf{y}}^m(\mathbf{X}^e, \theta)$ represents the predicted value of \mathbf{Y}^e via interpolating the data from the MRGP model of \mathbf{y}^m . After generating this fictitious realization of \mathbf{Y}^e , the modular Bayesian approach (Step 2b of the flowchart in Fig. 4.14) is used to estimate the hyperparameters $\hat{\phi}$ for substitution into Eq. (4.16). Because \mathbf{Y}^e is replaced by its prediction, this will tend to result in a small estimated variance parameters for the discrepancy function, which will naturally result in some level of underestimation of the identifiability in θ . However, this surrogate procedure is only used for *relative* ranking of the identifiability that results from the various combinations of responses, and the results (See Sect. 4.6) indicate that the surrogate analysis does a reasonable job of

preserving the relative ranking. The advantage of this approach is computational – instead of generating multiple realizations of \mathbf{Y}^e , only a single realization $\hat{\mathbf{y}}^m(\mathbf{X}^e, \boldsymbol{\theta})$ is generated.

There is an additional complication. The $\boldsymbol{\theta}$ in Eq. (4.16) represents the true parameters, and these are unknown. To handle this, Eq. (4.16) is replaced by the “averaged” observed Fisher information matrix, averaging (4.16) with respect to the prior distribution $p(\boldsymbol{\theta})$ of $\boldsymbol{\theta}$. To calculate this, Monte Carlo simulation is used, as outlined in Steps 2 and 3 of the flowchart in Fig. 4.15. Specifically, N'_{mc} realizations $\boldsymbol{\theta}^{(i)} (i = 1, 2, \dots, N'_{mc})$ are drawn from $p(\boldsymbol{\theta})$ and take the u th-row, v th-column entry ($u, v = 1, 2, \dots, r$) of our averaged observed Fisher information matrix to be:

$$[\hat{\mathcal{I}}]_{u,v} = \frac{1}{N'_{mc}} \sum_{i=1}^{N'_{mc}} \left\{ -\frac{\partial^2}{\partial \theta_u \partial \theta_v} \log p \left(\mathbf{Y}^m, \hat{\mathbf{y}}^m(\mathbf{X}^e, \boldsymbol{\theta}^{(i)}) | \boldsymbol{\theta}, \hat{\boldsymbol{\phi}}^{(i)} \right) \Big|_{\boldsymbol{\theta}=\boldsymbol{\theta}^{(i)}} \right\}, \quad (4.17)$$

where $\hat{\boldsymbol{\phi}}^{(i)}$ denotes the values of $\boldsymbol{\phi}$ estimated in the modular Bayesian algorithm on the i th MC replicate. Various scalar metrics of $\hat{\mathcal{I}}$ (e.g., trace, determinant, maximum eigenvalue, etc.) can be used as the surrogate measure of identifiability. For a simple case with a single calibration parameter $\boldsymbol{\theta}$, $\hat{\mathcal{I}}$ is a scalar. The larger $\hat{\mathcal{I}}$ is, the more information there is about $\boldsymbol{\theta}$ from \mathbf{Y}^m and \mathbf{Y}^e , and the more likely it is to achieve good identifiability.

After calculating $\hat{\mathcal{I}}$ from Eq. (4.17), the top N_c subsets of responses (based on one of the scalar measures of identifiability extracted from $\hat{\mathcal{I}}$) are chosen to be further analyzed in the full preposterior analysis. Figure 4.15 is a flowchart of the entire Fisher information-based surrogate preposterior procedure.

The surrogate analysis is clearly much more efficient than the full preposterior analysis. The number of MC replicates N'_{mc} can be significantly smaller than what is required in the preposterior analysis (N_{mc}), since the MC sampling now is only with respect to $\boldsymbol{\theta}$. In addition, and more importantly, the calculations in each MC replicate are much simpler. Within each MC replicate, neither an inner level MC simulation nor numerical integration is needed. The main computation within each MC replicate is to calculate the MLEs of the hyperparameters $\hat{\boldsymbol{\phi}}^{(i)}$ and then to evaluate the likelihood at a few discrete values in the neighborhood of $\boldsymbol{\theta}^{(i)}$ to calculate the second-order derivative in Eq. (4.17) numerically.

4.4 Single-Response Case Study: Simply Supported Beam Example

In this section, the same beam example (see Sects. 2.2 and 3.2) illustrates how the preposterior analysis can be used, after conducting the computer simulations but before conducting the physical experiments, to predict the identifiability that will

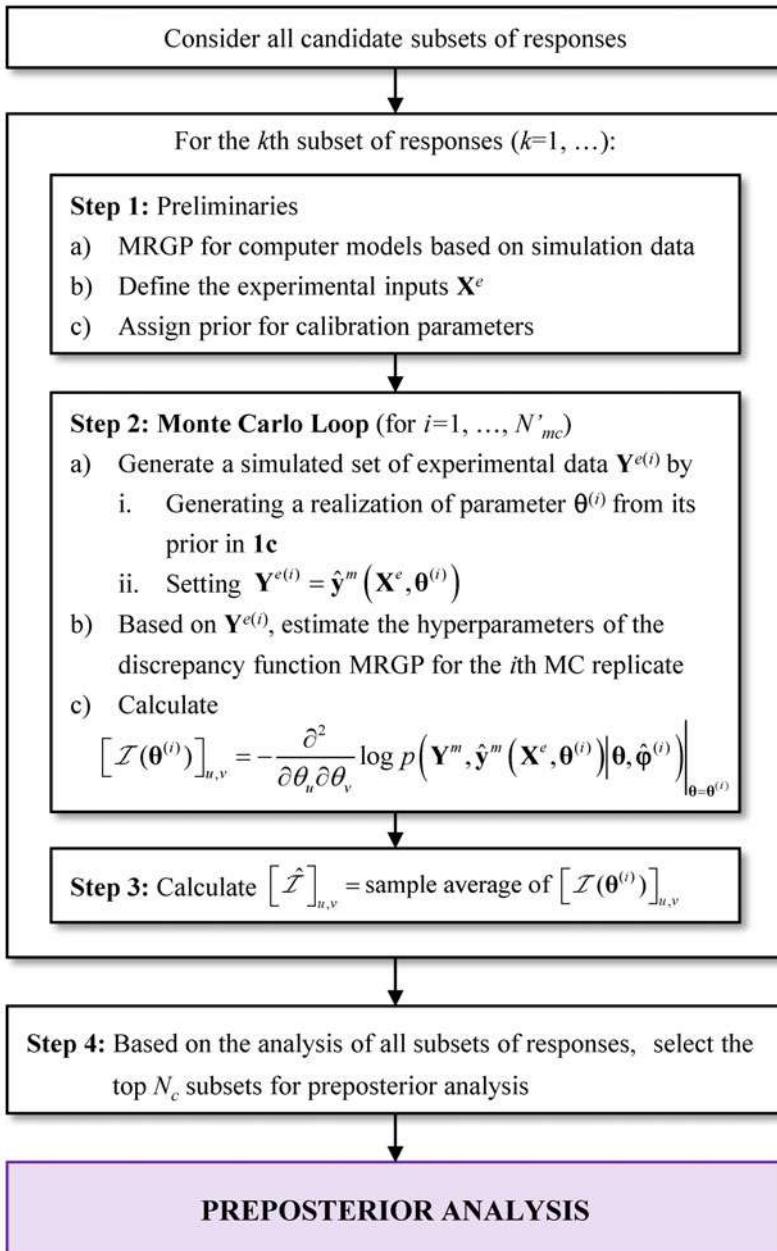

Fig. 4.15 Flowchart of the surrogate preposterior analysis

result from a proposed experimental design. The system in this example is inherently difficult to identify with a single response even with a large amount of observed physical experiments.

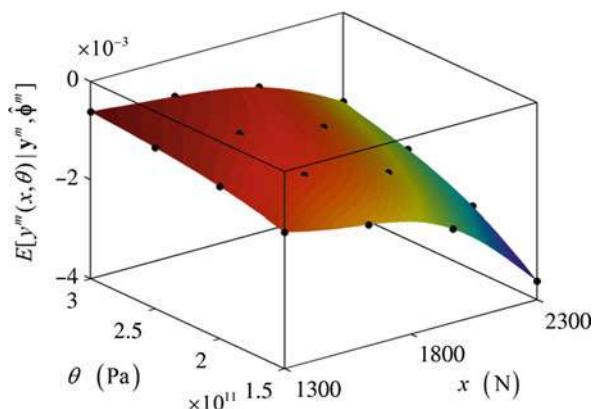

4.4.1 Computer Model, Physical Experiments, and Preliminaries

The design variable x is the magnitude of a static force applied to the midpoint of the beam, and the response y is the strain at the midpoint of the beam (at the top of the cross-section). The calibration parameter θ is the Young's modulus. For Step 1a, the simulations were observed on a 4×4 evenly spaced grid ($N_m = 16$) over the input space ($1300 \leq x \leq 2300$ N and $150 \leq \theta = 300$ GPa). The simulation response observations \mathbf{y}^m and the posterior mean of $y^m(x, \theta)$ from Step 1a are shown in Fig. 4.16. Because of the smooth nature of $y^m(x, \theta)$, there was very small posterior uncertainty in $y^m(x, \theta)$ over the entire input space.

Regarding Step 1b, different analyses will be conducted for different values of N_e . For each N_e , \mathbf{X}^e is evenly spaced over the input range $1300 \leq x \leq 2300$. For purposes of comparing the preposterior covariance to the posterior covariance, actual "physical" experimental data were generated via the same FEA model but using a more elaborate material law that results in a discrepancy between the computer model and the experimental data. Observation error with variance $\lambda = 6.63 \times 10^{-12}$ m² was added to the experimental data, and the true value of the Young's modulus calibration parameter was taken to be $\theta^* = 206.8$ GPa. These physical experimental data are not used in the preposterior algorithm of Fig. 4.14 and are used only to verify the results of the preposterior algorithm.

For Step 1c, $\phi^\delta \setminus \lambda$ is assigned a point mass prior with mass at $\{\boldsymbol{\beta}^\delta, \sigma_\delta^2, \boldsymbol{\omega}^\delta\} = \{0.00, 1.11 \times 10^{-7}, 0.002\}$. The value 1.11×10^{-7} m² for σ_δ^2 was chosen so that the bounds of the 99.7% prediction interval of the discrepancy function were approximately $[-1, 1] \times 10^{-3}$ m. The correlation parameters $\boldsymbol{\omega}^\delta$ were chosen to represent a relatively smooth GP model for the discrepancy function. λ is also assigned a point mass prior with mass at 6.63×10^{-12} m². Recall that the prior distributions for $\phi^\delta \setminus \lambda$ and λ are used only in Step 2a to generate random realizations of $\mathbf{y}^{e(i)}$. In general, the MLEs of $\phi^\delta \setminus \lambda$ and λ are calculated in Step 2b. For this example, however, λ is treated as a known value and is not estimated in Step 2b. This is reasonable in systems for which the random error variance can be estimated externally, simply by taking replicate experimental measurements at the same input

Fig. 4.16 Posterior mean of the computer model GP for the beam example. The bullets indicate \mathbf{y}^m

settings. Lastly, $p(\theta)$ was chosen to be a non-informative uniform distribution over the full range of θ .

4.4.2 Comparing the Preposterior and Posterior Covariances

We begin by comparing the fixed- θ preposterior covariance $\tilde{\Sigma}_\theta(\theta^t)$ for various θ^t to the actual posterior covariance based on the experimental data from the more elaborate FEA model. As described in Sect. 4.2, for each θ^t , $\tilde{\Sigma}_\theta(\theta^t)$ was calculated using the algorithm of Fig. 4.14 with $\theta^{(i)}$ from Step 2a-i replaced by the same value θ^t for all N_{mc} replicates. Figure 4.17 plots the fixed- θ preposterior standard deviation (STD) [i.e., the square root of $\tilde{\Sigma}_\theta(\theta^t)$] versus θ^t for two different experimental designs with $N_e = 3$ and $N_e = 8$. The individual points plotted at $\theta = 206.8 and represented by the shaded circle (for the design with $N_e = 3$) and shaded square (for the design with $N_e = 8$) are the actual posterior STDs of θ that result by applying Modules 1–3 of the standard modular Bayesian approach to a set of experimental data generated using the true value $\theta^* = 206.8. These individual points are included in Fig. 4.17 for purposes of comparing to the preposterior STDs that our algorithm calculates, which are represented by the series of connected points. In Fig. 4.17 both the fixed- θ preposterior STD and the posterior STD have been normalized (divided) by the STD of the prior $p(\theta)$.$$

Although the fixed- θ preposterior STDs differ from the posterior STD, their relative change as N_e increases is comparable. In particular, the relative difference in the fixed- θ preposterior covariance for the design with $N_e = 3$ and the design with $N_e = 8$ is reasonably independent of the fixed θ^t , and this relative difference is quite consistent with the relative difference in the actual posterior covariance for the

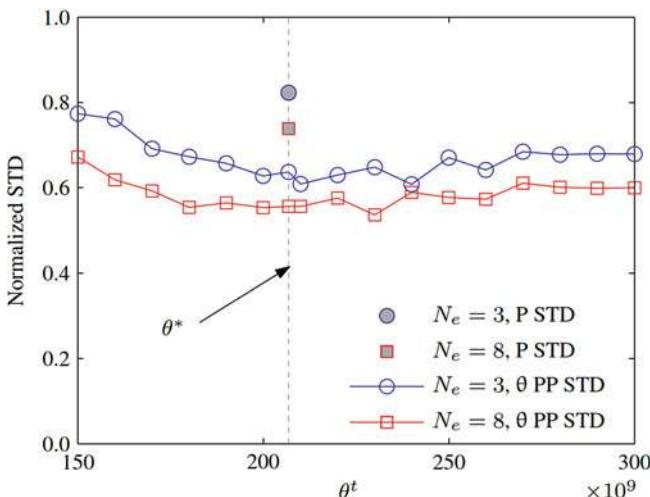

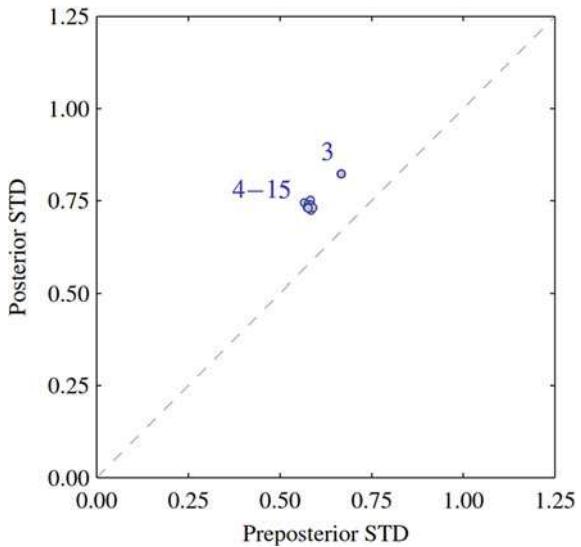

Fig. 4.17 Plot of the fixed- θ preposterior STD and the posterior STD (both normalized by the prior STD of θ) versus θ^t for the beam example. “ θ PP STD” is the fixed- θ preposterior STD and “P STD” is the posterior STD

Fig. 4.18 Plot of the preposterior STD versus the posterior STD (both normalized by the prior STD of θ) for the beam example. The numbers indicate N_e for each case

true $\theta^* = 206.8$ GPa. Consequently, the relative difference in the preposterior STD [which was calculated as the integral of the fixed- θ preposterior STD in Fig. 4.17, with respect to $p(\theta)$] accurately reflects the relative difference in the actual posterior STD in this example. Specifically, when N_e is increased from 3 to 8 in Fig. 4.17, the posterior STD decreases by 10.3% (from 0.8231 to 0.7383), and the preposterior STD decreases by 12.5% (from 0.6676 to 0.5840). This correctly indicates that the experimental design with $N_e = 8$ will result in somewhat better identifiability than the experimental design with $N_e = 3$, as measured by the posterior STD that would result after the experiments are conducted.

The preposterior STD was then calculated from the fixed- θ preposterior STDs in Fig. 4.17, as described in Sect. 4.2. The analyses were repeated for various N_e , and Fig. 4.18 shows a scatter plot of the preposterior STD versus the posterior STD (each normalized by prior STD θ) for $N_e = 3, 4, \dots, 15$. The scatter plot conveys a number of interesting characteristics of the beam example. Although the preposterior STD slightly underestimates the posterior STD for the different designs, the trend is the same: When N_e increases from 3 to 4, the preposterior STD correctly predicts that the posterior STD will decrease. Then, as N_e increases from 4 through 15, the preposterior STD again correctly predicts that there will be negligible further decrease in the posterior STD. The overall conclusion that a user might draw from this preposterior analysis is that the system inherently suffers from a lack of identifiability, because an increase in N_e beyond 4 results in almost no further improvement in the preposterior STD. Sections 2 and 3 discussed the reasons behind the lack of identifiability in detail and also demonstrated that identifiability is greatly improved when multiple responses are measured experimentally. In the next subsection, a second example will be in which the identifiability of the system continues to improve as experimental data are added.

4.5 Using the Preposterior Analysis to Select N_e

One way in which the preposterior analysis can be used is to help the user choose the number N_e of experimental runs [41]. Figure 4.19, which plots the normalized preposterior STD versus N_e for the beam example, illustrates how this might be accomplished. One might conclude that increasing N_e beyond 4 will provide little further knowledge of θ^* and that the beam system is inherently difficult to identify with only the single experimentally measured response (which was strain at the beam midpoint).

The beam example had only a single input variable x and used uniformly spaced grid designs. We now consider an example that uses Latin hypercube designs with two input variable and a calibration parameter. Suppose the computer model is:

$$y^m(x_1, x_2, \theta) = \sin(\theta x_1) + x_1 x_2, \\ x_1 \in [0, 1], \quad x_2 \in [0, 1], \quad \theta \in [0, 4],$$

and the physical experimental data are generated from the model:

$$y^e(x_1, x_2) = y^m(x_1, x_2, \theta^*) + \delta(x_1, x_2) + \varepsilon, \\ \varepsilon \sim \mathcal{N}(0, 0.01^2).$$

We began with a Latin hypercube design for the computer experiment with 40 points in three dimensions $\{x_1, x_2, \theta\}$. An optimal Latin hypercube design based on the maximin criterion was used. A Gaussian process model was fit to the computer experiment data via MLE in Step 1a of Fig. 4.14. For the physical experimental

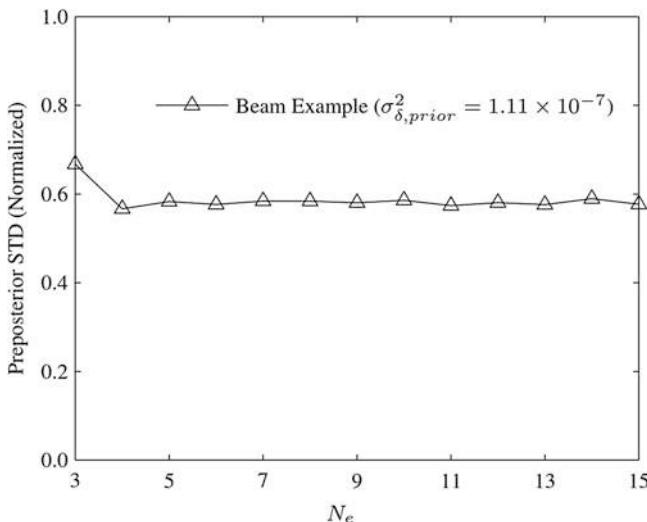

Fig. 4.19 Preposterior STD (normalized) versus N_e for the beam example

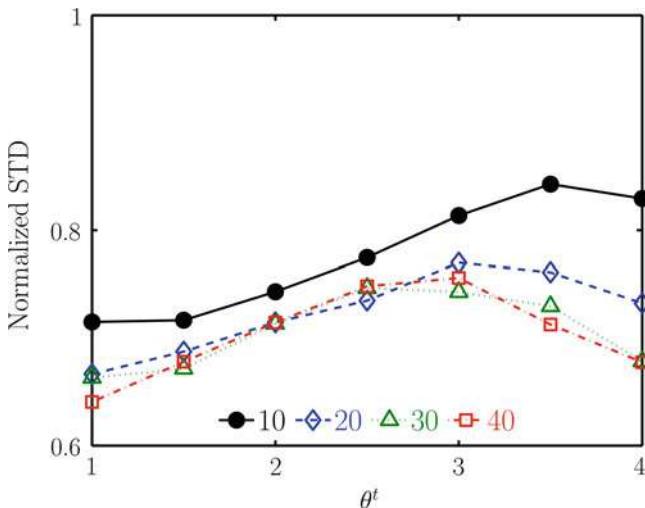

Fig. 4.20 Fixed- θ preposterior STD (normalized by the prior STD of θ) versus θ^t for Latin hypercube designs of various size N_e (N_e is specified in the legend)

design specified in Step 1b, maximin Latin hypercube designs of various size $N_e = \{10, 20, 30, 40, 50\}$ were used over two dimensions $\{x_1, x_2\}$. Because of the random nature of the Latin hypercube designs, none of the physical experimental designs had \mathbf{x} settings that coincided with the computer experiment \mathbf{x} settings. Next, in Step 1c-i, the GP hyperparameters of the discrepancy function were set to be $\beta^\delta = 0$, $\omega^\delta = 3$, and $\sigma_\delta = 0.75$, which corresponds to assigning them point mass priors. The relatively large value of σ_δ results in a variety of relatively large discrepancy functions being generated within Step 2 of the preposterior algorithm. In Step 1c-ii, $\lambda = 0.01^2$ was specified. Lastly, in Step 1c-iii, the prior for θ was specified to be uniform over the entire range $[0, 4]$.

From the preposterior analysis, Fig. 4.20 shows the resulting fixed- θ preposterior standard deviation versus θ^t for the designs with different N_e , and Fig. 4.21 shows the (normalized) preposterior standard deviation as a function of N_e . From Fig. 4.21, the preposterior standard deviation does not substantially decrease beyond $N_e = 30$ roughly.

4.6 Multi-response Case Study: Simply Supported Beam Example

In this section, the simply supported beam example is once again employed, to demonstrate the effectiveness of the preposterior and surrogate preposterior analyses approach under the multi-response scenario. The physical meanings of the six output

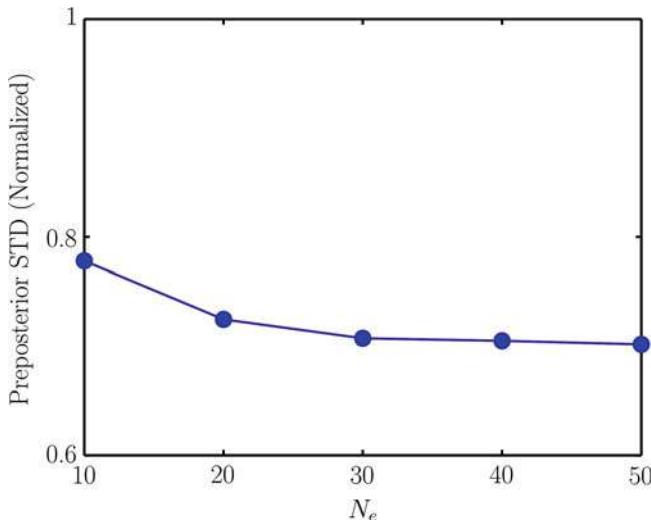

Fig. 4.21 Preposterior STD (normalized by the prior STD of θ) versus N_e for the Latin hypercube designs

variables y_i ($i = 1, \dots, 6$) that are calculated in the computer simulation are listed in Table 4.3. They are considered as candidates to measure experimentally.

As in Sects. 2.2 and 3.2, it turns out that the identifiability of this system is rather poor using any one of the six responses. On the other hand, using two responses together may potentially enhance identifiability. Section 3.2 provided detailed results of posterior analysis on each pair of the six responses and demonstrates the enhancement of identifiability. However, it did not provide a strategy for predicting which pair of responses will best enhance identifiability prior to conducting the physical experiment.

In this section, identifiability is predicted prior to collecting the physical experimental data, although the simulation data for all six responses are available on a 4×4 grid over the (x, θ) space with a range of $1300 \leq x \leq 2300$ N and $150 \leq \theta \leq 300$ GPa. The objective is to select which two out of six responses to measure experimentally, in order to best enhance identifiability. The preposterior and surrogate preposterior analyses using the simulation data are used to predict the degree of identifiability. The candidate subsets of responses that are considered are all 15 $\{y_i, y_j : i, j = 1, \dots, 6, i < j\}$. In the following discussion, the candidate subset $\{y_4, y_5\}$ is used to demonstrate the main procedures of the two analyses.

In the preliminary step of both preposterior and surrogate preposterior analyses, a MRGP model is built for $\{y_4, y_5\}$ from the simulation data. Figure 4.22 plots the predicted response surfaces from the MRGP model, which are quite close to the true simulation response surface, because the latter is relatively smooth in this example. The experimental settings \mathbf{X}^e for the input variable are defined as 11 points uniformly spaced over the design region, i.e., $\mathbf{X}^e = [1300, 1400, \dots, 2200, 2300]$ N.

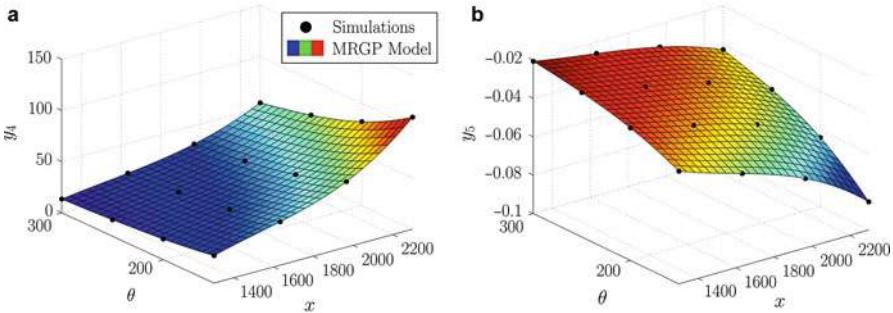

Fig. 4.22 The MRGP model for (a) y_4 and (b) y_5

The prior for the calibration parameter θ is a uniform distribution over $[150, 300]$ GPa. Additionally for the preposterior analysis, point mass priors are assigned to the hyperparameters of the discrepancy functions with masses at $\mathbf{B}^\delta = \mathbf{0}$, $\Sigma^\delta = \text{diag}(1.11 \times 10^{-7}, 1.11 \times 10^{-7})$, and $\omega^\delta = 2$. The experimental errors are assigned independent normal distributions: $\varepsilon_4 \sim \mathcal{N}(0, 0.0070)$ and $\varepsilon_5 \sim \mathcal{N}(0, 2.943 \times 10^{-9})$.

In the MC loop of the preposterior analysis, there are a total of $N_{mc} = 1600$ MC replicates for this specific subset of responses. Within the i th MC replicate, a realization of the simulation response $\mathbf{Y}^{m(i)}$ at the input settings \mathbf{X}^e is generated from the MRGP model fitted in Step 1a (the mean of which is shown in Fig. 4.22), a realization of the model discrepancy $\Delta^{(i)}$ is generated based on the specified prior for the hyperparameters, and a realization of the observational error $\mathbf{E}^{(i)}$ is generated based on the distributions of ε_4 and ε_5 . Based on this, a realization of experimental data $\mathbf{Y}^{e(i)}$ is calculated via Step 2a-iv and can be used for the multi-response modular Bayesian approach to calculate the sample posterior variance for the i th MC replicate. Assuming a uniform prior for θ over the range $[150, 300]$ GPa, the preposterior variance is estimated as the average of all 1600 sample posterior variances, which is $\tilde{\sigma}_\theta^2 = 2.0054 \text{ GPa}^2$.

In the MC loop of the surrogate preposterior analysis, N'_{mc} equally spaced values of θ are considered. Within the i th MC replicate, a realization of the simulation $\mathbf{Y}^{m(i)}$ is generated, as in the preposterior analysis. However, without generating $\Delta^{(i)}$ and $\mathbf{E}^{(i)}$, we directly take $\mathbf{Y}^{e(i)} = \mathbf{Y}^{m(i)}$ and apply the multi-response modular Bayesian approach to calculate the negative second-order derivative of log-likelihood function (as the term inside the brackets in Eq. (4.17)). The results for all 16 values of θ are plotted in Fig. 4.23b. The Fisher information-based scalar predictor \hat{I} , taken to be the average of the 16 values, is 351.8. Because θ is scalar with a uniform prior for this example, taking the average over the 16 evenly spaced values of θ is more computationally efficient than generating random draws of θ from its prior and using Eq. (4.17).

To better illustrate the relationship between the preposterior and the surrogate preposterior analyses, the preposterior analysis is conducted in the same “fixed- θ ” manner described in the preceding paragraph for the surrogate preposterior analysis.

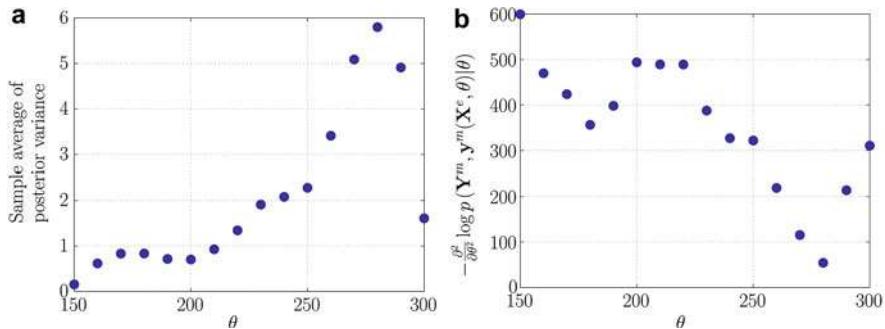

Fig. 4.23 16 equally spaced values of θ , and the corresponding (a) sample average of posterior variance (unit: GPa^2) using hypothetical data over 100 MC simulations per θ , and (b) negative second-order derivative of the log-likelihood function

That is, the 16 different values of θ equally spaced within $[150, 300]$ GPa are considered, and for each specific θ value, 100 MC replicates are used to calculate the sample posterior variance. A procedure identical to that described in Sect. 4.1, but with θ fixed over the 100 MC replicates, was used to estimate the preposterior variance (as the average of the 100 sample posterior variances over the 16 values of θ). The results are shown in Fig. 4.23a. Comparing Fig. 4.23a, b, a clear negative correlation can be seen between the preposterior variance and the Fisher information criterion. This is expected, considering that the preposterior variance is an estimate of the actual posterior variance, which is closely related to the inverse of the Fisher information; a larger value of the former generally corresponds to a larger value of the latter.

The same procedure was repeated for every other pair of responses. Table 4.6 shows the results of the preposterior and surrogate preposterior analyses. The ranks in columns 2 and 3 are based on the predicted identifiability; 1 corresponds to the smallest preposterior variance/largest $\hat{\mathcal{I}}$ and 15 to the largest preposterior variance/smallest $\hat{\mathcal{I}}$. The rankings provide us with predictions of which subsets are most likely to enhance identifiability (lower ranks) and which less likely (higher ranks). The “posterior” columns in Table 4.6, which are taken from Table 4.5, show the actual posterior covariances that resulted from each combination of measured responses after the experiments were conducted. They serve as a basis for comparison, and ideally we would like the rankings from the posterior analyses to coincide with the predicted rankings from the preposterior and surrogate preposterior analyses. It can be seen that the preposterior analysis is in good relative agreement with the posterior. Although the values of preposterior and posterior standard deviations are off by roughly a factor of 2.5, both analyses indicate that $\{y_4, y_5\}$ together lead to the best identifiability, while $\{y_1, y_2\}$ together lead to the worst identifiability. Overall, the rankings are in very close agreement. The improvement on identifiability relative to the worst case (i.e., $\{y_1, y_2\}$ for both analyses) is also calculated and provided in the table. The relative improvements are also in very close agreement. The

Table 4.6 Comparisons between posterior, preposterior, and surrogate preposterior analyses

Responses		Posterior			Preposterior			Surrogate preposterior	
y_i	y_j	σ_θ	Rank	Improvement	$\tilde{\sigma}_\theta$	Rank	Improvement	$\hat{\sigma}$	Rank
y_4	y_5	3.63	1	86.7%	1.4161	1	87.0%	351.8	1
y_4	y_6	3.90	2	85.8%	1.5224	3	86.0%	186.9	6
y_5	y_6	4.67	3	83.0%	1.6528	4	84.8%	218.2	3
y_3	y_6	4.86	4	82.2%	1.6618	5	84.7%	161.6	7
y_3	y_4	5.49	5	80.0%	1.4801	2	86.4%	273.0	2
y_3	y_5	6.27	6	77.1%	2.1117	6	80.6%	202.9	5
y_1	y_4	9.29	7	66.1%	3.0933	7	71.6%	209.6	4
y_1	y_3	10.13	8	63.0%	3.2583	8	70.1%	113.3	9
y_2	y_3	10.96	9	60.0%	3.6595	9	66.4%	93.34	10
y_2	y_5	15.42	10	43.4%	6.0765	11	44.2%	114.3	8
y_1	y_5	15.57	11	43.1%	5.5379	10	49.2%	90.92	11
y_2	y_4	18.35	12	33.9%	8.7816	12	19.4%	65.94	14
y_1	y_6	24.08	13	12.0%	9.1008	13	16.5%	81.19	12
y_2	y_6	26.46	14	3.3%	10.1850	14	6.5%	80.99	13
y_1	y_2	27.37	15	-	10.8931	15	-	47.09	15

results provided by the surrogate preposterior analysis are also in close agreement with the posterior standard deviation results, although slightly less so than the preposterior standard deviations. The top 7 pairs of responses coincide with the top 7 pairs from the actual posterior analysis. Hence, the surrogate preposterior analysis would have effectively narrowed down the candidate pairs to consider in the preposterior analysis. Considering its extremely low computational cost, the surrogate preposterior analysis is a useful enhancement to the preposterior analysis for reducing the number of response pairs to consider.

The results from three analyses in Table 4.6 are in good accordance with the underlying physics of the system. For example, the strain y_1 and the plastic strain y_2 are perfectly correlated with each other; their values are off by a constant (equal to the value of elastic strain) after plastic deformation. Therefore, their combination adds no more information about θ and enhances identifiability little beyond using either single response. In contrast, the internal energy y_4 and the midpoint displacement y_5 follow a nonlinear relationship, and thus the degree of improvement in identifiability is substantial.

It is not surprising to observe the absolute differences between the posterior variance and preposterior variances. In the MC simulations of the preposterior analysis, the hypothetical experimental data are generated based on discrepancy functions generated from their assigned prior distribution. In contrast, the posterior variance calculation is based on the single realization that is the actual discrepancy function. Consequently, the Bayesian analysis modules inside the MC loops are hypothetical and are not expected to obtain the same values of preposterior variance as the actual posterior variance. The surrogate preposterior analysis involves further

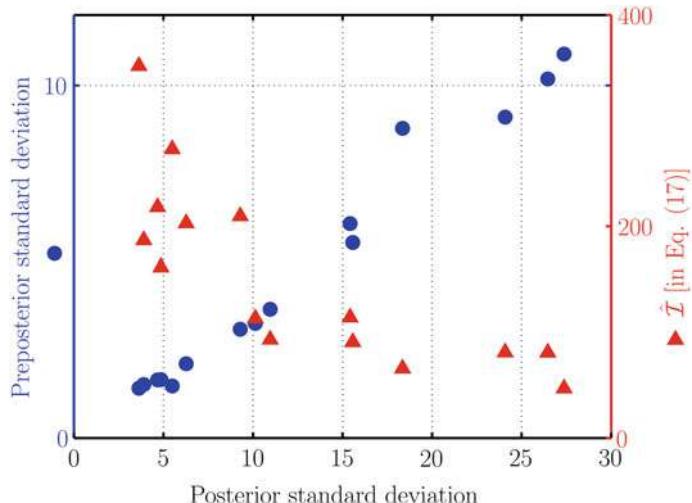

Fig. 4.24 Preposterior standard deviation and Fisher information-based identifiability predictor, versus posterior standard deviation, demonstrating very high correlation

approximations. However, it appears to accomplish its intended purpose, as the preposterior and surrogate preposterior analyses do a reasonable job of predicting the relative degree of identifiability and guide users in selecting the best set of responses to measure experimentally. Figure 4.24 illustrates this by plotting the preposterior standard deviation and the Fisher information criterion $\hat{\mathcal{I}}$ versus the actual posterior standard deviation. The preposterior standard deviation is roughly in proportion to the actual posterior standard deviation, and $\hat{\mathcal{I}}$ is negatively correlated with the posterior standard deviation, which indicates that for this case study preposterior and surrogate preposterior analyses are sufficient in predicting identifiability.

The improvement on identifiability is further illustrated in Figs. 4.25 and 4.26. While neither analyzing y_4 nor analyzing y_5 alone can provide an informative posterior distribution of θ (Fig. 4.25), uncertainty quantification considering both y_4 and y_5 provides a much tighter posterior distribution of θ , and the mean of the posterior is close to the true value of θ (Fig. 4.26a). In contrast, the subset of $\{y_1, y_2\}$ provides a dispersed posterior distribution of θ (Fig. 4.26b). The level of uncertainty is well predicted by both the preposterior and surrogate preposterior analyses.

4.7 Remarks on the Preposterior Analyses Method

Because of identifiability issues, it is often difficult to distinguish parameter uncertainty from uncertainty in the discrepancy function when using the GP-based method for calibrating computer models. In this section, it has been shown that the preposterior covariance of θ calculated via the algorithm of Fig. 4.14, and the

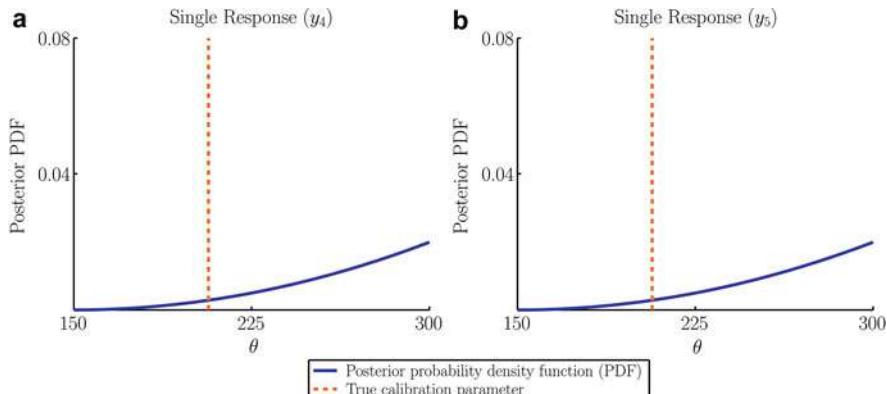

Fig. 4.25 Posterior distribution of the calibration parameter using a single response

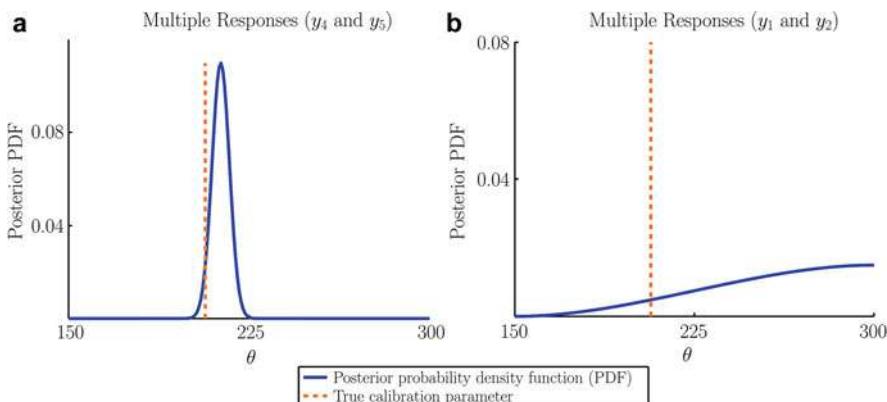

Fig. 4.26 Posterior distribution of the calibration parameter using multiple responses

Fisher information criterion $\hat{\mathcal{I}}$ calculated via the algorithm of Fig. 4.15, constitute reasonable predictions of the posterior covariance that will result when the physical experimental data are collected, at least for the examples considered. As such, the preposterior and the surrogate preposterior analyses can provide insight into the identifiability of a system and serve as criteria for helping to design an effective physical experimental design, based on the results of a previously conducted set of computer simulations.

Regarding the conditions on $\delta(\mathbf{x})$ required for reasonable identifiability, clearly there must be some, and $\delta(\mathbf{x})$ is not allowed to be any function. The assumption that $\delta(\mathbf{x})$ can be represented by a Gaussian process model is not a particularly strong one, because, for various choices of correlation function, a Gaussian process prior can produce an extremely wide variety of stochastic realizations of $\delta(\mathbf{x})$. This flexibility of the Gaussian process model is one of the reasons for its popularity in the calibration literature. As discussed in Sect. 2.3, good identifiability is more difficult

to achieve if $\delta(\mathbf{x})$ is not relatively smooth, which is reflected by the correlation parameters ω^δ (smaller ω^δ corresponds to a smoother discrepancy function). After collecting the physical experimental data, one can always estimate ω^δ to gauge the smoothness of $\delta(\mathbf{x})$. But perhaps the best and most direct measure of whether $\delta(\mathbf{x})$ is sufficiently smooth to allow identifiability is to simply look at the posterior standard deviation of θ , which directly reflects the impact of the smoothness of $\delta(\mathbf{x})$ on identifiability. However, prior to collecting the physical experimental data, it may be difficult to accurately gauge the smoothness of $\delta(\mathbf{x})$. In this case, if one specifies a specific ω^δ (or a range of ω^δ with some prior distribution assigned to it) to use in the preposterior algorithm, then the estimated preposterior covariance of θ should be interpreted as what would result if the discrepancy function truly had the assumed degree of smoothness. One should keep in mind that this complication (not knowing the actual smoothness of $\delta(\mathbf{x})$ until after the experimental data are collected, and hence not knowing how good the design will be until after the experiment is conducted) is certainly not unique to the calibration problem. In any experimental design problem, one never knows with certainty whether the design is good until after the experiment is conducted. For example, an experiment designed for estimating a linear model will end up being a very poorly designed experiment if, after conducting the experiment, it is discovered that the true response surface is really quadratic. The prevailing viewpoint in experimental design is to accept the fact that one may need to conduct a follow-up experiment based on what was observed in the initial experiment, and this same viewpoint applies to the calibration problem: If one designs a calibration experiment based on an assumed ω^δ , and, after conducting the experiment, it is discovered that the actual ω^δ is much different, then one could design and conduct a better follow-up experiment based on the improved knowledge of $\delta(\mathbf{x})$ learned from the initial experiment.

In the examples, the preposterior standard deviation has been used to compare and choose from among a small set of experiments that were designed using other methods. The examples considered evenly spaced grid designs and Latin hypercube designs of various sizes and focused on selecting the appropriate size. More generally, the algorithm in Figs. 4.14 and 4.15 could be used directly to compare any set of given designs (one would specify the input settings for each design in Step 1b). The approach could in principle also be used as a formal design optimization criterion to customize the exact values for the experimental \mathbf{x} settings, choose which of the simulation response variables to measure experimentally, etc. However, in its current form, the computational expense of the preposterior algorithm (Fig. 4.14) is prohibitive for these purposes. For the beam example (Sect. 4.4), each MC replicate (i.e., each iteration of Step 2 in Fig. 4.14) took roughly 0.018 min on average on a single-processor, 3 GHz, i7 machine. The computational expense is largely independent of the size N_e of the physical experiment if N_e is less than N_m , as will often be the case. Because Step 2 accounts for most of the computational expense of the entire algorithm, the overall expense is roughly proportional to N_{mc} . For example, using 1700 MC replicates for the beam example, the entire algorithm took roughly 31 min to calculate the preposterior standard deviation for each experimental design. Using 1700 MC replicates was more than

sufficient for this example, and no appreciable difference was found in the results when MC replicates were increased to 8500. The computational expense will also increase with the number of variables. For the example depicted in Figs. 4.20 and 4.21, each MC replicate took roughly 0.028 min on average, and this was also largely independent of N_e . In order to use the approach in a formal design optimization algorithm, one would have to calculate the preposterior standard deviation for a great many different candidate designs as the exact locations of the \mathbf{x} settings are varied. Hence, the surrogate preposterior analysis (Fig. 4.15) is needed to reduce computational expenses and to adapt the algorithm for these purposes.

5 Conclusions

To use a computer model for simulation-based design, designers must build confidence in using the model for predicting physical systems, which is accomplished by quantifying uncertainty via model updating. The model updating formulation proposed by Kennedy and O'Hagan is the most comprehensive and applicable to design under uncertainty. However, a limitation of this model updating formulation is that it can be difficult to distinguish between the effects of the calibration parameters (parameter uncertainty) and the discrepancy function (model discrepancy), which results in a lack of identifiability. It is important to identify, or differentiate, between these two sources of uncertainty in order to better understand the underlying sources of model uncertainty and ultimately further improve the model to better represent reality.

The degree of identifiability can be measured by the posterior covariance of the calibration parameters in a typical model uncertainty quantification framework. A better understanding of the identifiability problem is provided in this chapter in relation to model updating by using several illustrative examples. It was first shown how the calibration parameters and the discrepancy function were not identifiable in the simply supported beam example, even when significant amounts of simulation and experimental data are available. There are several different combinations of the computer model (with different values for the calibration parameter) and the estimated discrepancy function that combine to accurately predict the experimental response, which translates to poor identifiability. To improve identifiability, one can use informative prior distributions for the calibration parameters and/or the discrepancy function; however, this is a crude solution. Furthermore, in practice, informative priors typically do not exist. In the step function example in Sect. 2.3, it was shown that identifiability is possible under the relatively mild assumption of a smooth discrepancy function. In this example, the estimated discrepancy function is only smooth and consistent with the GP model when the calibration parameter equals the true value, which resulted in good identifiability. In conclusion, identifiability is a highly nuanced and difficult problem, but not impossible.

In spite of the identifiability challenges, good identifiability may often be achieved in model uncertainty quantification by measuring multiple experimental

responses that are automatically calculated in the simulation and that share a mutual dependence on a common set of calibration parameters. An intriguing phenomenon was observed that some combinations of responses may result in drastically different identifiability than others: By revisiting the beam example, it was shown that measuring certain responses will achieve substantial improvement in identifiability, while measuring other combinations of responses provides little improvement in identifiability beyond measuring only a single response. To take advantage of this, a method is needed for predicting multi-response identifiability prior to conducting the physical experiments, to allow users to choose the most appropriate set of responses to measure experimentally.

As it is generally not feasible, nor necessary, to measure experimentally all of the great many responses that are automatically calculated in the simulations, a preposterior analysis was introduced to address the issue of how to select the most appropriate subset of responses to measure experimentally, to best enhance identifiability. Prior to conducting the physical experiments but after conducting the computer simulations, the preposterior analysis can predict the relative improvement in identifiability that will result using different subsets of responses. It is based on Monte Carlo simulations within a modular Bayesian multi-response Gaussian process (MRGP) framework. The case studies showed that the approach is effective in predicting which subset of responses will provide the largest improvement in identifiability. Even though there are absolute differences between the preposterior and actual posterior covariances, the relative differences and the rankings derived from them are quite consistent, indicating that the method can be used effectively to choose the best combination of responses to measure experimentally.

Furthermore, to render the approach computationally feasible in engineering applications with a large number of responses, a simpler, surrogate preposterior analysis based on the expected Fisher information of the calibration parameters was introduced. The expected Fisher information matrix is the frequentist counterpart to the Bayesian preposterior covariance matrix of the parameters. It was demonstrated that, while being much faster to calculate than the preposterior covariance, it still provides a reasonable indication of the resulting identifiability. For real engineering applications with many system responses (and hence many different combinations of responses), it is recommended using the surrogate preposterior analysis to eliminate the responses that are unlikely to lead to good identifiability and reduce the number of response combinations that are considered in the preposterior analysis.

Appendix A: Estimates of the Hyperparameters for the Computer Model MRGP

To obtain the MLEs of the hyperparameters for the computer model MRGP model, the multivariate normal likelihood function is first constructed as:

$$\begin{aligned}
p(vec(\mathbf{Y}^m) | \mathbf{B}^m, \Sigma^m, \omega^m) &= (2\pi)^{-qN_m/2} |\Sigma^m|^{-N_m/2} |\mathbf{R}^m|^{-q/2} \\
&\times \exp \left\{ -\frac{1}{2} vec(\mathbf{Y}^m - \mathbf{H}^m \mathbf{B}^m)^T (\Sigma^m \otimes \mathbf{R}^m)^{-1} vec(\mathbf{Y}^m - \mathbf{H}^m \mathbf{B}^m) \right\},
\end{aligned} \tag{4.18}$$

where $vec(\cdot)$ is the vectorization of the matrix (stacking of the columns), \otimes denotes the Kronecker product, \mathbf{R}^m is a $N_m \times N_m$ correlation matrix whose i th-row, j th-column entry is $R^m((\mathbf{x}_i^m, \theta_i^m), (\mathbf{x}_j^m, \theta_j^m))$, and $\mathbf{H}^m = [\mathbf{h}^m(\mathbf{x}_1^m, \theta_1^m)^T, \dots, \mathbf{h}^m(\mathbf{x}_{N_m}^m, \theta_{N_m}^m)^T]^T$. Taking the log of Eq. (4.18) yields:

$$\begin{aligned}
\ln(p(vec(\mathbf{Y}^m) | \mathbf{B}^m, \Sigma^m, \omega^m)) &= -\frac{qN_m}{2} \ln(2\pi) - \frac{N_m}{2} \ln(|\Sigma^m|) - \frac{q}{2} \ln(|\mathbf{R}^m|) \\
&- \frac{1}{2} vec(\mathbf{Y}^m - \mathbf{H}^m \mathbf{B}^m)^T (\Sigma^m \otimes \mathbf{R}^m)^{-1} vec(\mathbf{Y}^m - \mathbf{H}^m \mathbf{B}^m).
\end{aligned} \tag{4.19}$$

The MLE of \mathbf{B}^m is found by setting the derivative of Eq. (4.19) with respect to \mathbf{B}^m equal to zero, which gives:

$$\hat{\mathbf{B}}^m = [(\mathbf{H}^m)^T (\mathbf{R}^m)^{-1} \mathbf{H}^m]^{-1} (\mathbf{H}^m)^T (\mathbf{R}^m)^{-1} \mathbf{Y}^m. \tag{4.20}$$

The MLE of Σ^m is found using result 4.10 of Ref. [52], which yields:

$$\hat{\Sigma}^m = \frac{1}{N_m} (\mathbf{Y}^m - \mathbf{H}^m \hat{\mathbf{B}}^m)^T (\mathbf{R}^m)^{-1} (\mathbf{Y}^m - \mathbf{H}^m \hat{\mathbf{B}}^m). \tag{4.21}$$

Finally, the MLE of ω^m , denoted by $\hat{\omega}^m$, is found by numerically maximizing Eq. (4.19) after plugging in the MLEs of \mathbf{B}^m and Σ^m .

Appendix B: Posterior Distributions of the Computer Responses

After observing \mathbf{Y}^m , the posterior of the computer response $y_i^m(\mathbf{x}, \theta)$ given \mathbf{Y}^m (and given ω^m and Σ^m and assuming a non-informative prior for \mathbf{B}^m) is Gaussian with mean and covariance:

$$\mathbb{E}[y^m(\mathbf{x}, \theta) | \mathbf{Y}^m, \phi^m] = \mathbf{h}^m(\mathbf{x}, \theta) \hat{\mathbf{B}}^m + \mathbf{r}^m(\mathbf{x}, \theta)^T (\mathbf{R}^m)^{-1} (\mathbf{Y}^m - \mathbf{H}^m \hat{\mathbf{B}}^m) \tag{4.22}$$

$$\begin{aligned}
\text{Cov}[y^m(\mathbf{x}, \theta), y^m(\mathbf{x}', \theta') | \mathbf{Y}^m, \phi^m] &= \Sigma^m \{ R^m((\mathbf{x}, \theta), (\mathbf{x}', \theta')) \\
&- \mathbf{r}^m(\mathbf{x}, \theta)^T (\mathbf{R}^m)^{-1} \mathbf{r}^m(\mathbf{x}', \theta') + [\mathbf{h}^m(\mathbf{x}, \theta)^T - (\mathbf{H}^m)^T (\mathbf{R}^m)^{-1} \mathbf{r}^m(\mathbf{x}, \theta)]^T \\
&\times [(\mathbf{H}^m)^T (\mathbf{R}^m)^{-1} \mathbf{H}^m]^{-1} [\mathbf{h}^m(\mathbf{x}, \theta)^T - (\mathbf{H}^m)^T (\mathbf{R}^m)^{-1} \mathbf{r}^m(\mathbf{x}, \theta)] \}
\end{aligned} \tag{4.23}$$

where $\mathbf{r}^m(\mathbf{x}, \boldsymbol{\theta})$ is a $N_m \times 1$ vector whose i th element is $R^m((\mathbf{x}_i^m, \boldsymbol{\theta}_i^m), (\mathbf{x}, \boldsymbol{\theta}))$. Using an empirical Bayes approach, the MLEs of the hyperparameters from Appendix A are plugged into Eqs. (4.22) and (4.23) to calculate the posterior distribution of the computer responses. Notice that Eqs. (4.22) and (4.23) are analogous to the single-response GP model results.

Appendix C: Estimates of the Hyperparameters for the Discrepancy Functions MRGP

To estimate the hyperparameters $\boldsymbol{\phi}^\delta = \{\mathbf{B}^\delta, \boldsymbol{\Sigma}^\delta, \boldsymbol{\omega}^\delta, \boldsymbol{\lambda}\}$ of the MRGP model representing the discrepancy functions, the procedure outlined by Kennedy and O'Hagan [1] is used and modified to handle multiple responses. This procedure begins by obtaining a posterior of the experimental responses given the simulation data and the hyperparameters from Module 1, which has prior mean and covariance:

$$\mathbb{E}[\mathbf{y}^e(\mathbf{x})|\mathbf{Y}^m, \hat{\boldsymbol{\phi}}^m, \boldsymbol{\theta} = \boldsymbol{\theta}^*] = \mathbb{E}[\mathbf{y}^m(\mathbf{x}, \boldsymbol{\theta}^*)|\mathbf{Y}^m, \hat{\boldsymbol{\phi}}^m] + \mathbf{h}^\delta(\mathbf{x})\mathbf{B}^\delta, \quad (4.24)$$

$$\begin{aligned} \text{Cov}[\mathbf{y}^e(\mathbf{x}), \mathbf{y}^e(\mathbf{x}')|\mathbf{Y}^m, \hat{\boldsymbol{\phi}}^m, \boldsymbol{\theta} = \boldsymbol{\theta}^*] &= \boldsymbol{\Sigma}^\delta R^\delta(\mathbf{x}, \mathbf{x}) + \boldsymbol{\lambda} \\ &\quad + \text{Cov}[\mathbf{y}^m(\mathbf{x}, \boldsymbol{\theta}^*), \mathbf{y}^m(\mathbf{x}', \boldsymbol{\theta}^*)|\mathbf{Y}^m, \hat{\boldsymbol{\phi}}^m], \end{aligned} \quad (4.25)$$

where $\hat{\boldsymbol{\phi}}^m$ are the MLEs of the hyperparameters for the computer model MRGP model. Since Eqs. (4.24) and (4.25) depend on the unknown true value of $\boldsymbol{\theta}^*$, these two equations are integrated with respect to the prior distribution of $\boldsymbol{\theta}(p(\boldsymbol{\theta}))$ via:

$$\begin{aligned} \mathbb{E}[\mathbf{y}^e(\mathbf{x})|\mathbf{Y}^m, \hat{\boldsymbol{\phi}}^m] &= \int \mathbb{E}[\mathbf{y}^e(\mathbf{x})|\mathbf{Y}^m, \hat{\boldsymbol{\phi}}^m, \boldsymbol{\theta}] p(\boldsymbol{\theta}) d\boldsymbol{\theta}, \\ \text{Cov}[\mathbf{y}^e(\mathbf{x}), \mathbf{y}^e(\mathbf{x}')|\mathbf{Y}^m, \hat{\boldsymbol{\phi}}^m] &= \int \text{Cov}[\mathbf{y}^e(\mathbf{x}), \mathbf{y}^e(\mathbf{x}')|\mathbf{Y}^m, \hat{\boldsymbol{\phi}}^m, \boldsymbol{\theta}] p(\boldsymbol{\theta}) d\boldsymbol{\theta}. \end{aligned} \quad (4.26)$$

Kennedy and O'Hagan [53] provide closed form solutions for Eq. (4.26) under the conditions of Gaussian correlation functions, constant regression functions, and normal prior distributions for $\boldsymbol{\theta}$ (for details, refer to Section 3 of [53] and Section 4.5 of [1]). In this chapter, similar closed form solutions are used except that a uniform prior distribution is assumed for $\boldsymbol{\theta}$.

After observing the experimental data, \mathbf{Y}^e , one can construct a multivariate normal likelihood function with mean and variance from Eq. (4.26). The MLEs of $\boldsymbol{\phi}^\delta$ maximize this likelihood function. The MLE of \mathbf{B}^δ can be found by setting the analytical derivative of this likelihood function with respect to \mathbf{B}^δ equal to zero (see Section 2 of Ref. [53]). However, there are no analytical derivatives with respect to the hyperparameters $\boldsymbol{\Sigma}^\delta, \boldsymbol{\omega}^\delta$, and $\boldsymbol{\lambda}$. Therefore, numerical optimization techniques are needed to find these MLEs.

Appendix D: Posterior Distribution of the Calibration Parameters

The posterior for the calibration parameters in Eq.(4.12) involves the likelihood function $p(\mathbf{d}|\boldsymbol{\theta}, \hat{\boldsymbol{\phi}})$ and the marginal posterior distribution for the data $p(\mathbf{d}|\hat{\boldsymbol{\phi}})$. The likelihood function is multivariate normal with mean vector and covariance matrix defined as:

$$\begin{aligned}\mathbf{m}(\boldsymbol{\theta}) &= \mathbf{H}(\boldsymbol{\theta})\hat{\mathbf{B}} \\ &= \begin{bmatrix} \mathbf{I}_q \otimes \mathbf{H}^m & \mathbf{0} \\ \mathbf{I}_q \otimes \mathbf{H}^m(\mathbf{X}^e, \boldsymbol{\theta}) & \mathbf{I}_q \otimes \mathbf{H}^\delta \end{bmatrix} \begin{bmatrix} \text{vec}(\hat{\mathbf{B}}^m) \\ \text{vec}(\hat{\mathbf{B}}^\delta) \end{bmatrix},\end{aligned}\quad (4.27)$$

$$\mathbf{V}(\boldsymbol{\theta}) = \begin{bmatrix} \hat{\Sigma}^m \otimes \mathbf{R}^m & \hat{\Sigma}^m \otimes \mathbf{C}^m \\ \hat{\Sigma}^m \otimes \mathbf{C}^{m T} & \hat{\Sigma}^m \otimes \mathbf{R}^m(\mathbf{X}^e, \boldsymbol{\theta}) + \hat{\Sigma}^\delta \otimes \mathbf{R}^\delta + \hat{\lambda} \otimes \mathbf{I}_{N_e} \end{bmatrix}, \quad (4.28)$$

where $\hat{\mathbf{B}} = (\mathbf{H}(\boldsymbol{\theta})^T \mathbf{V}(\boldsymbol{\theta})^{-1} \mathbf{H}(\boldsymbol{\theta}))^{-1} \mathbf{H}(\boldsymbol{\theta})^T \mathbf{V}(\boldsymbol{\theta})^{-1} \mathbf{d}$, which is calculated based on the entire data set (instead of using the estimates from Modules 1 and 2 for \mathbf{B}^m and \mathbf{B}^δ) as detailed in Section 4 of [53]. $\mathbf{H}^m(\mathbf{X}^e, \boldsymbol{\theta}) = [\mathbf{h}^m(\mathbf{x}_1^e, \boldsymbol{\theta})^T, \dots, \mathbf{h}^m(\mathbf{x}_{N_e}^m, \boldsymbol{\theta})^T]^T$ and $\mathbf{H}^\delta = [\mathbf{h}^\delta(\mathbf{x}_1^e)^T, \dots, \mathbf{h}^\delta(\mathbf{x}_{N_e}^\delta)^T]^T$ denote the specified regression functions for the computer model and the discrepancy functions at the input settings \mathbf{X}^e . \mathbf{C}^m denotes the $N_m \times N_e$ matrix with i th-row, j th-column entries $R^m((\mathbf{x}_i^m, \boldsymbol{\theta}_i^m), (\mathbf{x}_j^e, \boldsymbol{\theta}))$. $\mathbf{R}^m(\mathbf{X}^e, \boldsymbol{\theta})$ denotes the $N_e \times N_e$ matrix with i th-row, j th-column entries $R^m((\mathbf{x}_i^e, \boldsymbol{\theta}), (\mathbf{x}_j^e, \boldsymbol{\theta}))$. \mathbf{R}^δ denotes the $N_e \times N_e$ matrix with i th-row, j th-column entries $R^\delta(\mathbf{x}_i^e, \mathbf{x}_j^e)$. Finally, \mathbf{I}_q and \mathbf{I}_{N_e} denote the $q \times q$ and $N_e \times N_e$ identity matrices.

The marginal posterior distribution for the data $p(\mathbf{d}|\hat{\boldsymbol{\phi}})$ is:

$$p(\mathbf{d}|\hat{\boldsymbol{\phi}}) = \int p(\mathbf{d}|\boldsymbol{\theta}, \hat{\boldsymbol{\phi}}) p(\boldsymbol{\theta}) d\boldsymbol{\theta}, \quad (4.29)$$

which can be calculated using any numerical integration technique. In this chapter, Legendre-Gauss quadrature is used for the low-dimensional examples. Alternatively, Markov chain Monte Carlo (MCMC) could be used to sample complex posterior distributions such as those in Eq.(4.12).

Appendix E: Posterior Distribution of the Experimental Responses

Since a MRGP model represents the experimental responses, the conditional (given $\boldsymbol{\theta}$) posterior distribution at any point \mathbf{x} is Gaussian with mean and covariance defined as (assuming a non-informative prior on \mathbf{B}^m and \mathbf{B}^δ and using the empirical Bayes approach that treats $\boldsymbol{\phi} = \hat{\boldsymbol{\phi}}$ as fixed):

$$\mathbb{E}[\mathbf{y}^e(\mathbf{x})^T | \boldsymbol{\theta}, \mathbf{d}, \hat{\boldsymbol{\phi}}] = \mathbf{h}(\mathbf{x}, \boldsymbol{\theta})\hat{\mathbf{B}} + \mathbf{t}(\mathbf{x}, \boldsymbol{\theta})^T \mathbf{V}(\boldsymbol{\theta})^{-1}(\mathbf{d} - \mathbf{H}(\boldsymbol{\theta})\hat{\mathbf{B}}), \quad (4.30)$$

$$\begin{aligned} \text{Cov}[\mathbf{y}^e(\mathbf{x})^T, \mathbf{y}^e(\mathbf{x}')^T | \boldsymbol{\theta}, \mathbf{d}, \hat{\boldsymbol{\phi}}] &= \hat{\Sigma}^m R^m((\mathbf{x}, \boldsymbol{\theta}), (\mathbf{x}', \boldsymbol{\theta})) + \hat{\Sigma}^\delta R^\delta(\mathbf{x}, \mathbf{x}') \\ &+ \hat{\lambda} - \mathbf{t}(\mathbf{x}, \boldsymbol{\theta})^T \mathbf{V}(\boldsymbol{\theta})^{-1} \mathbf{t}(\mathbf{x}', \boldsymbol{\theta}) + (\mathbf{h}(\mathbf{x}, \boldsymbol{\theta})^T - \mathbf{H}(\boldsymbol{\theta})^T \mathbf{V}(\boldsymbol{\theta})^{-1} \mathbf{t}(\mathbf{x}, \boldsymbol{\theta}))^T \\ &\times (\mathbf{H}(\boldsymbol{\theta})^T \mathbf{V}(\boldsymbol{\theta})^{-1} \mathbf{H}(\boldsymbol{\theta}))^{-1} (\mathbf{h}(\mathbf{x}', \boldsymbol{\theta})^T - \mathbf{H}(\boldsymbol{\theta})^T \mathbf{V}(\boldsymbol{\theta})^{-1} \mathbf{t}(\mathbf{x}', \boldsymbol{\theta})), \end{aligned} \quad (4.31)$$

where:

$$\mathbf{t}(\mathbf{x}, \boldsymbol{\theta}) = \begin{bmatrix} \hat{\Sigma}^m \otimes \mathbf{R}^m((\mathbf{X}^m, \boldsymbol{\Theta}^m), (\mathbf{x}, \boldsymbol{\theta})) \\ \hat{\Sigma}^m \otimes \mathbf{R}^m((\mathbf{X}^e, \boldsymbol{\theta}), (\mathbf{x}, \boldsymbol{\theta})) + \hat{\Sigma}^\delta \otimes \mathbf{R}^\delta(\mathbf{X}^e, \mathbf{x}) \end{bmatrix}, \quad (4.32)$$

$$\mathbf{h}(\mathbf{x}, \boldsymbol{\theta}) = [\mathbf{I}_q \otimes \mathbf{h}^m(\mathbf{x}, \boldsymbol{\theta}) \ \mathbf{I}_q \otimes \mathbf{h}^\delta(\mathbf{x})]. \quad (4.33)$$

$\mathbf{R}^m((\mathbf{X}^m, \boldsymbol{\Theta}^m), (\mathbf{x}, \boldsymbol{\theta}))$ is a $N_m \times 1$ vector whose i th entry is $R^m((\mathbf{x}_i^m, \boldsymbol{\theta}_i^m), (\mathbf{x}, \boldsymbol{\theta}))$, $\mathbf{R}^m((\mathbf{X}^e, \boldsymbol{\theta}), (\mathbf{x}, \boldsymbol{\theta}))$ is a $N_e \times 1$ vector whose i th entry is $R^m((\mathbf{x}_i^e, \boldsymbol{\theta}), (\mathbf{x}, \boldsymbol{\theta}))$, and $\mathbf{R}^\delta(\mathbf{X}^e, \mathbf{x})$ is a $N_e \times 1$ vector whose i th entry is $R^\delta(\mathbf{x}_i^e, \mathbf{x})$.

To calculate the unconditional posterior distributions (marginalized with respect to $\boldsymbol{\theta}$) of the experimental responses, the conditional posterior distributions are marginalized with respect to the posterior distribution of the calibration parameters from Module 3. The mean and covariance of the unconditional posterior distributions can be written as:

$$\mathbb{E}[\mathbf{y}^e(\mathbf{x})^T | \mathbf{d}, \hat{\boldsymbol{\phi}}] = \mathbb{E}[\mathbb{E}[\mathbf{y}^e(\mathbf{x})^T | \boldsymbol{\theta}, \mathbf{d}, \hat{\boldsymbol{\phi}}]], \quad (4.34)$$

$$\begin{aligned} \text{Cov}[\mathbf{y}^e(\mathbf{x})^T, \mathbf{y}^e(\mathbf{x}')^T | \mathbf{d}, \hat{\boldsymbol{\phi}}] &= \mathbb{E}[\text{Cov}[\mathbf{y}^e(\mathbf{x})^T, \mathbf{y}^e(\mathbf{x}')^T | \boldsymbol{\theta}, \mathbf{d}, \hat{\boldsymbol{\phi}}]] \\ &+ \text{Cov}[\mathbb{E}[\mathbf{y}^e(\mathbf{x})^T | \boldsymbol{\theta}, \mathbf{d}, \hat{\boldsymbol{\phi}}], \mathbb{E}[\mathbf{y}^e(\mathbf{x}')^T | \boldsymbol{\theta}, \mathbf{d}, \hat{\boldsymbol{\phi}}]], \end{aligned} \quad (4.35)$$

where the outer expectation and covariance are with respect to the posterior distribution of the calibration parameters. Equations (4.34) and (4.35) are derived using the law of total expectation and the law of total covariance [54]. Due to the complexity of the posterior distribution of the calibration parameters, the marginalization requires numerical integration methods. For the examples in this chapter, Legendre-Gauss quadrature is used.

Validation of Physical Models in the Presence of Uncertainty

5

Robert D. Moser and Todd A. Oliver

Abstract

As the field of computational modeling continues to mature and simulation results are used to inform more critical decisions, validation of the physical models that form the basis of these simulations takes on increasing importance. While model validation is not a new concept, traditional techniques such as visual comparison of model outputs and experimental observations without accounting for uncertainties are insufficient for assessing model validity, particularly for the case where the intended purpose of the model is to make extrapolative predictions. This work provides an overview of validation of physical models in the presence of uncertainty. In particular, two issues are discussed: comparison of model outputs and observational data when both the model and observations are uncertain, and the process of building confidence in extrapolative predictions. For comparing uncertain model outputs and data, a Bayesian probabilistic perspective is adopted in which the problem of assessing the consistency of the model and the observations becomes one of Bayesian model checking. A broadly applicable approach to Bayesian model checking for physical models is described. For validating extrapolative predictions, a recently developed process termed predictive validation is discussed. This process relies on the ideas of Bayesian model checking but goes beyond comparison of model and data to assess the conditions necessary for reliable extrapolation using physics-based models.

1 Introduction

Over the last century, the field of computational modeling has grown tremendously, from virtually nonexistent to pervasive. During this time, simultaneous advances in simulation algorithms and computer hardware have enabled the development and application of increasingly complicated and detailed models to represent evermore complex physical phenomena. These advances are revolutionizing the ways in which models are used in the design and analysis of complex systems, enabling simulation results to be used in support of critical design and operational decisions [13, 26]. With continued advances in models, algorithms, and hardware, numerical simulations will only become more critical in modern science and engineering.

Given the importance of computational modeling, it is increasingly important to assess the reliability, in light of the purpose of a given simulation, of the models that form the basis of computational simulations. This reliability assessment is the domain of validation. While the concept of model validation is not new, it has recently received renewed attention due to the rapid growth in the use of models as a basis for making decisions [2, 4, 29]. This article provides an overview of the state of the art in validation of physical models in the presence of uncertainty.

In science and engineering, the word validation is often used to refer to simple comparisons between model outputs and experimental data such as plotting the model results and data on the same axes to allow visual assessment of agreement or lack thereof. While comparisons between model and data are at the core of any validation procedure, there are a number of problems with such naive comparisons. First, these comparisons tend to lead to qualitative rather than quantitative assessments of agreement. While such qualitative assessments are often

instructive and important, they are clearly incomplete, particularly as a basis for making decisions regarding model validity. Second, in naive comparisons, it is common to ignore or only partially account for uncertainty – e.g., uncertainty in the experimental observations or the model input parameters. Without accounting for these uncertainties, it is not possible to appropriately determine whether the model and data agree. Third, by focusing entirely on the agreement in the observable quantities, such comparisons neglect the intended uses of the model and, in general, cannot on their own determine whether the model is sufficient for the intended purposes.

These drawbacks of straightforward but naive comparisons highlight the two primary difficulties in model validation. First, one must quantitatively measure the agreement between model outputs and experimental observations while accounting for uncertainties in both. This fact is widely recognized, particularly in the statistics community, and there are a number of possible approaches. Second, depending on the intended use of the model, an assessment of the agreement between model outputs and available data is not sufficient for validation. Recognizing the purpose of the model is crucial to designing an appropriate validation approach.

1.1 Measuring Agreement Under Uncertainty

While the intended uses of a model will be important in a complete assessment of the validity of the model for those uses, all validation methods rely in some way on an assessment of whether the model is consistent with some set of observational data. In general, both the observations and the model – either through input parameters, the model structure, or both – are subject to uncertainties that must be accounted for in this comparison. Indeed, if both the model and the experiments are free from any uncertainty, then they can only be consistent if the model perfectly reproduces all the data. To define consistency in the far more common situation where at least some aspect of the model and/or data is uncertain, one must supply mathematical representations of all relevant uncertainties, a quantitative method for comparing uncertain quantities using the chosen representations of uncertainty, and a tolerance defining how closely model and data must “agree” to be declared consistent.

A wide range of formalisms have been proposed to represent uncertainty [8, 10, 12, 21, 28, 34], and there is still considerable controversy in the literature regarding the most appropriate approach, especially for so-called “epistemic” uncertainty (see below). This work focuses on the Bayesian interpretation of probability, where probability provides a representation of the degree of plausibility of a proposition, to represent all uncertainties [21, 35]. This choice is popular and has many advantages, including a well-defined method for updating probabilistic models to incorporate new data (Bayes’ theorem) and an extensive and rapidly growing set of available algorithms for both forward and inverse UQ [1, 9, 23, 24, 27, 31]. While a full discussion of the controversy over uncertainty representations is beyond the scope of this article, for the purposes of model validation, most uncertainty representations that have been proposed are either overly simplistic (e.g., using

only intervals to represent uncertainty) or reduce to probability in special cases (e.g., mixed interval/probability methods [11] or Dempster-Shafer theory [33, 34]). Thus, independent of the noted controversy regarding uncertainty representations, a method for assessing consistency between model outputs and data, where both are represented using probability, is required.

One subtlety that arises in a validation assessment is that there are two types of uncertainty that may occur in a complex physical system. First is uncontrolled variabilities in the system, which, in the context of a validation test, result in observations that differ with repetition of the test. Such uncertainties are called aleatoric (from Latin *alea* for dice game). Probabilistic representations of aleatoric uncertainties describe frequencies of occurrence. The second form of uncertainty arises from incomplete knowledge of the system, which in the context of a validation test results in no variability in the observation with repetition of the test. Such uncertainties are called epistemic and can be represented using the Bayesian interpretation of probability. In this case, probability describes the plausibility of outcomes [8, 21, 35]. Because the interpretation of probability is different for aleatoric and epistemic uncertainties, they will need to be distinguished when formulating validation criteria (see Sect. 2.2.2).

Note that what is considered epistemic or aleatoric depends on the details of the problem. In some validation scenarios, a parameter or input could be constrained to be the same on repeated observations, while in another scenario, it is uncontrolled. A simple example is a mechanical part which has uncertainties in geometry due to manufacturing variability. In a validation scenario in which the same part is used in repeated observations, this uncertainty is epistemic. But, in a scenario in which repeated observations are made each with a different part, the uncertainty is aleatoric.

Given the choice of probability to represent uncertainty, it is natural to define consistency in terms of the plausibility of the observations arising from the probabilistic model of the experiment, which represents uncertainties in both physical model and the observation process. Of course, there are still many ways to define a “plausible outcome.” Here, the plausibility of the data as an outcome of the model is defined using highest posterior density credibility sets and tail probabilities of the observable or relevant test quantities. These ideas are described in more detail in Sect. 2.

1.2 Different Uses of Models

Computational models are used for many different purposes. In science and engineering, these different purposes can be split into three broad categories: (1) investigation of the consequences of theories, (2) analysis of experimental data, and (3) prediction.

Scientific theories often lead to models that are sufficiently complex that computations are required to evaluate whether the theory is consistent with reality. When computation is used in this way, the computational model will be an expression of

the theory in a scenario in which experimental data will be available. In addition to the theory being tested, the computational model may include representations (models) of, for example, the experimental facility and the diagnostic instruments. These auxiliary models should be endowed with uncertainties as appropriate. The validation question is then a simple one: given the uncertainties in the auxiliary models and the experimental data, is the data consistent with the computational model? This can be assessed using the techniques discussed in Sect. 2. If an inconsistency is detected, then either the theory being tested or one or more of the auxiliary models is invalid. Assuming the auxiliary models have been sufficiently tested so that their reliability is not in doubt, the theory being tested must be rejected. Alternatively, a lack of detectable inconsistency implies only that the analysis has failed to invalidate the theory.

Models are also used to analyze data obtained from experiments. In particular, it is often the case that the quantity one wishes to measure, e.g., the flow velocity at a point in a wind tunnel experiment, is not directly observable. Instead, one measures a different quantity, e.g., a voltage in a hot wire anemometer circuit, which is related to the quantity of interest (QoI) through a model. As when investigating the consequences of a theory, any detectable inconsistency between the model output and a reliable reference for the quantity being inferred – to be clear, this reliable reference must be from an independent source, such as a different instrument in a calibration experiment – cause the model to be invalid for data analysis purposes. However, a lack of detectable inconsistency does not imply that the model is valid for data analysis. One must also ensure that the intended data analysis does not require the model to extrapolate beyond the range of independent reference data. This extra step is necessary because once the model is used in an extrapolatory mode, it is being used to make predictions, which requires substantially more validation effort, as discussed below.

The most difficult validation situation is when one wishes to use the model to make predictions. To understand this difficulty, it is necessary to be precise about what it means to make a prediction. A prediction is a model-based computation of a specific QoI for which there is no observational data, for instance, because the quantity cannot be measured, because the scenario of interest cannot be produced in the laboratory, or because the system being modeled has not yet been built. Indeed, the prediction is necessary precisely because the QoI is not experimentally observable at the time the information is required, e.g., to inform a decision-making process. Thus, prediction implies extrapolation.

It is well known that a model may be adequate for computing one quantity while not another or in one region of the scenario space and not another. Thus, when extrapolation is involved, it is insufficient to simply compare the model against data to determine consistency. This consistency is necessary but not sufficient because it does not account for the fact that the prediction quantity and scenario are different from the observed quantities and scenarios. Thus, a key challenge in model validation for prediction is in determining the implications of the agreement or disagreement between the model output and the validation data on the accuracy and reliability of the desired prediction. For example, one important question is,

given some observed discrepancy between the model and data, is the model likely to produce predictions of the QoI with unacceptably large error?

While this type of question has generally been left to expert judgment [2, 4], a recently proposed predictive validation process aims to systematically and quantitatively address such issues [30]. The process involves developing stochastic models to represent uncertainty in both the physical model and validation data, allowing rigorous assessment of the agreement between the model and data under uncertainty, as discussed in Sect. 2. Further, these stochastic models, coupled with the common structure of physics-based models, allow one to pose a much richer set of validation questions and assessments to determine whether extrapolation with the model to the prediction is supported by the available data and other knowledge. This predictive validation process will be discussed further in Sect. 3.

2 Comparing Model Outputs and Data in the Presence of Uncertainty

Appropriate validation processes for mathematical models of physical systems depend on the purpose of the model, as discussed in Sect. 1. But, regardless of this purpose, the process will rely on the comparison of outputs of the mathematical models with observations of physical systems to which the model can be applied. Such comparisons are complicated by the presence of uncertainties in both the mathematical model and the observations. In the presence of uncertainty, the relatively straightforward question of whether a model and observations “agree” becomes a more subtle question of whether a model with all its uncertainties is consistent with the observations and all their uncertainties. This section discusses sources of uncertainty in validation tests (Sect. 2.1) and techniques for making comparisons in the presence of uncertainty (Sect. 2.2). Section 2.3 gives some general guidance on selecting validation data.

2.1 Sources of Uncertainty in Validation Tests

To analyze the sources of uncertainty in validation tests, it is helpful to introduce an abstract structure for such a test. Consider a mathematical model \mathcal{U} of some physical phenomenon, which is a mapping from some set of input quantities x to output quantities u (in general, a model for a quantity will be indicated by a calligraphic upper case symbol). The model will in general involve a set of model parameters α_u , which had to be calibrated using data from observations of the phenomenon. The α_u are generally uncertain. In addition, in some situations, the model may be known to be imperfect, so that there is an error ε_u . Therefore,

$$u = \mathcal{U}(x; \alpha_u) + \varepsilon_u, \quad (5.1)$$

where the error is represented here as additive, though other choices are possible. The error ε_u is imperfectly known and may be represented by an “inadequacy model” $\mathcal{E}_u(x; \beta_u)$ [30], with inadequacy model parameters β_u that are also calibrated and uncertain.

Observations of the phenomenon modeled by \mathcal{U} are generally made in the context of some larger system. This larger system has observable quantities v , which will be the basis of the validation test. The validation system must also be modeled with a model \mathcal{V} that is a mapping from a set of inputs y and the modeled quantities u to the observables v . The dependence on u is necessary since the system involves the phenomenon being modeled by \mathcal{U} . The model \mathcal{V} will in general involve model parameters α_v , which are uncertain, and \mathcal{V} may itself be imperfect with error ε_v , which is modeled as \mathcal{E}_v with parameters β_v . Thus, a preliminary representation of the validation system is given by

$$v = \mathcal{V}(u, y; \alpha_v) + \mathcal{E}_v(u, y; \beta_v) = \tilde{\mathcal{V}}(u, y; \alpha_v, \beta_v), \quad (5.2)$$

where $\tilde{\mathcal{V}}$ is the validation system model enriched with the inadequacy model \mathcal{E}_v .

To complete the validation model, u in (5.2) is expressed in terms of the model \mathcal{U} , which means that the inputs x to \mathcal{U} must be determined from the inputs y to \mathcal{V} using a third model \mathcal{X} with parameters α_x , which may also be imperfect, introducing uncertain errors ε_x , modeled as \mathcal{E}_x with parameters β_x , yielding

$$x = \mathcal{X}(y; \alpha_x) + \mathcal{E}_x(y; \beta_x) = \tilde{\mathcal{X}}(y; \alpha_x, \beta_x). \quad (5.3)$$

Because the model \mathcal{U} of the phenomenon is introduced into a larger model of the validation system, it is called an “embedded model” [30].

Finally, errors δ_v are introduced in the physical observations of v themselves, commonly identified as observation or instrument error. The complete model of the validation test is then

$$v = \tilde{\mathcal{V}}[\mathcal{U}(\tilde{\mathcal{X}}(y; \alpha_x, \beta_x), \alpha_u) + \mathcal{E}_u(\tilde{\mathcal{X}}(y; \alpha_x, \beta_x)), y; \alpha_v, \beta_v] + \delta_v. \quad (5.4)$$

Here, the \mathcal{E}_u term is retained explicitly to emphasize that the validation test is directed at the physical model \mathcal{U} and the associated inadequacy model \mathcal{E}_u , if any. In this model of the validation test, there are four types of uncertainties: uncertainties in the model parameters ($\alpha_x, \alpha_u, \alpha_v, \beta_x, \beta_u$, and β_v); uncertainties in the validation inputs y ; uncertainties due to the model errors (\mathcal{E}_u , \mathcal{E}_x , and \mathcal{E}_v); and finally uncertainties due to the observation or instrument errors (δ_v). Note that in some cases, it may be convenient to include the response of the measuring instrument(s) in the validation system model \mathcal{V} . In this case, the instrument errors are included in ε_v .

Clearly, the design of an experimental observation will seek to minimize the uncertainties not directly related to the model being studied (i.e., other than the uncertainties in α_u and \mathcal{E}_u). Furthermore, in the event that the model of the validation (5.4) is found to be inconsistent with observations of v , all that can be said

is that at least one of the models involved ($\mathcal{U} + \mathcal{E}_u$, $\tilde{\mathcal{V}}$, $\tilde{\mathcal{X}}$ and/or the representation of the observation error) or some input to one of these models is inconsistent with reality. For such a validation to meaningfully test the model \mathcal{U} of the phenomenon of interest, the validation problem should, if possible, be designed so that auxiliary models \mathcal{V} and \mathcal{X} are much more reliable than \mathcal{U} . In this way, any inconsistency between model and observation will strongly implicate the model \mathcal{U} that is being tested.

This abstract structure of a validation test might be better understood through reference to a relatively simple example. Let \mathcal{U} be a simple homogeneous linear elastic constitutive model for the stress-strain relationship in some solid part, with u being the stress tensor field and x the strain tensor field. The parameters α_u are the Lamé constants or equivalently the Young's modulus and the Poisson ratio for the material. No inadequacy model is included. A validation test might be conducted by placing the part in a testing machine, which applies a specified overall load force through a fixture in which the part is mounted. The observed quantities v could be the displacement of one or more points on the part, and δ_v would represent the error in determining this displacement experimentally.

The validation system model \mathcal{V} would include an equilibrium continuum equation for the part and possibly the fixture, a model for the connection between the part and the fixture, and a representation of the load characteristics of the testing machine. Parameters α_v might include those describing the material of the fixture, the connection between part and fixture, and the testing machine. The inputs y could include the applied load, the geometry of the part, the load configuration, and other settings of the testing machine. The error ε_v might account for uncontrolled non-idealities in the way the part is mounted in the fixture or in the testing machine. Finally, as a consequence of determining the displacement of points on the part using a continuum representation, the displacement everywhere would be determined. The model \mathcal{X} would then include the mapping from the displacement field in the continuum model used in \mathcal{V} to the strain field, which would not introduce any additional modeling errors ε_x because it is a simple kinematic definition .

The validation system model (5.4) defines the expected relation between the generally uncertain inputs y and observations v . This model includes uncertainties due to the model parameters (the α 's), the modeling errors (the ε 's), and the observation or instrument errors (δ). With a mathematical characterization of these uncertainties, (5.4) makes an uncertain claim as to the values of the observed quantities. The validation test is then to make observations \hat{v} of the physical system and determine whether the \hat{v} are consistent with the uncertain claims regarding v . Assessing this consistency is the subject of the following section.

2.2 Assessing Consistency of Models and Data

From the above discussion, it is clear that a mathematical representation of the many uncertainties in the validation system is needed. A number of such uncertainty representations have been proposed, and as discussed in Sect. 1, many of the issues

surrounding validation under uncertainty are not unique to any particular uncertainty representation. However, in the current discussion of how one actually makes an assessment of the consistency of models and observation in the presence of uncertainty, it will be helpful to consider a particular uncertainty representation: Bayesian probability. This representation is used here for the reasons discussed in Sect. 1.

Since, for the purposes of this work, uncertainty is represented using Bayesian probability, the question of consistency of the model with data falls in the domain of Bayesian model checking. There is a rich literature on this subject, which, for brevity, cannot be discussed extensively here. Instead, a broadly applicable approach to model checking, which is generally consistent with common notions of validation for models of physical systems, is described. The ideas outlined are most closely aligned with those of Andrew Gelman and collaborators [14–18], and the reader is directed to these references for a more detailed statistical perspective. In particular, see [16] for a broad perspective on the meaning and practice of Bayesian model checking.

2.2.1 Single Observation of a Single Observable

The simplest case to consider is that of a validation test with a single observable v , which is taken here to be a real-valued continuous random variable. When uncertainties are represented using Bayesian probability, the validation system model (5.4) yields a probability density $p(v)$ for v . If a single measurement of v is made, yielding a value \hat{v} , the question is then whether the model expressed as the probability density $p(v)$ is consistent with the observation \hat{v} . A straightforward way to assess this consistency is to plot the distribution $p(v)$, as in Fig. 5.1. Indeed graphical representations of model and data are often very informative. It is clear in this figure that if the observation is $\hat{v} = v_i$ for $i = 1, 2$, or 3 , then the observation is consistent with the model because these points fall within the significant probability mass of the distribution. On the other hand, if $\hat{v} = v_i$ for $i = 4$ or 5 , it is clear that the model is inconsistent with the observation. In making these assessments, one asks how likely it is for the observed valued \hat{v} to arise as a sample from a random variable with distribution $p(v)$, and for the values v_i for $i = 1, \dots, 5$, the answer to this question is clear. If, however, $\hat{v} = v_6$, the answer is not obvious, and for these marginal cases, some criterion would be needed to decide whether model and data are consistent. More usefully, a continuum of levels of consistency may be admitted, and one may ask for a measure of the (in)consistency between the model and data.

This is a general issue in statistical analysis. A common approach is to consider the probability of obtaining an observation more extreme than the observation in hand. That is, one can compute the “tail probability” $P_>$ as

$$P_> = P(v > \hat{v}) = \int_{\hat{v}}^{\infty} p(v) dv \quad (5.5)$$

which is the probability, according to the model, of an observation being greater than \hat{v} ($P_<$ is defined analogously). This is the well-known (Bayesian) p -value, and

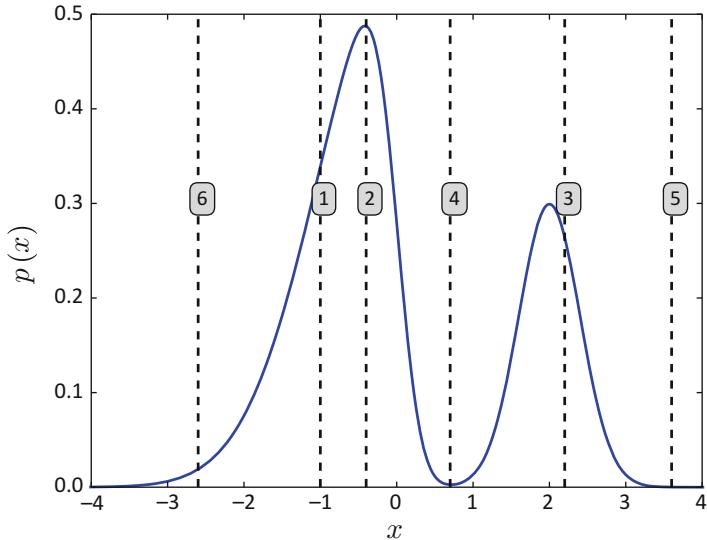

Fig. 5.1 Hypothetical model output distribution and a number of possible observations illustrating observations that are clearly consistent with the output distribution ($i = 1, 2, 3$), observations that are clearly inconsistent ($i = 4, 5$), and observations where the agreement is marginal ($i = 6$)

if it is sufficiently small (e.g., 0.05 or 0.01), one could conclude that \hat{v} is an unlikely outcome of the model, so that the validity of the model is suspect. This leads to the concept of a credibility interval, an interval in which, according to the model, it is highly probable (e.g., probability of 0.95 or 0.99) that an observation will fall. Given a probability distribution $p(v)$, there are many possible credibility intervals, or more generally credibility sets, with a given probability. One could, for example, choose a credibility interval centered on the mean of the distribution or one defined so that the probability of obtaining an observation greater than the upper bound of the interval is equal to that of an observation less than the lower bound. Either of these credibility intervals has the disturbing property of including the point v_4 in Fig. 5.1, which is clearly not a likely draw from the distribution plotted.

A credibility region that is more consistent with an intuitive understanding of credible observations for skewed and/or multimodal distributions such as that shown in Fig. 5.1 is the highest posterior density (HPD) credibility region [7]. The β -HPD ($0 \leq \beta \leq 1$) credible region S is the set for which the probability of belonging to S is β and the probability density for each point in S is greater than that of points outside S . Thus, for a multimodal distribution like that shown in Fig. 5.1, an HPD region may consist of multiple disjoint intervals [20] around the peaks, leaving out the low probability density regions between the peaks.

However, because HPD credibility sets are defined in terms of the probability density, they are not invariant to a change of variables. This is particularly undesirable when formulating a validation metric because it means that one's

conclusions about model validity would depend on the arbitrary choice of variables (e.g., whether one considers the observable to be the frequency or the period of an oscillation). To avoid this problem, a modification of the HPD set is introduced in which the credible set is defined in terms of the probability density relative to a specified distribution q [30]. An appropriate definition of q would be one that represents no information about v [21]. Using this definition of the highest posterior *relative density* (HPRD), a conceptually attractive credibility metric can be defined as $\gamma = 1 - \beta_{\min}$, where β_{\min} is the smallest value of β for which the observation \hat{v} is in the HPRD-credibility set for v according to the model. That is,

$$\gamma = 1 - \int_S p(v) d v, \quad \text{where } S = \left\{ v : \frac{p(v)}{q(v)} \geq \frac{p(\hat{v})}{q(\hat{v})} \right\}. \quad (5.6)$$

When γ is smaller than some tolerance, say less than 0.05 or 0.01, \hat{v} is considered an implausible outcome of the model – i.e., there is an inconsistency between the model and the observation.

2.2.2 Multiple Observations of a Single Observable

Of course, it is common to make multiple measurements of the observable v , especially if the measurement is noisy. Consider the case where the observational uncertainties represented in the model – which lead to the appearance of δ_v in (5.4) – are purely aleatoric and independent for each observation. Further, assume for the purposes of this discussion that any epistemic uncertainties in the model are negligible. In this case, the model implies that each observation is an independent sample of the distribution $p(v)$, and the validation question is whether a set of N observations \hat{v}_i for $i = 1, 2 \dots N$ is consistent with sampling from $p(v)$. It is clearly erroneous to check whether each individual observation is in a given credibility region, as the probability of at least one sample falling outside the credibility region will increase to 1 as N increases, even if the samples are in fact drawn according to the model distribution $p(v)$. A number of correction methods for this effect have been developed in the statistics literature [19, 25].

More generally, one must determine whether a given vector of observational values $\hat{V} = (\hat{v}_1, \dots, \hat{v}_N)$ is unlikely to have arisen as instances of random variables, in this case iid random variables with distribution $p(v)$, which is a common problem in statistical hypothesis testing. An obvious extension to the HPRD regions described above can be defined in terms of the joint distribution $p(V)$ of the vector of N iid random variables $V = (v_1, \dots, v_N)$, which because of independence can be written as:

$$p(V) = \prod_{i=1}^N p(v_i). \quad (5.7)$$

The HPRD-credibility metric can then be written as:

$$\gamma = 1 - \int_S p(V) d V, \quad \text{where } S = \left\{ V : \frac{p(V)}{q(V)} \geq \frac{p(\hat{V})}{q(\hat{V})} \right\}. \quad (5.8)$$

While this directly answers the question of how credible the observations are as samples from the model distribution, it is generally difficult to compute when N is large since it involves evaluating a high-dimensional integral over a complex region. An alternative approach is to consider one or more test quantities [17, 18]. A test quantity $T(V)$ is a mapping from an N -vector to a scalar. When evaluated for a random vector, it is a random scalar, which is designed to summarize some important feature of V . The idea then is to ask whether $T(\hat{V})$ is a plausible sample from the distribution of $T(V)$. One could, for example, compute p -values for this comparison. The HPRD metric could also be used, but $p(T(V))$ which is part of its definition is usually difficult to compute.

In addition to being potentially more tractable, the use of test statistics has another advantage. With rare exceptions, the uncertainty representations leading to the stochastic model being validated are based on crude and/or convenient assumptions about the uncertainties. Indeed, iid Gaussian random variables are often used to model experimental noise, and while this is sometimes justified, it is often assumed purely out of convenience. Thus, one does not necessarily expect, nor is it generally required, for the model distribution $p(v)$ to be representative of the random processes that led to the variability in \hat{v} from observation to observation. In this case, it is necessary only that the uncertainty representations will characterize what is important about the uncertainty for the purposes for which the model is to be used. While the HPRD metric given in (5.8) does not take this into account, validating using test quantities gives one the opportunity to choose T to characterize an important aspect of the uncertainty. For example, if the model is to be used to evaluate extreme deviations from nominal behavior or conditions, then it might make sense to perform validation comparisons based on the test quantity $T(V) = \max_i v_i$. A few example test quantities are discussed in the next subsection.

Finally, the assumption of negligible epistemic uncertainty, while useful in simplifying this discussion, is not generally applicable. This assumption can be removed by marginalizing over the epistemic uncertainties represented in the model, as described in Sect. 2.2.4.

2.2.3 Defining Test Quantities

To select validation test quantities, one should consider what characteristics of the aleatoric uncertainty are important in the context of the model and its planned use. One common consideration is that the mean and variance should be consistent with observations. A straightforward test quantity is simply the sample average $A(V)$, that is,

$$A(V) = \frac{1}{N} \sum_{i=1}^N v_i \quad (5.9)$$

The validation comparison then reduces to asking whether the distribution of $p(A(V))$ implied by the model is consistent with the observation $A(\hat{V})$. Since the v_i determined from the model are iid, if N is sufficiently large, the central limit

theorem implies that $A(V)$ is approximately $\mathcal{N}(\mu, \sigma^2/N)$, where μ and σ^2 are the mean and variance of v . This leads to the Z-test in statistics.

To test whether the variability of v is consistent with the observed variability of \hat{v} , the test quantity

$$X^2(V) = \sum_{i=1}^N \frac{(v_i - \mu)^2}{\sigma^2} \quad (5.10)$$

could be used, which is a χ^2 discrepancy. Note that this test quantity is different because it depends explicitly on characteristics of the model (mean and variance). If in addition to being iid, the v obtained from the model are normally distributed, the model distribution $p(X^2(V))$ will be the χ^2 distribution, with N degrees of freedom.

When the test quantity has a known distribution, as $A(V)$ and $X^2(V)$ discussed above do, it simplifies assessing consistency using, for example, HPRD criteria or p-values. This is so because tail integrals of these distributions are known. However, it is not necessary that exact distributions be known, since the relevant integrals can be approximated using Monte Carlo or other uncertainty propagation algorithms.

For example, in some problems, one is concerned with improbable events with large consequences. In this case, one is interested in the tail of the distribution of v and the extreme values that v may take. A simple test quantity that is sensitive to this aspect of the distribution of v is the maximum attained value. That is,

$$M(V) = \max_i v_i \quad (5.11)$$

The random variable $M(V)$ that is implied by the model can be sampled by simply generating N samples of v and determining the maximum. Thus the p-value relative to the observation $M(\hat{Z})$ can be computed by Monte Carlo simulation.

There is a large literature on statistical test quantities (cf. [22]) for use in a wide variety of applications. Texts on statistics should be consulted for more details. Among commonly used statistical tests are those which test whether a population is consistent with a distribution with known characteristics (e.g., the mean and/or variance) as with the average and χ^2 test quantities discussed above. These are also useful when the model can be used to compute these characteristics with much higher statistical accuracy than they can be estimated from the data (e.g., one can generate many more samples from the model than there are data samples). In other situations, the model may be expensive to validate, so that the number of samples of the posterior distribution of the model is limited. In this case, test quantities that test whether two populations are drawn from distributions with the same characteristics are useful. A simple example is the two sample t-test (Welch's test), which is used to test whether two populations have the same mean.

2.2.4 General Posterior Model Checks

The discussion in Sects. 2.2.1 and 2.2.2 is instructive but does not apply to the usual situation. In particular, it is common to have multiple observations of

multiple different quantities, the predictions of which are affected by both epistemic and aleatoric uncertainties. This section generalizes the validation comparisons discussed previously to this more complicated situation.

Consider the model of the observable expressed in (5.4). This model includes uncertain parameters, the α 's and β 's; representations of modeling errors, ε_u , ε_x , and ε_v ; and the representation of the observation errors δ_v . Generally, the uncertainties in the parameters are considered to be epistemic, that is, there are ideal values of these parameters, which are imperfectly known. Their values do not change from observation to observation in the same system. The observation error δ_v is often considered to be aleatoric, for example, from instrument noise. However, there may also be systematic errors in the measurements, which are imperfectly known and thus epistemically uncertain. Similarly, depending on the nature of the phenomena involved and how they are modeled, the errors ε_u , ε_x , and ε_v in the models \mathcal{U} , \mathcal{X} , and \mathcal{V} may be epistemic, aleatoric, or a mixture of the two. The models for these uncertainties could then include an epistemic part and an aleatoric part, that is,

$$\varepsilon_x \approx \mathcal{E}_x^e + \mathcal{E}_x^a, \quad \delta_v \approx \mathcal{D}_v^e + \mathcal{D}_v^a, \quad (5.12)$$

where superscript e and a are for epistemic and aleatoric, respectively. One challenge is then to compare the model and possibly repeated observations under these mixed uncertainties.

In addition to multiple observations, there may be multiple observables. These observables may be of the same quantity (e.g., the temperature) for different values of the model inputs y (e.g., at different points in space or time) or of different quantities (e.g., the temperature and the pressure). The observable v should thus be considered to be a vector of observables of dimension n . In general, the aleatoric uncertainties in the various observables will be correlated. In the model, these correlations will arise both from the way the aleatoric inadequacy uncertainties impact the observables through the model and from correlations inherent in the dependencies of the aleatoric uncertainties (the \mathcal{E}^a 's and \mathcal{D}_v^a) on model inputs. Due to the presence of aleatoric uncertainties, a validation test may make multiple (N) observations \hat{v} of the observable vector v , resulting in a set of observations $\hat{V} = \{\hat{v}_1, \dots, \hat{v}_N\}$, which are taken to be independent and identically distributed (iid) here.

To facilitate further discussion, let us consolidate the epistemic uncertainties (including those associated with \mathcal{E}_u^e , \mathcal{E}_x^e , \mathcal{E}_v^e and \mathcal{D}_v^e) into a vector θ , which may be infinite dimensional. The validation model for the observables (5.4) can then be considered to be a statistical model \mathcal{S} for the aleatorically uncertain v , which depends on the epistemically uncertain θ , that is, $v = \mathcal{S}(\theta)$. The validation question is then whether the set of observations \hat{V} is consistent with \mathcal{S} , given what is known about θ .

If θ is known precisely (i.e., no epistemic uncertainty), then the situation is similar to that discussed in Sect. 2.2.2. For a given θ , the model \mathcal{S} defines a probability distribution $p(v|\theta)$ in the n -dimensional space of observables. The observables are not independent, so this is not a simple product of one-dimensional distributions, but this introduces no conceptual difficulties. A set of N observations

then defines a probability space of dimension nN . Because the observations are iid, the probability distribution is written:

$$p(V|\mathcal{S}, \theta) = \prod_{i=1}^N p(v_i|\mathcal{S}, \theta). \quad (5.13)$$

Here, the probability density is conditional on the model \mathcal{S} because these are the distributions of outputs v implied by the model. Consistency of \hat{V} with \mathcal{S} can then in principle be determined through something like the HPRD-credibility metric (5.6). However, as discussed in Sect. 2.2.2, this is generally not computationally tractable, nor is it generally desirable. Alternatively, one or more test quantities T may be defined to characterize what is important about the aleatoric variation of v , and as discussed in Sect. 2.2.2, the consistency between the observed $T(\hat{V})$ and the distribution obtained from the model $p(T(V)|\mathcal{S}, \theta)$ can be tested. For example, one could use the p-value $P_>$, which now depends on θ .

When the parameters θ are uncertain, with uncertainty that is entirely epistemic by construction, the validation question is whether the observed value of the test quantity $T(\hat{V})$ is plausible for plausible values of θ . In validation, it is presumed that the parameters in the models (the α 's and β 's in (5.4)) have been calibrated (e.g., via Bayesian inference) and that the epistemic uncertainties are now expressed as probability distributions $p(\theta|\mathcal{S}, \hat{w})$, where \hat{w} represents the data for the observables w used to calibrate the parameters. This calibration data may or may not be included in the validation data \hat{v} . In Bayesian inference, this is the posterior distribution, and so the relevant distribution of $T(V)$ or $P_>$ is that induced by the posterior distribution of θ .

As suggested by Box [6], Rubin [32], and Gelman et al. [17], in this situation, the consistency of the observations \hat{V} with the model can be determined by considering the distribution of $T(V)$ implied by the distribution of θ :

$$p(T(V)|\mathcal{S}, \hat{w}) = \int_{\theta} p(T(V)|\mathcal{S}, \theta) p(\theta|\mathcal{S}, \hat{w}) d\theta. \quad (5.14)$$

This is termed the posterior predictive distribution by Gelman *et al* in [17], though they were referring to the case in which \hat{w} is the same as \hat{v} . It then can be determined whether the observed value $T(\hat{V})$ of the test quantity is consistent with the distribution $p(T(V)|w)$, using, for example, p-values:

$$P_> = \int_{\theta} P(T(V) > T(\hat{V})|\mathcal{S}, \theta) p(\theta|\mathcal{S}, \hat{w}) d\theta. \quad (5.15)$$

2.3 Data for Validation

Of course, to perform a validation comparison, it is necessary to have data to which to compare. The question is, what should this data be? Logically, it is required that for a model to be valid, it must be consistent with all available relevant observational

data. While true, this does not provide useful guidance for designing experimental observations for the purpose of validation. Selecting appropriate validation data requires consideration of several problem-specific issues, so it is difficult to specify generally applicable techniques for designing validation tests. Instead, a list of broad guidelines for designing validation experiments is provided.

1. Often, the first point at which models are confronted with data is when they are calibrated. As part of the calibration process, the calibrated model should also be validated against the calibration data. Because the model has been calibrated to fit the calibration data, consistency with the data will not greatly increase confidence in the model. But if the model is inconsistent with the data with which it has been calibrated, it is a very strong indictment of the model. With parsimonious models, which describe a rich phenomenon with few parameters, failure to reproduce the calibration data is a common mode of validation failure.
2. To increase confidence in the validity of a model, it should be tested against data that was not used in its calibration. Sometimes this is done by holding back some portion of the calibration data set so that it can be used only for validation, which leads to cross-validation techniques [3]. This is generally of limited utility for physics-based models. A much stronger validation test is to use a completely different data set, from experiments with different validation models \mathcal{V} in (5.4). For example, calibration of a model might be done using a set of relatively simple experiments in a laboratory facility, while validation experiments are in more complex scenarios in completely different facilities.
3. The development of computational models often involves various approximations and assumptions. To increase confidence in the models, one should design validation experiments that test these approximations, that is, experiments and measurements should be designed so that the observed quantities are expected to be sensitive to any errors introduced by the approximation. Sensitivity analysis applied to the model can help identify such experiments. Furthermore, test quantities used in validation assessment should also be designed to be sensitive to the approximations being tested.
4. Models of complex physical systems commonly involve sub-models (embedded models) of several physical phenomena that are of questionable reliability. When possible, the individual embedded models should be calibrated and validated separately, using experiments that are designed to probe the modeled phenomena individually. The resulting experiments will generally be much simpler, less expensive, easier to instrument, and easier to simulate than the complete system. This simplicity could allow many more experiments and more measurements to be used for calibration and/or validation. When possible, further experiments simultaneously involving a few of the relevant phenomena should be performed to validate models in combination. Experiments of increasing complexity and involving more phenomena can then be pursued, until measurements in systems similar in complexity to the target system are performed. This structure has been described as a “validation pyramid” [5], with abundant simple inexpensive,

data-rich experiments at the bottom and increasingly expensive and limited experiments as one goes up the pyramid.

The role of the experiments higher in the validation pyramid is generally different from those lower down. The lower level experiments are designed to calibrate models and validate that the models provide a quantitatively accurate representation of the modeled phenomena. Experiments higher in the pyramid are intended to test the modeling of the interactions of different phenomena. Finally, measurements in systems as similar as possible to the target system, at conditions as close as possible to the conditions of interest, are used to detect whether there are unexpected phenomena or interactions that may affect predictions in the target system.

5. As discussed in Sect. 3, when a computational model is used for predictions of unobserved QoIs, the reliability of the predictions depends on the embedded models being used in conditions that have been well tested, with validation observations that are sensitive to errors in the model in the same way as the prediction QoIs. Validation tests should therefore be designed to challenge embedded models as they will be challenged in the prediction scenarios. The conditions that the embedded model experiences during predictions can be evaluated through model simulations of the prediction scenario, and sensitivities of the QoIs to an embedded model can be determined through sensitivity analysis conducted in the system model.

3 Validating Models for Prediction

As mentioned in Sect. 1, when a physical model is being used to make predictions, a detectable inconsistency between the model output and experimental data is not, on its own, sufficient to invalidate the model for use in the prediction. Indeed, it is common in engineering to use models which are known to be inconsistent with some relevant data but which are sufficient for the predictions for which they are to be used. In this situation, the important validation question is not whether the model is scientifically valid – often it is known *a priori* that it is not – but rather whether a prediction made with the model is reliable. This is generally a much more difficult question since it is essentially asking whether an extrapolation from available information will be reliable. Recently, a process for addressing this question in the context of physics-based mathematical models was developed [30]. This section will outline the components of this process.

3.1 Mathematical Structure for Prediction

An abstract structure of a validation test is defined in Sect. 2.1. Here, this mathematical structure is extended to include features common in models of physical systems. To fix the main ideas, this structure is presented first in the simplest possible context (Sect. 3.1.1), with a more general abstraction outlined briefly in Sect. 3.1.2.

3.1.1 Simplest Case

Mathematical models of the response of physical systems are generally based in part, indeed to the greatest extent possible, on physical theories that are known a priori to be reliable in the context of the desired prediction. The mathematical expression of these theories is a reliable, but incomplete, model of the system, which can be written as:

$$\mathcal{R}(u, \tau; r) = 0, \quad (5.16)$$

where \mathcal{R} is an operator expressing the reliable theory, u is the state, r is a set of variables that defines the problem scenario, and τ is an additional quantity that must be known to solve the system of equations. For instance, in fluid mechanics, \mathcal{R} could be a nonlinear differential operator expressing conservation of mass, momentum, and energy with u including the fluid density, velocity, and temperature fields. In this case, τ would include the pressure, viscous stresses, and heat flux, and r would include parameters like the Reynolds and Mach numbers as well as details of the flow geometry and boundary conditions.

This structure in which the model is based at least in part on reliable theory is common in physics-based models. The foundation on theory whose validity is not in question will be important for making predictions. However, the reliable theory on its own rarely forms a closed system of equations, which is represented in (5.16) by τ . If τ could be determined from u and r using a model as reliable as \mathcal{R} itself, then the combination of (5.16) with this high-fidelity model for τ would form a closed system of equations, and solutions of this system would be known to be reliable.

In general, such models – i.e., models that are both closed and known a priori to be highly reliable – are not available in the context of complex prediction problems. Instead the quantity τ must be represented using a lower-fidelity model or a model whose reliability is not known a priori. In this case, the model for τ , denoted \mathcal{T} , is referred to as an embedded model:

$$\tau = \mathcal{T}(u; s, \theta), \quad (5.17)$$

where s is a set of scenario parameters, possibly distinct from r , for the embedded model, and θ is a set of calibration or tuning parameters. Since the embedded model \mathcal{T} is not known a priori to be reliable for the desired prediction, it will be the focus of the validation process.

The system of equations consisting of (5.16) and (5.17) is closed, but for calibration, validation, and prediction, some additional relationships are necessary. In particular, expressions for the experimental observables v and the prediction QoIs q are required. Here, it is assumed that there are maps \mathcal{V} and \mathcal{Q} that determine v and q , respectively, from the model state u , the modeled quantity τ , and the global scenario r :

$$v = \mathcal{V}(u, \tau; r), \quad (5.18)$$

$$q = \mathcal{Q}(u, \tau; r). \quad (5.19)$$

This closed set of Eqs. (5.16), (5.17), (5.18), and (5.19), which allows calculation of both the experimental observables and predictions QoIs, is referred to as a composite model, since it is a composition of high- and low-fidelity components.

Because the foundation of the composite model is a reliable theory whose validity is not questioned, it is possible for such a model to make reliable predictions despite the fact that a less reliable embedded model is also involved. All that is required is that the less reliable embedded model should not be used outside the range where it has been calibrated and tested. This restriction does not necessarily limit the reliability of the composite model in extrapolation since the relevant scenario space for each embedded model is specific to that embedded model, not the composite model in which it is embedded. For example, an elastic constitutive relation for the deformation of a material can only be relied upon provided the strain remains within the bounds in which it has been calibrated and tested. Despite this restriction, a model for a complex structure made from the material, which is based on conservation of momentum, can reliably predict a wide range of structural responses.

3.1.2 Generalizations

The simple problem statement in Sect. 3.1.1 is sufficient to introduce many of the concepts that are critical in validation for prediction, including the distinction between the QoI and available observable quantities and the notion of an embedded model. However, there are several important generalizations that are required to represent the validation and prediction process in complex physical systems. These are outlined below. A more detailed description can be found in [30].

- **Multiple embedded models:** In a complex system, there will generally be multiple physical phenomena for which an embedded model is needed (e.g., thermodynamic models, chemical kinetics models, and molecular transport embedded models in a composite model of a combustion system). Thus, the composite model will generally depend on N_τ quantities τ_i , each with associated models \mathcal{T}_i , calibration parameters θ_i , and scenario parameters s_i .
- **Multiple reliable models:** The experimental systems in which measurements are made for validation and calibration are commonly different from, usually simpler than, the prediction system. For each of N_e experiments, there will in general be a different reliable model \mathcal{R}^j , with associated state variables u^j , observables v^j , scenario parameters r^j , and set of quantities requiring embedded models $\{\tau\}^j$. There are also, therefore, N_e observation models \mathcal{V}^j and sets of embedded models $\{\mathcal{T}\}^j$. For each experiment, the set of modeled quantities $\{\tau\}^j$ must include at least one member of the set of modeled quantities $\{\tau\}^0$ used in the prediction model, but may include other quantities requiring embedded models that are not relevant to the prediction (e.g., to represent an instrument or the laboratory facility).
- **Differing state variables:** In general, the different reliable models for each experiment \mathcal{R}^j have different state variables u^j . The dependence of an

embedded model \mathcal{T}_k^0 on these different states must be represented. To this end, each embedded model \mathcal{T}_k^0 is formulated to be dependent on an argument w_k that is consistent for the prediction and all experiments. There is then a mapping defined by the operator \mathcal{W}_k^j that maps the state variable u^j to the argument w_k .

With these extensions, a generalized version of the problem statement described in Sect. 3.1.1 can be formulated:

$$\begin{aligned} \mathcal{R}(u, \{\tau\}^0, r) &= 0 \\ q &= \mathcal{Q}(u, \{\tau\}^0, r) \\ \mathcal{R}^j(u^j, \{\tau\}^j, r^j) &= 0 \quad \text{for } 1 \leq j \leq N_e \\ v^j &= \mathcal{V}^j(u^j, \{\tau\}^j, r^j) \quad \text{for } 1 \leq j \leq N_e \end{aligned} \quad (5.20)$$

In this formulation, the embedded models required for the prediction ($j = 0$) and the validation scenarios ($1 \leq j \leq N_e$) are given by

$$\tau_k^j = \mathcal{T}_k^j(\mathcal{W}_k^j(u), \theta_k^j, s_k^j) \quad \text{for } 1 \leq k \leq N_\tau^j \quad (5.21)$$

where N_τ^j is the number of embedded models in scenario j .

Like the simple problem statement from Sect. 3.1.1, in this generalized problem the high-fidelity theory forming the basis of the model can enable reliable predictions, despite the need to extrapolate from available data. However, additional complexity arises from confounding introduced by the presence of multiple embedded models in the validation experiments. To avoid this confounding, one would ideally use experiments where there are no extra embedded models beyond those needed for the prediction or where any such extra embedded models introduce small error or uncertainty in the context of the experiment. Of course, the assessment of any extra embedded models would itself form another validation exercise.

To further avoid confounding uncertainties, it is preferable to use experiments in which only one of the embedded models used in the prediction model is exercised. Such experiments are powerful because they provide the most direct assessment possible of the embedded model in question. However, even if experiments that separately exercise all of the embedded models necessary for prediction are available, in general these experiments alone are not sufficient for validation because they cannot exercise couplings and interactions between the modeled phenomena. This fact leads to the idea of a validation pyramid [5], as discussed in Sect. 2.3.

3.2 Validation for Prediction

A fundamental challenge in the validation of predictions is that even if a model is consistent with all available data, as determined by the techniques discussed in

Sect. 2, this does not imply that the model is valid for making predictions. The reason is that the prediction QoI may be sensitive to some error or omission in the model that the observed quantities are not. To preclude this possibility and gain confidence in the prediction, further assessments of the validation process are needed. These are discussed in Sect. 3.2.2 below.

The opposite situation represents a different fundamental challenge in the validation of predictions. Even if a model is found to be inconsistent with available data, this does not imply that the model is invalid for making the desired predictions. The reason is that the prediction QoI may be insensitive to the error or omission in the model that caused the inconsistency with the observations. To determine whether a prediction can be made despite the errors in the model requires that the impact of the modeling errors on the predicted QoI be quantified. This quantification of uncertainty due to model inadequacy is discussed in Sect. 3.2.1.

3.2.1 Accounting for Model Error

If a discrepancy between a model and observations is detected, it may nonetheless be possible to make a reliable prediction, provided the impact of model error responsible for this discrepancy on the predicted QoI can be quantified. This can be difficult because there is no direct mapping from the observables to the QoIs – i.e., given only v , one cannot directly evaluate q . Referring to the problem statement in Sect. 3.1.1, it is clear that any model error must be due to the embedded model \mathcal{T} , since all the other components of the model (\mathcal{R} , \mathcal{V} , and \mathcal{Q}) are presumed to be reliable. In essence, the embedded model must be enriched to include a representation for the uncertainty introduced by model errors. In the simple case from Sect. 3.1.1, one could write

$$\tau \approx \mathcal{T}(u, s; \theta) + \mathcal{E}_\tau(u, s; \alpha), \quad (5.22)$$

where \mathcal{E}_τ is an uncertainty representation of the model error ε_τ , which may depend on additional parameters α . Given the choice to use probability to represent uncertainty, it is natural that \mathcal{E}_τ is a stochastic model, even when the physical phenomenon being modeled is inherently deterministic. Of course, an additive model is not necessary; other choices are possible. More importantly, the form of \mathcal{E}_τ must be specified. The specification of a stochastic model \mathcal{E}_τ is driven by physical knowledge about the nature of the error as well as practical considerations necessary to make computations with the model tractable. For example, when the enriched model (5.22) is introduced into (5.16) so that it can be solved for u , which is now stochastic, the fact that \mathcal{E}_τ depends on u will in general make this solution difficult. To ameliorate this problem, one can attempt to formulate \mathcal{E}_τ to be independent of u or to define \mathcal{E}_τ through an auxiliary equation of the form $f(u, \mathcal{E}_\tau; z) = 0$, where z is an auxiliary random variable that is independent of u . In this latter case, the auxiliary equation can then be solved together with (5.16). Other practical formulations for introducing u dependence in \mathcal{E}_τ may also be possible. Although general principles for developing physics-based uncertainty models need

to be developed, the specification of such a model is clearly problem-dependent and, thus, will not be discussed further here.

For the current purposes, it is sufficient to observe that the model \mathcal{E}_τ is posed at the source of the structural inadequacy – i.e., in the embedded model for τ . The combination of the physical and uncertainty models forms an enriched composite model, which takes the following form in the general case corresponding to (5.20):

$$\begin{aligned}\mathcal{R}(u, \{\mathcal{T}\}^0 + \{\mathcal{E}_\tau\}^0, r) &= 0 \\ q = \mathcal{Q}(u, \{\mathcal{T}\}^0 + \{\mathcal{E}_\tau\}^0, r) \\ \mathcal{R}^i(u^i, \{\mathcal{T}\}^i + \{\mathcal{E}_\tau\}^i, r^i) &= 0 \quad \text{for } 1 \leq i \leq N_e \\ v^i = \mathcal{V}^i(u^i, \{\mathcal{T}\}^i + \{\mathcal{E}_\tau\}^i, r^i) &\quad \text{for } 1 \leq i \leq N_e\end{aligned}\tag{5.23}$$

The inadequacy models, $\{\mathcal{E}_\tau\}^0$ and $\{\mathcal{E}_\tau\}^i$, appear naturally in the calculation of both the observables and the QoIs, both directly through the possible dependence of \mathcal{V}^i and \mathcal{Q} on embedded models and indirectly via the dependence of the state u on the embedded models appearing in \mathcal{R} . The structural uncertainty can therefore be propagated to both the observables and the QoIs without additional modeling assumptions. Furthermore, one can learn about the inadequacies – i.e., calibrate and test the corresponding models – from data on the observables and then transfer that knowledge to the prediction of the QoIs. This ability enables quantification of the impact of modeling inadequacies on the unobserved QoIs.

Enriching the embedded models with representations of the uncertainty due to model inadequacy is done with the goal of explaining all observed discrepancies between the model and observations. Therefore, with these enrichments included, the validation process discussed in Sect. 2 should reveal no inconsistencies with all relevant data. Once this is confirmed, there is no longer a validation failure, and one may proceed to evaluating whether the validation process is sufficient to warrant confidence in predictions of the QoIs.

3.2.2 Predictive Assessment

Since prediction requires extrapolation from available information, a prediction cannot be validated based on agreement between the predictive model (or some part of it) and data. This agreement alone is only sufficient to determine that the model is capable of predicting the observed quantities in the observed scenarios. To go beyond this, additional knowledge about the model and its relationship to both the validation experiments and the prediction are required. In particular, one must assess whether:

1. The calibration and validation of the embedded models are sufficient to give confidence in the prediction
2. The embedded models are being used within their domain of applicability
3. The resulting prediction with its uncertainties is sufficient for the purpose for which the prediction is being made

These predictive assessments are outlined in the following paragraphs and in more detail in [30].

Adequacy of Calibration and Validation

The fundamental issue in assessing the adequacy of the calibration and validation is whether the available data inform and challenge the model in ways that are relevant to the desired prediction. This assessment is necessarily based, at least in part, on knowledge regarding the physics of the problem. For example, in many domains, arguments based on dimensional analysis can help determine the relevance of an experiment on a scale model to the case of interest. Whenever possible, such information must be used. To augment such traditional analyses, one must consider whether the QoIs are sensitive to some characteristic of an embedded model, or the associated inadequacy model, that has not been adequately informed and tested in the preceding calibration and validation processes. In particular, if the QoIs are sensitive to an aspect of the model to which the data are insensitive, then the prediction depends in some important way on things that have not been constrained by the data. In this case, the prediction can only be credible if there is other reliable information that informs this aspect of the embedded models. To assess this then requires a sensitivity analysis to identify what is important about the embedded models for making the predictions. This sensitivity analysis is necessarily concerned with the sensitivities after calibration, because it is the calibrated model that is to be used for prediction. There are several ways in which the calibration and validation processes might be found to be insufficient. The most relevant examples are described briefly below:

1. Suppose that the prediction QoI is highly sensitive to one of the embedded models \mathcal{T} , as measured, for example, by the Fréchet derivative of the QoI with respect to \mathcal{T} at some representative θ . If none of the validation quantities are sensitive to \mathcal{T} , then the validation process has not provided a test of the validity of \mathcal{T} , and a prediction based on \mathcal{T} would be unreliable. More plausibly, it may be that none of the validation quantities for scenarios higher in the validation pyramid are sensitive to \mathcal{T} . The integration of \mathcal{T} into a composite model similar to that used in the predictions would then not have been tested, which would make its use in the prediction suspect [30]. To guard against this and similar possible failures of \mathcal{T} , the predictive assessment process should determine whether validation quantities in scenarios “close enough” to the prediction scenario are sufficiently sensitive to \mathcal{T} to provide a good test of its use in the prediction. The determination of what is “close enough” and what constitutes sufficient sensitivity must be made based on knowledge of the model and the approximations that went into it and of the way the models are embedded into the composite models of the validation and prediction scenarios.
2. Suppose that the prediction QoI is highly sensitive to the value of a particular parameter θ in an embedded model. In this case, it is important to determine whether the value of this parameter is well constrained by reliable information. If, for example, none of the calibration data has informed the value of θ , then

only other available information (prior information in the Bayesian context) has determined its value. Further, if none of the validation quantities are sensitive to the value of θ , then the validation process has not tested whether the information used to determine θ is in fact valid in the current context. The prediction QoI is then being determined to a significant extent by the untested prior information used to determine θ , which leaves little confidence in the reliability of the prediction, unless the prior information is itself highly reliable (e.g., θ is the speed of light). Alternatively, when the available prior information is questionable (e.g., θ is the reaction rate of a poorly understood chemical reaction), the predictions based on θ will not be reliable.

3. Suppose that uncertainty in the prediction QoI is largely due to the uncertainty model \mathcal{E} representing the inadequacy of the embedded model \mathcal{T} . In this case, it is important to ensure that \mathcal{E} is a valid description of the inadequacy of \mathcal{T} . As with the embedded model sensitivities discussed above, validation tests from high on the validation pyramid are most valuable for assessing whether the uncertainty model represents inadequacy in the context of a composite model similar to that for the prediction. If, however, the available validation data are for quantities that are insensitive to \mathcal{E} , then the veracity of \mathcal{E} in representing the uncertainty in the QoI will be suspect. Reliable predictions will then be possible only if there is independent information that the inadequacy representation is trustworthy.

Domain of Applicability of Embedded Models

In general, it is expected that the embedded models making up the composite model to be used in a prediction will involve various approximations and/or will have been informed by a limited set of calibration data. This will limit the range of scenarios for which the model can be considered reliable, either because the approximations will become invalid or because the model will be used outside the range for which it was calibrated. It is therefore clearly necessary to ensure that the embedded models are being used in a scenario regime in which they are expected to be reliable.

As discussed in Sect. 3.1, reliable extrapolative predictions are possible because the scenario parameters relevant to an embedded model need not be the same as those for the global composite model in which it is embedded. For example, when modeling the structural response of a building, the scenario parameters include the structural configuration and the loads. However, the scenario parameters for the linear elasticity embedded model used for the internal stresses would be the local magnitude of the strain, as well as other local variables such as the temperature. For each embedded model then, one needs to identify the scenario parameters that characterize the applicability of the model and the range of those parameters over which the model and its calibration are expected to be reliable. It is then a simple matter of checking the solution of the composite model to see if any of the embedded models are being used “out of range.” For some embedded models, defining the range of applicability in this way is straightforward. However, for some types of embedded models – e.g., an embedded model that involves an additional equation

that has nonlocal dependence on the state – defining the relevant scenario space and, hence, the region of scenario space that defines the domain of applicability is significantly more difficult.

Sufficiency of the Prediction and Uncertainties

The focus of the previous assessments is on ensuring that the calibration and validation processes have been sufficiently rigorous to warrant confidence in an extrapolative prediction and its uncertainty. However, a prediction with an uncertainty that is too large to inform the decision for which the prediction is being performed is not sufficient, even if that uncertainty has been determined to be a good representation of what can be predicted about the QoI. The requirements for prediction uncertainty to inform a decision based on the prediction depend on the nature of the decision, and determination of this requirement is outside the scope of the current discussion. However, once such a requirement is known, the prediction uncertainties can be checked to determine whether these requirements are met and therefore whether the prediction is useful.

Of course, when the prediction uncertainty fails to meet the established tolerance, some action must be taken to reduce this uncertainty. While a full discussion of this process is beyond the scope of the current discussion, the predictive validation activities previously described provide a wealth of information that can provide guidance as to how to proceed. For example, parameters that have large posterior uncertainty and that are influential to the QoIs are good candidates for further calibration based on new experiments. Alternatively, embedded models for which the associated inadequacy model introduces significant uncertainty are good candidates for new model development.

A Major Caveat

The predictive assessment process can determine whether, given what is known about the system, the calibration and validation processes are sufficient to make a reliable prediction. But the well-known problem of “unknown unknowns” remains. If the system being simulated involves an unrecognized phenomenon, then clearly an embedded model to represent it will not be included in the composite model for the system. As with the examples above, the prediction QoI could be particularly sensitive to this phenomenon, while the validation observables are not sensitive. In this situation, one would not be able to detect that anything is missing from the composite model. Further one could not even identify that the validation observables were insufficient, that is, the predictive assessment could not detect the inadequacy of the validation process. This is a special case of a broader issue. The predictive validation process developed here relies explicitly on reliable knowledge about the system and the models used to represent it. This knowledge is considered to not need independent validation and is thus what allows for extrapolative predictions. However, if this externally supplied information is in fact incorrect, then the predictive validation process may not be able to detect it.

4 Conclusions and Challenges

As the importance of computational simulations in science and engineering continues to grow, so does the importance of validating the physical models that form the basis of those simulations. Validation is traditionally defined as a comparison between model outputs and experimental observations intended to reveal any important discrepancies between the model and reality. To make this process rigorous, one must account for uncertainties that affect the experimental observations and the computational results. Thus, in order to draw validation conclusions, it is necessary to define metrics that measure the agreement or lack thereof between uncertain experimental observations and uncertain model outputs. When these uncertainties are represented using probability, a number of such “validation metrics” are available, including highest posterior density credibility intervals and Bayesian p -values, both of which can be used in combination with appropriately chosen test quantities when necessary or desirable.

When the purpose of the computational simulation is prediction, agreement between uncertain model outputs and available uncertain data is in general necessary but not sufficient for validating the prediction because prediction requires extrapolation. In this situation, predictive validation is a process for building confidence in simulation-based predictions by exploiting typical features of physics-based models.

A number of issues remain before systematic validation methodologies like those described here can become standard in computational science and engineering. First, all of the ideas described here depend heavily on the development of probabilistic models to represent uncertainties. In some situations, such as when abundant sample data are available for an aleatorically uncertain variable, these models are straightforward to build. However, in many cases, particularly those involving complex epistemic uncertainties, this process is less clear. For example, general techniques and best practices for representing uncertainty due to model inadequacy, particularly when the modeled quantity is a field, and for representing correlations between experimental measurements when few replications are available must be developed. These difficulties are often related to the more general problem of representing qualitative information such as expert opinion that, while often crucial in accurately characterizing likely values of epistemic parameters or realistic modeling errors, can be challenging to represent quantitatively in a defensible manner.

Second, the methods discussed here require uncertainty propagation through the models being validated. When these models are computationally expensive and/or the space of uncertain variables is high dimensional, it is well known that typical algorithms, such as Monte Carlo sampling or stochastic collocation, often require too many forward model evaluations to be computationally tractable. Better algorithms are necessary to enable routine uncertainty analysis using complex models. The required algorithmic advances are also necessary to enable routine validation of these models.

Abstract

The past century has seen a steady increase in the need of estimating and predicting complex systems and making (possibly critical) decisions with limited information. Although computers have made possible the numerical evaluation of sophisticated statistical models, these models are still designed *by humans* because there is currently no known recipe or algorithm for dividing the design of a statistical model into a sequence of arithmetic operations. Indeed enabling computers to *think as humans*, especially when faced with uncertainty, is challenging in several major ways: (1) Finding optimal statistical models remains to be formulated as a well-posed problem when information on the system of interest is incomplete and comes in the form of a complex combination of sample data, partial knowledge of constitutive relations and a limited description of the distribution of input random variables. (2) The space of admissible scenarios along with the space of relevant information, assumptions, and/or beliefs, tends to be infinite dimensional, whereas calculus on a computer is necessarily discrete and finite. With this purpose, this paper explores the foundations of a rigorous framework for the scientific computation of optimal statistical estimators/models and reviews their connections with decision theory, machine learning, Bayesian inference, stochastic optimization, robust optimization, optimal uncertainty quantification, and information-based complexity.

1 Introduction

During the past century, the need to solve large complex problems in applications such as fluid dynamics, neutron transport, or ballistic prediction drove the parallel development of computers and numerical methods for solving ODEs and PDEs. It is now clear that this development lead to a paradigm shift. Before: each new PDE required the development of new theoretical methods and the employment of large teams of mathematicians and physicists; in most cases, information on solutions was

only qualitative and based on general analytical bounds on fundamental solutions. After: mathematical analysis and computer science worked in synergy to give birth to robust numerical methods (such as finite element methods) capable of solving a large spectrum of PDEs without requiring the level of expertise of an A. L. Cauchy or level of insight of a R. P. Feynman. This transformation can be traced back to sophisticated calculations performed by arrays of *human computers* organized as parallel clusters such as in the pioneering work of Lewis Fry Richardson [1, 90], who in 1922 had a room full of clerks attempt to solve finite-difference equations for the purposes of weather forecasting, and the 1947 paper by John Von Neumann and Herman Goldstine on Numerical Inverting of Matrices of High Order [154]. Although Richardson's predictions failed due to the use of unfiltered data/initial conditions/equations and large time-steps not satisfying the CFL stability condition [90], his vision was shared by Von Neumann [90] in his proposal of the Meteorology Research Project to the US Navy in 1946, qualified by Platzman [120] as "perhaps the most visionary prospectus for numerical weather prediction since the publication of Richardsons book a quarter-century earlier."

The past century has also seen a steady increase in the need of estimating and predicting complex systems and making (possibly critical) decisions with limited information. Although computers have made possible the numerical evaluation of sophisticated statistical models, these models are still designed by *humans* through the employment of multidisciplinary teams of physicists, computer scientists, and statisticians. Contrary to the original *human computers* (such as the ones pioneered by L. F. Richardson or overseen by R. P. Feynman at Los Alamos), these *human teams* do not follow a specific algorithm (such as the one envisioned in Richardson's Forecast Factory where 64,000 human computers would have been working in parallel and at high speed to compute world weather charts [90]) because there is currently no known recipe or algorithm for dividing the design of a statistical model into a sequence of arithmetic operations. Furthermore, while *human computers* were given a specific PDE or ODE to solve, these *human teams* are not given a well-posed problem with a well-defined notion of solution. As a consequence, different *human teams* come up with different *solutions* to the design of the statistical model along with different estimates on uncertainties.

Indeed enabling computers to *think* as *humans*, especially when faced with uncertainty, is challenging in several major ways: (1) There is currently no known recipe or algorithm for dividing the design of a statistical model into a sequence of arithmetic operations. (2) Formulating the search for an optimal statistical estimator/model as a well-posed problem is not obvious when information on the *system of interest* is incomplete and comes in the form of a complex combination of sample data, partial knowledge of constitutive relations, and a limited description of the distribution of input random variables. (3) The space of admissible scenarios along with the space of relevant information, assumptions, and/or beliefs tends to be infinite dimensional, whereas calculus on a computer is necessarily discrete and finite.

The purpose of this paper is to explore the foundations of a rigorous/rational framework for the scientific computation of optimal statistical estimators/models for complex systems and review their connections with decision theory, machine

learning, Bayesian inference, stochastic optimization, robust optimization, optimal uncertainty quantification, and information-based complexity, the most fundamental of these being the simultaneous emphasis on *computation* and *performance* as in machine learning initiated by Valiant [149].

2 The UQ Problem Without Sample Data

2.1 Čebyšev, Markov, and Krein

Let us start with a simple warm-up problem.

Problem 1. Let \mathcal{A} be the set of measures of probability on $[0, 1]$ having mean less than $m \in (0, 1)$. Let μ^\dagger be an unknown element of \mathcal{A} and let $a \in (m, 1)$. What is $\mu^\dagger[X \geq a]$?

Observe that given the limited information on μ^\dagger , $\mu^\dagger[X \geq a]$ could a priori be any number in the interval $[\mathcal{L}(\mathcal{A}), \mathcal{U}(\mathcal{A})]$ obtained by computing the sup (inf) of $\mu[X \geq a]$ with respect to all possible candidates for μ^\dagger , i.e.,

$$\mathcal{U}(\mathcal{A}) := \sup_{\mu \in \mathcal{A}} \mu[X \geq a] \quad (6.1)$$

and

$$\mathcal{L}(\mathcal{A}) := \inf_{\mu \in \mathcal{A}} \mu[X \geq a]$$

where

$$\mathcal{A} := \{\mu \in \mathcal{M}([0, 1]) \mid \mathbb{E}_\mu[X] \leq m\}$$

and $\mathcal{M}([0, 1])$ is the set of Borel probability measures on $[0, 1]$. It is easy to observe that the extremum of (6.1) can be achieved only when μ is the weighted sum of a Dirac mass at 0 and a Dirac mass at a . It follows that, although (6.1) is an infinite dimensional optimization problem, it can be reduced to the simple one-dimensional optimization problem obtained by letting $p \in [0, 1]$ denote the weight of the Dirac mass at 1 and $1 - p$ the weight of the Dirac mass at 0: *Maximize p subject to $ap = m$* , producing the Markov bound $\frac{m}{a}$ as solution.

Problems such as (1) can be traced back to Čebyšev [77, Pg. 4] “Given: length, weight, position of the centroid and moment of inertia of a material rod with a density varying from point to point. It is required to find the most accurate limits for the weight of a certain segment of this rod.” According to Krein [77], although Čebyšev did solve this problem, it was his student Markov who supplied the proof in his thesis. See Krein [77] for an account of the history of this subject along with substantial contributions by Krein.

2.2 Optimal Uncertainty Quantification

The generalization of the process described in Sect. 2.1 to complex systems involving imperfectly known functions and measures is the point of view of optimal uncertainty quantification (OUQ) [3, 69, 72, 96, 114, 142]. Instead of developing sophisticated mathematical solutions, the OUQ approach is to develop optimization problems and reductions, so that their solution may be implemented on a computer, as in Bertsimas and Popescu's [15] convex optimization approach to Čebyšev inequalities, and the Decision Analysis framework of Smith [133].

To present this generalization, for a topological space \mathcal{X} , let $\mathcal{F}(\mathcal{X})$ be the space of real-valued measurable functions and $\mathcal{M}(\mathcal{X})$ be the set of Borel probability measures on \mathcal{X} . Let \mathcal{A} be an arbitrary subset of $\mathcal{F}(\mathcal{X}) \times \mathcal{M}(\mathcal{X})$, and let $\Phi: \mathcal{A} \rightarrow \mathbb{R}$ be a function producing a quantity of interest.

Problem 2. Let (f^\dagger, μ^\dagger) be an unknown element of \mathcal{A} . What is $\Phi(f^\dagger, \mu^\dagger)$?

Therefore, in the absence of sample data, in the context of this generalization, one is interested in estimating $\Phi(f^\dagger, \mu^\dagger)$, where $(f^\dagger, \mu^\dagger) \in \mathcal{F}(\mathcal{X}) \times \mathcal{M}(\mathcal{X})$ corresponds to an *unknown reality*: the function f^\dagger represents a *response function* of interest, and μ^\dagger represents the probability distribution of the inputs of f^\dagger . If \mathcal{A} represents all that is known about (f^\dagger, μ^\dagger) (in the sense that $(f^\dagger, \mu^\dagger) \in \mathcal{A}$ and that any $(f, \mu) \in \mathcal{A}$ could, a priori, be (f^\dagger, μ^\dagger) given the available information), then [114] shows that the quantities

$$\mathcal{U}(\mathcal{A}) := \sup_{(f, \mu) \in \mathcal{A}} \Phi(f, \mu) \quad (6.2)$$

$$\mathcal{L}(\mathcal{A}) := \inf_{(f, \mu) \in \mathcal{A}} \Phi(f, \mu) \quad (6.3)$$

determine the inequality

$$\mathcal{L}(\mathcal{A}) \leq \Phi(f^\dagger, \mu^\dagger) \leq \mathcal{U}(\mathcal{A}), \quad (6.4)$$

to be optimal given the available information $(f^\dagger, \mu^\dagger) \in \mathcal{A}$ as follows: It is simple to see that the inequality (6.4) follows from the assumption that $(f^\dagger, \mu^\dagger) \in \mathcal{A}$. Moreover, for any $\varepsilon > 0$, there exists a $(f, \mu) \in \mathcal{A}$ such that

$$\mathcal{U}(\mathcal{A}) - \varepsilon < \Phi(f, \mu) \leq \mathcal{U}(\mathcal{A}).$$

Consequently since all that is known about (f^\dagger, μ^\dagger) is that $(f^\dagger, \mu^\dagger) \in \mathcal{A}$, it follows that the upper bound $\Phi(f^\dagger, \mu^\dagger) \leq \mathcal{U}(\mathcal{A})$ is the best obtainable given that information, and the lower bound is optimal in the same sense.

Although the OUQ optimization problems (6.2) and (6.3) are extremely large and although some are computationally intractable, an important subclass enjoys significant and practical finite-dimensional reduction properties [114]. First, by [114, Cor. 4.4], although the optimization variables (f, μ) lie in a product space of functions and probability measures, for OUQ problems governed by linear

inequality constraints on generalized moments, the search can be reduced to one over probability measures that are products of finite convex combinations of Dirac masses with explicit upper bounds on the number of Dirac masses.

Furthermore, in the special case that all constraints are generalized moments of functions of f , the dependency on the coordinate positions of the Dirac masses is eliminated by observing that the search over admissible functions reduces to a search over functions on an m -fold product of finite discrete spaces, and the search over m -fold products of finite convex combinations of Dirac masses reduces to a search over the products of probability measures on this m -fold product of finite discrete spaces [114, Thm. 4.7]. Finally, by [114, Thm. 4.9], using the lattice structure of the space of functions, the search over these functions can be reduced to a search over a finite set.

Fundamental to this development is Winkler's [169] generalization of the characterization of the extreme points of compact (in the weak topology) sets of probability measures constrained by a finite number of generalized moment inequalities defined by continuous functions to *non-compact sets of tight measures*, in particular probability measures on Borel subsets of Polish metric spaces, defined by Borel measurable moment functions, along with his [168] development of Choquet theory for weakly closed convex *non-compact* sets of tight measures. These results are based on Kendall's [71] equivalence between a linearly compact Choquet simplex and a vector lattice and results of Dubins [31] concerning the extreme points of affinely constrained convex sets in terms of the extreme points of the unconstrained set. It is interesting to note that Winkler [169] uses Kendall's result to derive a strong sharpening of Dubins result [31]. Winkler's results allow the extension of existing optimization results over measures on compact metric spaces constrained by continuous generalized moment functions to optimization over measures on Borel subsets of Polish spaces constrained by Borel measurable moment functions. For systems with symmetry, the Choquet theorem of Varadarajan [151] can be used to show that the Dirac masses can be replaced by the ergodic measures in these results. The inclusion of sets of functions along with sets of measures in the optimization problems facilitates the application to systems with imprecisely known response functions. In particular, a result of Ressel [121], providing conditions under which the map $(f, \mu) \rightarrow f_*\mu$ from function/measure pairs to the induced law is Borel measurable, facilitates the extension of these techniques from sets of *measures* to sets of *random variables*. In general, the inclusion of functions in the domain of optimization requires the development of generalized programming techniques such as generalized Benders decompositions described in Geoffrion [46]. Moreover, as has been so successful in machine learning, it will be convenient to approximate the space of measurable functions $\mathcal{F}(\mathcal{X})$ by some reproducing kernel Hilbert space $\mathcal{H}(\mathcal{X}) \subset \mathcal{F}(\mathcal{X})$ producing an approximation $\mathcal{H}(\mathcal{X}) \times \mathcal{M}(\mathcal{X}) \subset \mathcal{F}(\mathcal{X}) \times \mathcal{M}(\mathcal{X})$ to the full base space. Under the mild assumption that \mathcal{X} is an analytic subset of a Polish space and $\mathcal{H}(\mathcal{X})$ possesses a measurable feature map, it has recently been shown in [111] that $\mathcal{H}(\mathcal{X})$ is separable. Consequently, since all separable Hilbert spaces are isomorphic with ℓ^2 , it follows that the space $\ell^2 \times \mathcal{M}(\mathcal{X})$ is a universal representation space for the approximation of $\mathcal{F}(\mathcal{X}) \times \mathcal{M}(\mathcal{X})$. Moreover, in that case, since \mathcal{X} is separable and metric, so is $\mathcal{M}(\mathcal{X})$ in the weak topology, and since

$\mathcal{H}(\mathcal{X})$ is Polish, it follows that the approximation space $\mathcal{H}(\mathcal{X}) \times \mathcal{M}(\mathcal{X})$ is the product of a Polish space and a separable metric space. When furthermore \mathcal{X} is Polish, it follows that the approximation space is the product of Polish spaces and therefore Polish.

Example 1. A classic example is $\Phi(f, \mu) := \mu[f \geq a]$ where a is a safety margin. In the certification context, one is interested in showing that $\mu^\dagger[f^\dagger \geq a] \leq \varepsilon$, where ε is a safety certification threshold (i.e., the maximum acceptable μ^\dagger -probability of the system f^\dagger exceeding the safety margin a). If $\mathcal{U}(\mathcal{A}) \leq \varepsilon$, then the system associated with (f^\dagger, μ^\dagger) is safe even in the worst-case scenario (given the information represented by \mathcal{A}). If $\mathcal{L}(\mathcal{A}) > \varepsilon$, then the system associated with (f^\dagger, μ^\dagger) is unsafe even in the best-case scenario (given the information represented by \mathcal{A}). If $\mathcal{L}(\mathcal{A}) \leq \varepsilon < \mathcal{U}(\mathcal{A})$, then the safety of the system cannot be decided (although one could declare the system to be unsafe due to lack of information).

2.3 Worst-Case Analysis

The proposed solutions to Problems 1 and 2 are particular instances of worst-case analysis that, as noted by [135] and [127, p.5], is an old concept that could be summarized by the popular adage *When in doubt, assume the worst!* or:

The gods to-day stand friendly, that we may,
 Lovers of peace, lead on our days to age
 But, since the affairs of men rests still uncertain,
 Lets reason with the worst that may befall.

Julius Caesar, Act 5, Scene 1
 William Shakespeare (1564–1616)

As noted in [114], an example of worst-case analysis in seismic engineering is that of Drenick's *critical excitation* [30] which seeks to quantify the safety of a structure to the worst earthquake given a constraint on its magnitude. The combination of structural optimization (in various fields of engineering) to produce an optimal design given the (deterministic) worst-case scenario has been referred to as *optimization and anti-optimization* [35]. The main difference between OUQ and anti-optimization lies in the fact that the former is based on an optimization over (admissible) functions and measures (f, μ) , while the latter only involves an optimization over f . Because of its robustness, many engineers have adopted the (deterministic) worst-case scenario approach to UQ [35, Chap. 10] when a high reliability is required.

2.4 Stochastic and Robust Optimization

Robust control [176] and robust optimization [7, 14] have been founded upon the worst-case approach to uncertainty. Recall that robust optimization describes optimization involving uncertain parameters. While these uncertain

parameters are modeled as random variables (of known distribution) in stochastic programming [26], robust optimization only assumes that they are contained in known (ambiguity) sets. Although, as noted in [35], *probabilistic methods do not find appreciation among theoreticians and practitioners alike* because “probabilistic reliability studies involve assumptions on the probability densities, whose knowledge regarding relevant input quantities is central,” the deterministic worst-case approach (limited to optimization problems over f) is sometimes “too pessimistic to be practical” [30, 35] because “it does not take into account the *improbability* that (possibly independent or weakly correlated) random variables conspire to produce a failure event” [114] (which constitutes one motivation for considering ambiguity sets involving both measures and functions). Therefore OUQ and *distributionally robust optimization* (DRO) [7, 14, 49, 53, 166, 174, 177] could be seen as middle ground between the deterministic worst-case approach of robust optimization [7, 14] and approaches of *stochastic programming* and *chance-constrained optimization* [19, 24] by defining optimization objectives and constraints in terms of expected values and probabilities with respect to imperfectly known distributions.

Although stochastic optimization has different objectives than OUQ and DRO, many of its optimization results, such as those found in Birge and Wets [16], and Ermoliev [36] and Gaivoronski, [44], are useful. In particular, the well-developed subject of Edmundson and Madansky bounds such as Edmundson [34]; Madansky [91, 92]; Gassman and Ziemba [45]; Huang, Ziemba, and Ben-Tal [57]; Frauendorfer [41]; Ben-Tal and Hochman [8]; Huang, Vertinsky, and Ziemba [56]; and Kall [67] provide powerful results. Recently Hanasusanto, Roitch, Kuhn, and Wiesemann [53] derive explicit conic reformulations for tractable problem classes and suggest efficiently computable conservative approximations for intractable ones. In some cases, e.g., Bertsimas and Popescu’s [15] and Han et al. [52], DRO/OUQ optimization problems can be reduced to convex optimization.

2.5 Čebyšev Inequalities and Optimization Theory

As noted in [114], inequalities (6.4) can be seen as a generalization of Čebyšev inequalities. The history of classical inequalities can be found in [70], and some generalizations in [15] and [150]; in the latter works, the connection between Čebyšev inequalities and optimization theory is developed based on the work of Mulholland and Rogers [98], Godwin [48], Isii [60–62], Olkin and Pratt [106], Marshall and Olkin [94], and the classical Markov–Krein theorem [70, pages 82 & 157], among others. We also refer to the field of majorization, as discussed in Marshall and Olkin [95], the inequalities of Anderson [5], Hoeffding [54], Joe [64], Bentkus et al. [12], Bentkus [10, 11], Pinelis [118, 119], and Boucheron, Lugosi, and Massart [20]. Moreover, the solution of the resulting nonconvex optimization problems benefit from duality theories for nonconvex optimization problems such as Rockafellar [123] and the development of convex envelopes for them, as can be found, for example, in Rikun [122] and Sherali [131].

3 The UQ Problem with Sample Data

3.1 From Game Theory to Decision Theory

To motivate the general formulation in the presence of sample data, consider another simple warm-up problem.

Problem 3. Let \mathcal{A} be the set of measures of probability on $[0, 1]$ having mean less than $m \in (0, 1)$. Let μ^\dagger be an unknown element of \mathcal{A} and let $a \in (m, 1)$. You observe $d := (d_1, \dots, d_n)$, n i.i.d. samples from μ^\dagger . What is the *sharpest estimate* of $\mu^\dagger[X \geq a]$?

The only difference between Problems 3 and 1 lies in the availability of data sampled from the underlying unknown distribution. Observe that, in presence of this sample data, the notions of *sharpest estimate* or *smallest interval of confidence* are far from being transparent and call for clear and precise definitions. Note also that if the constraint $\mathbb{E}_{\mu^\dagger}[X] \leq m$ is ignored, and the number n of sample data is large, then one could use the central limit theorem or a concentration inequality (such as Hoeffding's inequality) to derive an interval of confidence for $\mu^\dagger[X \geq a]$. A nontrivial question of practical importance is what to do when n is not large.

Writing $\Phi(\mu^\dagger) := \mu^\dagger[X \geq a]$ as the quantity of interest, observe that an estimation of $\Phi(\mu^\dagger)$ is a function (which will be written θ) of the data d . Ideally one would like to choose θ so that the estimation error $\theta(d) - \Phi(\mu^\dagger)$ is as close as possible to zero. Since d is random, a more robust notion of error is that of a statistical error $\mathcal{E}(\theta, \mu^\dagger)$ defined by weighting the error with respect to a real measurable positive loss function $V: \mathbb{R} \rightarrow \mathbb{R}$ and the distribution of the data, i.e.,

$$\mathcal{E}(\theta, \mu^\dagger) := \mathbb{E}_{d \sim (\mu^\dagger)^n} [V[\theta(d) - \Phi(\mu^\dagger)]] \quad (6.5)$$

Note that for $V(x) = x^2$, the statistical error $\mathcal{E}(\theta, \mu^\dagger)$ defined in (6.5) is the mean squared error with respect to the distribution of the data d of the estimation error. For $V(x) = \mathbb{1}_{[\gamma, \infty)}(|x|)$ defined for some $\gamma > 0$, $\mathcal{E}(\theta, \mu^\dagger)$ is the probability with respect to the distribution of d that the estimation error is larger than γ .

Now since μ^\dagger is unknown, the statistical error $\mathcal{E}(\theta, \mu^\dagger)$ of any θ is also unknown. However one can still identify the least upper bound on that statistical error through a worst-case scenario with respect to all possible candidates for μ^\dagger , i.e.,

$$\sup_{\mu \in \mathcal{A}} \mathcal{E}(\theta, \mu). \quad (6.6)$$

The sharpest estimator (possibly within a given class) is then naturally obtained as the minimizer of (6.6) over all functions θ of the data d within that class, i.e., as the minimizer of

$$\inf_{\theta} \sup_{\mu \in \mathcal{A}} \mathcal{E}(\theta, \mu). \quad (6.7)$$

Observe that the optimal estimator is identified independently from the observation/realization of the data and if the minimum of (6.7) is not achieved then one can still use a near-optimal θ . Then, when the data is observed, the estimate of the quantity of interest $\Phi(\mu^\dagger)$ is then derived by evaluating the near-optimal θ on the data d . The notion of optimality described here is that of Wald's statistical decision theory [156–158, 160, 161], evidently influenced by Von Neumann's game theory [153, 155]. In Wald's formulation [157], which cites both Von Neumann [153] and Von Neumann and Morgenstern [155], the statistician finds himself in an adversarial game played against the Universe in which he tries to minimize a risk function $\mathcal{E}(\theta, \mu)$ with respect to θ in a worst-case scenario with respect to what the Universe's choice of μ could be.

3.2 The Optimization Approach to Statistics

The optimization approach to statistics is not new and this section will now give a short, albeit incomplete, description of its development, primarily using Lehmann's account [87]. Accordingly, it began with Gauss and Laplace with the nonparametric result referred to as the Gauss-Markov theorem, asserting that the least squares estimates are the linear unbiased estimates with minimum variance. Then, in Fisher's fundamental paper [39], for parametric models, he proposes the maximum likelihood estimator and claims (but does not prove) that such estimators are consistent and asymptotically efficient. According to Lehmann, "the situation is complex, but under suitable restrictions Fisher's conjecture is essentially correct . . ." The Fisher's maximum likelihood principle was first proposed on intuitive grounds and then its optimality properties developed. However, according to Lehmann [86, Pg. 1011], Pearson then asked Neyman "Why these tests rather than any of the many other that could be proposed? This question resulted in Neyman and Pearson's 1928 papers [104] on the likelihood ratio method, which gives the same answer as Fisher's tests under normality assumptions. However, Neyman was not satisfied. He agreed that the likelihood ratio principle was appealing but felt that it was lacking a logically convincing justification. This then led to the publication of Neyman and Pearson [105], containing their now famous Neyman-Pearson lemma, which according to Lehmann [87], "In a certain sense this is the true start of optimality theory." In a major extension of the Neyman-Pearson work, Huber [58] proves a *robust* version of the Neyman-Pearson lemma, in particular, providing an optimality criteria defining the robust estimator, giving rise to a rigorous theory of robust statistics based on optimality; see Huber's Wald lecture [59]. Robustness is particularly suited to the Wald framework since robustness considerations are easily formulated with the proper choices of admissible functions and measures in the Wald framework. Another example is Kiefer's introduction of optimality into experimental design, resulting in Kiefer's 40 papers on Optimum Experimental Designs [74].

Not everyone was happy with "optimality" as a guiding principle. For example, Lehmann [87] states that at a 1958 meeting of the Royal Statistical Society at which Kiefer presented a survey talk [73] on Optimum Experimental Designs, Barnard

quotes Kiefer as saying of procedures proposed in a paper by Box and Wilson that they “often [are] not even well-defined rules of operation.” Barnard’s reply:

in the field of practical human activity, rules of operation which are not well-defined may be preferable to rules which are.

Wynn [173], in his introduction to a reprint of Kiefer’s paper, calls this “a clash of statistical cultures.” Indeed, it is interesting to read the generally negative responses to Kiefer’s article [73] and the remarkable rebuttal by Kiefer therein. Tukey had other criticisms regarding “The tyranny of the best” in [147] and “The dangers of optimization” in [148]. In the latter he writes:

Some [statisticians] seem to equate [optimization] to statistics an attitude which, if widely adopted, is guaranteed to produce a dried-up, encysted field with little chance of real growth.

For an account of how the Exploratory Data Analysis approach of Tukey fits within the Fisher/Neyman–Pearson debate, see Lehnard [88].

Let us also remark on the influence that Student – William Sealy Gosset – had on both Fisher and Pearson. As presented in Lehmann’s [85] “‘Student’ and small-sample theory,” quoting F. N. David [79]: “I think he [Gosset] was really the big influence in statistics. . . He asked the questions and Pearson or Fisher put them into statistical language and then Neyman came to work with the mathematics. But I think most of it stems from Gosset.” The aim of Lehmann’s paper [85] is to consider to what extent David’s conclusion is justified. Indeed, the claim is surprising since Gosset is mainly known for only one contribution, that is, Student [141], with the introduction of Student’s t-test and its analysis under the normal distribution. According to Lehmann, “Today the pathbreaking nature of this paper is generally recognized and has been widely commented upon, . . .” Gosset’s primary concern in communicating with both Fisher and Pearson was the robustness of the test to non-normality. Lehmann concludes that “the main ideas leading to Pearson’s research were indeed provided by Student.” See Lehmann [85] for the full account, including Gosset’s relationship to the Fisher–Pearson debate, Pearson [116] for a statistical biography of Gosset, and Fisher [40] for a eulogy. Consequently, modern statistics appears to owe a lot to Gosset. Moreover, the reason for the pseudonym was a policy by Gosset’s employer, the brewery Arthur Guinness, Sons, and Co., against work done for the firm being made public. Allowing Gosset to publish under a pseudonym was a concession that resulted in the birth of the statistician Student. Consequently, the authors would like to take this opportunity to thank the Guinness Brewery for its influence on statistics today, and for such a fine beer.

3.3 Abraham Wald

Following Neyman and Pearson’s breakthrough, a different approach to optimality was introduced in Wald [156] and then developed in a sequence of papers culminating in Wald’s [161] book Statistical Decision Functions. Evidence of the influence of Neyman on Wald can be found in the citation of Neyman [102] in

the introduction of Wald [156]. Brown [22] quotes the students of Neyman in 1966 from [103]:

The concepts of confidence intervals and of the Neyman-Pearson theory have proved immensely fruitful. A natural but far reaching extension of their scope can be found in Abraham Wald's theory of statistical decision functions. The elaboration and application of the statistical tools related to these ideas has already occupied a generation of statisticians. It continues to be the main lifestream of theoretical statistics.

Brown's purpose was to address if the last sentence in the quote was still true in 2000.

Wolfowitz [170] describes the primary accomplishments of Wald's statistical decision theory as follows:

Wald's greatest achievement was the theory of statistical decision functions, which includes almost all problems which are the *raison d'être* of statistics.

Leonard [89, Chp. 12] portrays Von Neumann's return to game theory as "partly an early reaction to upheaval and war." However he adds that eventually Von Neumann became personally involved in the war effort and "with that involvement came a significant, unforeseeable moment in the history of game theory: this new mathematics made its wartime entrance into the world, not as the abstract theory of social order central to the book, but as a problem solving technique." Moreover, on pages 278–280, Leonard discusses the statistical research groups at Berkeley, Columbia, and Princeton, in particular Wald at Columbia, and how the effort to develop inspection and testing procedures leads Wald to the development of sequential methods "apparently yielding significant economies in inspection in the Navy," leading to the publication of Wald and Wolfowitz' [162] proof of the optimality of the sequential probability ratio test and Wald's book [159] *Sequential Analysis*. Leonard's claim essentially is that the war stimulated these fine theoretical minds to pursue activities with real application value. In this regard, it is relevant to note Mangel and Samaniego's [93] stimulating description of Wald's work on aircraft survivability, along with the contemporary, albeit somewhat vague, description of "How a Story from World War II shapes Facebook today" by Wilson [167]. Indeed, in the problem of how to allocate armoring to the allied bombers based on their condition upon return from their missions, it was discovered that armoring where the previous planes had been hit was not improving their rate of return. Wald's ingenious insight was that these were the returning bombers not the ones which had been shot down. So the places where the returning bombers were hit are more likely to be the places where one *does not* need to add armoring. Evidently, his rigorous and unconventional innovations to transform this intuition into a real methodology saved many lives. Wolfowitz [170] states:

Wald not only posed his statistical problems clearly and precisely, but he posed them to fit the practical problem and to accord with the decisions the statistician was called on to make. This, in my opinion, was the key to his success—a high level of mathematical talent of the most abstract sort, and a true feeling for, and insight into, practical problems. The combination of the two in his person at such high levels was what gave him his outstanding character.

The section on Von Neumann and Remak (along with the Notes that follows it) in Kurz and Salvadori [78] describes Wald and Von Neumann's relations. Brown [21] credits Wald as the creator of the minmax idea in statistics, evidently given axiomatic justification by Gilboa and Schmeidler [47]. This certainly had something to do with his friendship with Morgenstern and his relationship with Von Neumann, who together authored the famous book [155], but this influence can be explicitly seen in Wald's [157] citation of Von Neumann [153] and Von Neumann and Morgenstern [155] in his introduction [157] of the minmax idea in statistical decision theory. Indeed, Wolfowitz states that:

... he was also spurred on by the connection between the newly announced results of [Von Neumann and Morgenstern] [155] and his own theory, and by the general interest among economists and others aroused by the theory of games.

Wolfowitz asserts that Wald's work [156] Contributions to the Theory of Statistical Estimation and Testing Hypotheses is “probably his most important paper” but that it “went almost completely unnoticed,” possibly because “The use of Bayes solutions was deterrent” and “Wald did not really emphasize that he was using Bayes solutions only as a tool.” Moreover, although Wolfowitz considered Wald's Statistical Decision Functions [161] his greatest achievement, he also says:

The statistician who wants to apply the results of [161] to specific problems is likely to be disappointed. Except for special problems, the complete classes are difficult to characterize in a simple manner and have not yet been characterized. Satisfactory general methods are not yet known for obtaining minimax solutions. If one is not always going to use a minimax solution (to which serious objections have been raised) or a solution satisfying some given criterion, then the statistician should have the opportunity to choose from among “representative” decision functions on the basis of their risk functions. These are not available except for the simplest cases. It is clear that much remains to be done before the use of decision functions becomes common. The theory provides a rational basis for attacking almost any statistical problem, and, when some computational help is available and one makes some reasonable compromises in the interest of computational feasibility, one can obtain a practical answer to many problems which the classical theory is unable to answer or answers in an unsatisfactory manner.

Wolfowitz [170], Morgenstern [97], and Hotelling [55] provide a description of Wald's impact at the time of his passing. The influence of Wald's minimax paradigm can also be observed on (1) decision making under severe uncertainty [134–136], (2) stochastic programming [130] (minimax analysis of stochastic problems), (3) minimax solutions of stochastic linear programming problems [175], (4) robust convex optimization [9] (where one must find the best decision in view of the worst-case parameter values within deterministic uncertainty sets), (4) econometrics [143], and (5) Savage's minimax regret model [128].

3.4 Generalization to Unknown Pairs of Functions and Measures and to Arbitrary Sample Data

In practice, complex systems of interest may involve, both an imperfectly known response function f^\dagger and an imperfectly known probability measure μ^\dagger as illustrated in the following problem.

Problem 4. Let \mathcal{A} be a set of real functions and measures of probability on $[0, 1]$ such that $(f, \mu) \in \mathcal{A}$ if and only if $\mathbb{E}_\mu[X] \leq m$ and $\sup_{x \in [0, 1]} |g(x) - f(x)| \leq 0.1$ where g is some given real function on $[0, 1]$. Let (f^\dagger, μ^\dagger) be an unknown element of \mathcal{A} and let $a \in \mathbb{R}$. Let (X_1, \dots, X_n) be n i.i.d. samples from μ^\dagger , you observe (d_1, \dots, d_n) with $d_i = (X_i, f^\dagger(X_i))$. What is the “sharpest” estimate of $\mu^\dagger[f(X) \geq a]$?

Problem 4 is an illustration of a situation in which the response function f^\dagger and the probability measure μ^\dagger are not directly observed and the sample data arrives in the form of realizations of random variables, the distribution of which is related to (f^\dagger, μ^\dagger) . To simplify the current presentation, assume that this relation is, in general, determined by a function of (f^\dagger, μ^\dagger) and use the following notation: \mathbb{D} will denote the observable space (i.e., the space in which the sample data d take values, assumed to be a metrizable Suslin space) and d will denote the \mathbb{D} -valued random variable corresponding to the observed sample data. To represent the dependence of the distribution of d on the unknown state $(f^\dagger, \mu^\dagger) \in \mathcal{A}$, introduce a measurable function

$$\mathbb{D}: \mathcal{A} \rightarrow \mathcal{M}(\mathcal{D}), \quad (6.8)$$

where $\mathcal{M}(\mathcal{D})$ is given the Borel structure corresponding to the weak topology, to define this relation. The idea is that $\mathbb{D}(f, \mu)$ is the probability distribution of the observed sample data d if $(f^\dagger, \mu^\dagger) = (f, \mu)$, and for this reason it may be called the *data map* (or, even more loosely, the *observation operator*). Now consider the following problem.

Problem 5. Let \mathcal{A} be a known subset of $\mathcal{F}(\mathcal{X}) \times \mathcal{M}(\mathcal{X})$ as in Problem 2 and let \mathbb{D} be a known data map as in (6.8). Let Φ be a known measurable semi-bounded function mapping \mathcal{A} onto \mathbb{R} . Let (f^\dagger, μ^\dagger) be an unknown element of \mathcal{A} . You observe $d \in \mathcal{D}$ sampled from the distribution $\mathbb{D}(f^\dagger, \mu^\dagger)$. What is the sharpest estimation of $\Phi(f^\dagger, \mu^\dagger)$?

3.5 Model Error and Optimal Models

As in Wald’s statistical decision theory [157], a natural notion of optimality can be obtained by formulating Problem 5 as an adversarial game in which player A

chooses $(f^\dagger, \mu^\dagger) \in \mathcal{A}$ and player B (knowing \mathcal{A} and \mathbb{D}) chooses a function θ of the observed data d . As in (6.5) this notion of optimality requires the introduction of a risk function:

$$\mathcal{E}(\theta, (f, \mu)) := \mathbb{E}_{d \sim \mathbb{D}(f, \mu)} [V[\theta(d) - \Phi(f, \mu)]] \quad (6.9)$$

where $V: \mathbb{R} \rightarrow \mathbb{R}$ is a real positive measurable loss function. As in (6.6) the least upper bound on that statistical error $\mathcal{E}(\theta, (f, \mu))$ is obtained as through a worst-case scenario with respect to all possible candidates for (f, μ) (player's A choice), i.e.,

$$\sup_{(f, \mu) \in \mathcal{A}} \mathcal{E}(\theta, (f, \mu)) \quad (6.10)$$

and an optimal estimator/model (possibly within a given class) is then naturally obtained as the minimizer of (6.10) over all functions θ of the data d in that class (player's B choice), i.e., as the minimizer of

$$\inf_{\theta} \sup_{(f, \mu) \in \mathcal{A}} \mathcal{E}(\theta, (f, \mu)). \quad (6.11)$$

Since in real applications true optimality will never be achieved, it is natural to generalize to considering near-minimizers of (6.11) as near-optimal models/estimators.

Remark 1. In situations where the data map is imperfectly known (e.g., when the data d is corrupted by some noise of imperfectly known distribution), one has to include a supremum over all possible candidates $\mathbb{D} \in \mathfrak{D}$ in the calculation of the least upper bound on the statistical error.

3.6 Mean Squared Error, Variance, and Bias

For $(f, \mu) \in \mathcal{A}$ write $\text{Var}_{d \sim \mathbb{D}(f, \mu)} [\theta(d)]$ the variance of the random variable $\theta(d)$ when d is distributed according to $\mathbb{D}(f, \mu)$, i.e.,

$$\text{Var}_{d \sim \mathbb{D}(f, \mu)} [\theta(d)] := \mathbb{E}_{d \sim \mathbb{D}(f, \mu)} [(\theta(d))^2] - [\mathbb{E}_{d \sim \mathbb{D}(f, \mu)} [\theta(d)]]^2$$

The following equation, whose proof is straightforward, shows that for $V(x) = x^2$, the least upper bound on the mean squared error of θ is equal to the least upper bound on the sum of the variance of θ and the square of its bias:

$$\sup_{(f, \mu) \in \mathcal{A}} \mathcal{E}(\theta, (f, \mu)) = \sup_{(f, \mu) \in \mathcal{A}} \left[\text{Var}_{d \sim \mathbb{D}(f, \mu)} [\theta(d)] + (\mathbb{E}_{d \sim \mathbb{D}(f, \mu)} [\theta(d)] - \Phi(f, \mu))^2 \right]$$

Therefore, for $V(x) = x^2$, the bias/variance tradeoff is made explicit.

3.7 Optimal Interval of Confidence

Although \mathcal{E} can a priori be defined to be any risk function, taking $V(x) = \mathbb{1}_{[\gamma, \infty]}(|x|)$ (for some $\gamma > 0$) in (6.5) allows for a transparent and objective identification of optimal intervals of confidence. Indeed, writing,

$$\mathcal{E}_\gamma(\theta, (f, \mu)) := \mathbb{P}_{d \sim \mathbb{D}(f, \mu)} \left[|\theta(d) - \Phi(f, \mu)| \geq \gamma \right]$$

note that $\sup_{(f, \mu) \in \mathcal{A}} \mathcal{E}_\gamma(\theta, (f, \mu))$ is the least upper bound on the probability (with respect to the distribution of d) that the difference between the true value of the quantity of interest $\Phi(f^\dagger, \mu^\dagger)$ and its estimated value $\theta(d)$ is larger than γ . Let $\epsilon \in [0, 1]$. Define

$$\gamma_\epsilon := \inf \left\{ \gamma > 0 \mid \inf_{\theta} \sup_{(f, \mu) \in \mathcal{A}} \mathcal{E}_\gamma(\theta, (f, \mu)) \leq \epsilon \right\},$$

and observe that if θ_ϵ is a minimizer of $\inf_{\theta} \sup_{(f, \mu) \in \mathcal{A}} \mathcal{E}_{\gamma_\epsilon}(\theta, (f, \mu))$ then $[\theta_\epsilon(d) - \gamma_\epsilon, \theta_\epsilon(d) + \gamma_\epsilon]$ is the smallest interval of confidence (random interval obtained as a function of the data) containing $\Phi(f^\dagger, \mu^\dagger)$ with probability at least $1 - \epsilon$. Observe also that this formulation is a natural extension of the OUQ formulation as described in [114]. Indeed, in the absence of sample data, it is easy to show that θ_1 is the midpoint of the optimal interval $[\mathcal{L}(\mathcal{A}), \mathcal{U}(\mathcal{A})]$.

Remark 2. We refer to [37, 38, 137] and in particular to Stein's notorious paradox [138] for the importance of a careful choice for loss function.

3.8 Ordering the Space of Experiments

A natural objective of UQ and statistics is the design of experiments, their comparisons, and the identification of optimal ones. Introduced in Blackwell [17] and Kiefer [73], with a more modern perspective in Le Cam [83] and Strasser [139], here observe that (6.11), as a function of \mathbb{D} , induces an order (transitive, total, but not antisymmetric) on the space of data maps that has a natural experimental design interpretation. More precisely if the data maps \mathbb{D}_1 and \mathbb{D}_2 are interpreted as the distribution of the outcome of two possible experiments, and if the value of (6.11) is smaller for \mathbb{D}_2 than \mathbb{D}_1 , then \mathbb{D}_2 is a preferable experiment.

3.9 Mixing Models

Given estimators $\theta_1, \dots, \theta_n$ can one obtain a better estimator by mixing those estimators? If V is convex (or quasi-convex), then the problem of finding an $\alpha \in [0, 1]^n$ minimizing the statistical error of $\sum_{i=1}^n \alpha_i \theta_i$ under the constraint

$\sum_{i=1}^n \alpha_i = 1$ is a finite-dimensional convex optimization problem in α . If estimators are seen as models of reality, then this observation supports the idea that one can obtain improved models by mixing them (with the goal of achieving minimal statistical errors).

4 The Complete Class Theorem and Bayesian Inference

4.1 The Bayesian Approach

The Bayesian answer to Problem 5 is to assume that (f^\dagger, μ^\dagger) is a sample from some (prior) measure π on \mathcal{A} and then condition the expectation of $\Phi(f, \mu)$ with respect to the observation of the data, i.e., use

$$\mathbb{E}_{(f, \mu) \sim \pi, d \sim \mathbb{D}(f, \mu)} [\Phi(f, \mu) | d] \quad (6.12)$$

as the estimator $\theta(d)$. This requires giving \mathcal{A} the structure of a measurable space such that important quantities of interest such as $(f, \mu) \rightarrow \mu[f(X) \geq a]$ and $(f, \mu) \rightarrow \mathbb{E}_\mu[f]$ are measurable. This can be achieved using results of Ressel [121] providing conditions under which the map $(f, \mu) \rightarrow f_*\mu$ from function/measure pairs to the induced law is Borel measurable. We will henceforth assume \mathcal{A} to be a Suslin space and proceed to construct the measure of probability $\pi \odot \mathbb{D}$ of $((f, \mu), d)$ on $\mathcal{A} \times \mathcal{D}$ via a natural generalization of the Campbell measure and Palm distribution associated with a random measure as described in [68]; see also [25, Ch. 13] for a more current treatment. We refer to Sect. 6 of the appendix for the details of the construction of the distribution $\pi \odot \mathbb{D}$ of $((f, \mu), d)$ when $(f, \mu) \sim \pi$ and $d \sim \mathbb{D}(f, \mu)$, and of the marginal distribution $\pi \cdot \mathbb{D}$ of $\pi \odot \mathbb{D}$ on the data space \mathcal{D} , and the resulting regular conditional expectation (6.12). Consequently, the nested expectation $\mathbb{E}_{(f, \mu) \sim \pi, d \sim \mathbb{D}(f, \mu)}$ appearing in (6.12) will from now on be rigorously written as the expectation $\mathbb{E}_{((f, \mu), d) \sim \pi \odot \mathbb{D}}$.

Statistical error when (f^\dagger, μ^\dagger) is random. When (f^\dagger, μ^\dagger) is a random realization of π^\dagger , one may consider averaging the statistical error (6.9) with respect to π^\dagger and introduce

$$\mathcal{E}(\theta, \pi^\dagger) := \mathbb{E}_{((f, \mu), d) \sim \pi^\dagger \odot \mathbb{D}} [V[\theta(d) - \Phi(f, \mu)]] \quad (6.13)$$

When π^\dagger is an unknown element of a subset Π of $\mathcal{M}(\mathcal{A})$, the least upper bound on the statistical error (6.13) given the available information is obtained by taking the sup of (6.13) with respect to all possible candidates for π^\dagger , i.e.,

$$\sup_{\pi \in \Pi} \mathcal{E}(\theta, \pi) \quad (6.14)$$

When \mathcal{A} is Suslin and when (f^\dagger, μ^\dagger) is not a random sample from π^\dagger but simply an unknown element of \mathcal{A} , then a straightforward application of the reduction theorems of [114] implies that when $\Pi = \mathcal{M}(\mathcal{A})$, then (6.14) is equal to (6.11), i.e.,

$$\sup_{(f,\mu) \in \mathcal{A}} \mathcal{E}(\theta, (f, \mu)) = \sup_{\pi \in \mathcal{M}(\mathcal{A})} \mathcal{E}(\theta, \pi) \quad (6.15)$$

4.2 Relation Between Adversarial Model Error and Bayesian Error

When Φ has a second moment with respect to π , one can utilize the classical variational description of conditional expectation as follows: Letting $L^2_{\pi \cdot \mathbb{D}}(\mathcal{D})$ denote the space of $(\pi \cdot \mathbb{D}$ a.e. equivalence classes of) real-valued measurable functions on \mathcal{D} that are square-integrable with respect to the measure $\pi \cdot \mathbb{D}$, one has (see Sect. 6)

$$\mathbb{E}_{\pi \odot \mathbb{D}}[\Phi | d] := \arg \min_{h \in L^2_{\pi \cdot \mathbb{D}}(\mathcal{D})} \mathbb{E}_{(f,\mu,d) \sim \pi \odot \mathbb{D}} \left[(\Phi(f, \mu) - h(d))^2 \right].$$

In other words, if (f, μ) is sampled from the measure π , $\mathbb{E}_{\pi \odot \mathbb{D}}[\Phi(f, \mu) | d]$ is the best mean-square approximation of $\Phi(f, \mu)$ in the space of square-integrable functions of d . As with the regular conditional probabilities, the real-valued function on \mathcal{D}

$$\theta_\pi(d) = \mathbb{E}_{(f,\mu,D) \sim \pi \odot \mathbb{D}} [\Phi(f, \mu) | D = d], \quad d \in \mathcal{D} \quad (6.16)$$

is uniquely defined up to subsets of \mathcal{D} of $(\pi \cdot \mathbb{D})$ -measure zero.

Using the orthogonal projection property of the conditional expectation, one obtains that if $V(x) = x^2$, then for arbitrary θ ,

$$\mathcal{E}(\theta, \pi) = \mathcal{E}(\theta_\pi, \pi) + \mathbb{E}_{d \sim \pi \cdot \mathbb{D}} \left[\theta(d) - \theta_\pi(d) \right]^2 \quad (6.17)$$

Therefore, if $\Pi \subset \mathcal{M}(\mathcal{A})$ is an admissible set of priors, then (6.17) implies that

$$\inf_{\theta} \sup_{\pi \in \Pi} \mathcal{E}(\theta, \pi) \geq \sup_{\pi \in \Pi} \mathcal{E}(\theta_\pi, \pi).$$

In particular, when $\Pi = \mathcal{M}(\mathcal{A})$ (6.15) implies that

$$\inf_{\theta} \sup_{(f,\mu) \in \mathcal{A}} \mathcal{E}(\theta, (f, \mu)) \geq \sup_{\pi \in \mathcal{M}(\mathcal{A})} \mathcal{E}(\theta_\pi, \pi). \quad (6.18)$$

Therefore, the mean squared error of the best estimator assuming $(f^\dagger, \mu^\dagger) \in \mathcal{A}$ to be unknown is bounded below by the largest mean squared error of the Bayesian estimator obtained by assuming that (f^\dagger, μ^\dagger) is distributed according to some $\pi \in \mathcal{M}(\mathcal{A})$. In the next section, it will be shown that a complete class theorem can be used to obtain that (6.18) is actually an equality. In that case, (6.18) can be used to

quantify the approximate optimality of an estimator by comparing the least upper bound $\sup_{(f,\mu) \in \mathcal{M}(\mathcal{A})} \mathcal{E}(\theta, (f, \mu))$ on the error of that estimator with $\mathcal{E}(\theta_\pi, \pi)$ for a carefully chosen π .

4.3 Complete Class Theorem

A fundamental question is whether (6.18) is an equality: is the adversarial error of the best estimator equal to the non-adversarial error of the worst Bayesian estimator? Is the best estimator Bayesian or an approximation thereof? A remarkable result of decision theory [156–158, 160, 161] is the complete class theorem which states (in the formulation of this paper) that if (1) the admissible measures μ are absolutely continuous with respect the Lebesgue measure, (2) the loss function V in the definition of $\mathcal{E}(\theta, (f, \mu))$ is convex in θ and (3) the decision space is compact, then optimal estimators live in the Bayesian class and non-Bayesian estimators cannot be optimal. The idea of the proof of this result is to use the compactness of the decision space and the continuity of the loss function to approximate the decision theory game by a finite game and recall that optimal strategies of adversarial finite zero-sum games are mixed strategies [99, 100].

Le Cam [81], see also [83], has substantially extended Wald's theory in the sense that requirements of boundedness, or even finiteness, of the loss function are replaced by a requirement of lower semicontinuity, and the requirements of the compactness of the decision space and the absolute continuity of the admissible measures with respect the Lebesgue measure are removed. These vast generalizations come at some price of abstraction yet reveal the relevance and utility of an appropriate complete Banach lattice of measures. In particular, this framework of Le Cam appears to facilitate efficient concrete approximation.

As an illustration, let us describe a complete class theorem on a space of admissible measures, without the inclusion of functions, where the observation map consists of taking n -i.i.d. samples, as in Eq. (6.5). Let $\mathcal{A} \subset \mathcal{M}(\mathcal{X})$ be a subset of the Borel probability measures on a topological space \mathcal{X} and consider a quantity of interest $\Phi : \mathcal{A} \rightarrow \mathbb{R}$. For $\mu \in \mathcal{A}$, the data d is generated by i.i.d. sampling with respect to μ^n . That is $d \sim \mu^n$. For $\mu^\dagger \in \mathcal{A}$, the statistical error $\mathcal{E}(\theta, \mu^\dagger)$ of an estimator $\theta : \mathcal{X}^n \rightarrow \mathbb{R}$ of $\Phi(\mu^\dagger)$ is defined in terms of a loss function $V : \mathbb{R} \rightarrow \mathbb{R}$ as in (6.5). Define the least upper bound on that statistical error and the sharpest estimator as in (6.6) and (6.7).

Let $\Theta := \{\theta : \mathcal{X}^n \rightarrow \mathbb{R}, \theta \text{ measurable}\}$ denote the space of estimators. Since, in general, the game $\mathcal{E}(\theta, \mu)$, $\theta \in \Theta$, $\mu \in \mathcal{A}$ will not have a value, that is, one will have a strict inequality:

$$\sup_{\mu \in \mathcal{A}} \inf_{\theta \in \Theta} \mathcal{E}(\theta, \mu) < \inf_{\theta \in \Theta} \sup_{\mu \in \mathcal{A}} \mathcal{E}(\theta, \mu),$$

classical arguments in game theory suggest that one extend to random estimators and random selection in \mathcal{A} . To that end, let the set of randomized estimators $\mathcal{R} := \{\hat{\theta} : \mathcal{X}^n \times \mathcal{B}(\mathbb{R}) \rightarrow [0, 1], \hat{\theta} \text{ Markov}\}$ be the set of Markov kernels.

To define a topology for \mathcal{R} , define a linear space of measures as follows. Let $\mathcal{A}^n := \{\mu^n \in \mathcal{M}(\mathcal{X}^n) : \mu \in \mathcal{A}\}$ denote the corresponding set of measures generating sample data. Say that \mathcal{A}^n is dominated if there exists an $\omega \in \mathcal{M}(\mathcal{X}^n)$ such that every $\mu^n \in \mathcal{A}^n$ is absolutely continuous with respect to ω . According to the Halmos–Savage lemma [50], see also Strasser [139, Lem. 20.3], the set \mathcal{A}^n is dominated if and only if there exists a countable mixture $\mu^* := \sum_{i=1}^{\infty} \alpha_i \mu_i^n$, with $\alpha_i \geq 0, \mu_i \in \mathcal{A}, i = 1, \dots, \infty$, and $\sum_{i=1}^{\infty} \alpha_i = 1$, such that $\mu^n \sim \mu^*, \mu \in \mathcal{A}$. A construct at the heart of Le Cam's approach is a natural linear space notion of a mixture space of \mathcal{A} , called the L -space $L(\mathcal{A}^n) := L^1(\mu^*)$. It follows easily, see [139, Lem. 41.1], that $L(\mathcal{A}^n)$ is the set of signed measures which are absolutely continuous with respect to μ^* . When \mathcal{A} is not dominated, a natural generalization of this construction [139, Def. 41.3] due to Le Cam [81] is used. A crucial property of the L -space $L(\mathcal{A}^n)$ is that not only is it a Banach lattice (see Strasser [139, Cor. 41.4]), but by [139, Lem. 41.5] it is a complete lattice. The utility of the concept of a complete lattice to the complete class theorems can clearly be seen in the proof of the lemma in Section 2 of Wald and Wolfowitz' [163] proof of the complete class theorem when the number of decisions and the number of distributions is finite. Then, the natural action of a randomized estimator on the bounded continuous function/mixture pairs $C_b(R) \times L(\mathcal{A}^n)$ is

$$f \hat{\theta} v := \int \int f(r) \hat{\theta}(x^n, dr) v(dx^n), \quad f \in C_b(R), v \in L(\mathcal{A}^n).$$

Let \mathcal{R} be endowed with the topology of pointwise convergence with respect to this action, that is, the weak topology with respect to integration against $C_b(R) \times L(\mathcal{A}^n)$. Moreover, this weak topology also facilitates a definition of the space $\overline{\mathcal{R}}$ of *generalized* random estimators as bilinear real-valued maps $\vartheta : C_b(R) \times L(\mathcal{A}^n) \rightarrow \mathbb{R}$ satisfying $|\vartheta(f, \mu)| \leq \|f\|_{\infty} \|\mu\|$, $\vartheta(f, \mu) \geq 0$ for $f \geq 0, \mu \geq 0$, and $\vartheta(1, \mu) = \mu(\mathcal{X})$. By [139, Thm. 42.3], the set of generalized random estimators $\overline{\mathcal{R}}$ is compact and convex, and by [139, Thm. 42.5] of Le Cam [82], \mathcal{R} is dense in $\overline{\mathcal{R}}$ in the weak topology. Moreover, when \mathcal{A}^n is dominated and one can restrict to a compact subset $C \in \mathbb{R}$ of the decision space, then Strasser [139, Cor. 42.8] asserts that $\overline{\mathcal{R}} = \mathcal{R}$.

Returning to our illustration, if one let $W_\mu, \mu \in \mathcal{A}$ be defined by $W_\mu(r) := V(r - \Phi(\mu))$, $r \in \mathbb{R}, \mu \in \mathcal{A}$ denote the associated family of loss functions, one can now define a generalization of the statistical error function $\mathcal{E}(\theta, \mu)$ of (6.5) to randomized estimators $\hat{\theta}$ by

$$\mathcal{E}(\hat{\theta}, \mu) := \int \int W_\mu(r) \hat{\theta}(x^n, dr) \mu^n(dx^n), \quad \hat{\theta} \in \mathcal{R}, \mu \in \mathcal{A}.$$

This definition reduces to the previous one (6.5) when the random estimator $\hat{\theta}$ corresponds to a point estimator θ and extends naturally to $\overline{\mathcal{R}}$. Finally, one says that an estimator $\vartheta^* \in \overline{\mathcal{R}}$ is Bayesian if there exists a probability measure m with finite support on \mathcal{A} such that

$$\int \mathcal{E}(\vartheta^*, \mu) m(d\mu) \leq \int \mathcal{E}(\vartheta, \mu) m(d\mu), \quad \vartheta \in \overline{\mathcal{R}}.$$

The following complete class theorem follows from Strasser [139, Thm. 47.9, Cor. 42.8] since one can naturally compactify the decision space \mathbb{R} when the quantity of interest Φ is bounded and the loss function V is sublevel compact, that is has compact sublevel sets.

Theorem 1. *Suppose that the loss function V is sublevel compact and the quantity of interest $\Phi : \mathcal{A} \rightarrow \mathbb{R}$ is bounded. Then, for each generalized randomized estimator $\vartheta \in \overline{\mathcal{R}}$, there exists a weak limit $\vartheta^* \in \overline{\mathcal{R}}$ of Bayesian estimators such that*

$$\mathcal{E}(\vartheta^*, \mu) \leq \mathcal{E}(\vartheta, \mu), \quad \mu \in \mathcal{A}.$$

If, in addition, \mathcal{A} is dominated, then there exists such a $\vartheta^* \in \mathcal{R}$.

A comprehensive connection of these results, where Bayesian estimators are defined only in terms of measures of finite support on \mathcal{A} , with the framework of Sect. 4 where Bayesian estimators are defined in terms of Borel measures on \mathcal{A} , is not available yet. Nevertheless it appears that much can be done in this regard. In particular, one can suspect that when \mathcal{A} is a closed convex set of probability measures equipped with the weak topology and \mathcal{X} is a Borel subset of a Polish space, that if the loss function V is convex and Φ is affine and measurable, the Choquet theory of Winkler [168, 169] can be used to facilitate this connection. Indeed, as mentioned above, complete class theorems are available for much more general loss functions than continuous or convex, more general decision spaces than \mathbb{R} , and without absolute continuity assumptions. Moreover, it is interesting to note that, although randomization was introduced to obtain minmax results, when the loss function V is strictly convex, Bayesian estimators can be shown to be *non-random*. This can be explicitly observed in the definition (6.16) of Bayesian estimators when $V(x) := x^2$ and is understood much more generally in Dvoretzky, Wald, and Wolfowitz [33]. We conjecture that further simplifications can be obtained by allowing *approximate* versions of complete class theorems, Bayesian estimators, optimality, and saddle points, as in Scovel, Hush, and Steinwart's [129] extension of classical Lagrangian duality theory to include approximations.

5 Incorporating Complexity and Computation

Although decision theory provides well-posed notions of optimality and performance in statistical estimation, it does not address the complexity of the actual computation of optimal or nearly optimal estimators and their evaluation against the data. Indeed, although the abstract identification of an optimal estimator as the solution of an optimization problem provides a clear objective, practical applications

require the actual implementation of the estimator on a machine and its numerical evaluation against the data.

5.1 Machine Wald

The simultaneous emphasis on *performance* and *computation* can be traced back to PAC (probably approximately correct) learning initiated by Valiant [149] which has laid down the foundations of machine learning (ML). Indeed, as asserted by Wasserman in his 2013 lecture, “The Rise of the Machines” [164, Sec. 1.5]:

There is another interesting difference that is worth pondering. Consider the problem of estimating a mixture of Gaussians. In Statistics we think of this as a solved problem. You use, for example, maximum likelihood which is implemented by the EM algorithm. But the EM algorithm does not solve the problem. There is no guarantee that the EM algorithm will actually find the MLE; it's a shot in the dark. The same comment applies to MCMC methods. In ML, when you say you've solved the problem, you mean that there is a polynomial time algorithm with provable guarantees.

That is, on even par with the rigorous performance analysis, machine learning also requires that solutions be efficiently implementable on a computer, and often such efficiency is established by proving bounds on the amount of computation required to produce such a solution with a given algorithm. Although Wald’s theory of optimal statistical decisions has resulted in many important statistical discoveries, looking through the three Lehmann symposia of Rojo and Pérez–Abreu [126] in 2004 and Rojo [124, 125] in 2006 and 2009, it is clear that the incorporation of the analysis of the computational algorithm, both in terms of its computational efficiency and its statistical optimality, has not begun. Therefore a natural answer to fundamental challenges in UQ appears to be the full incorporation of *computation* into a natural generalization of Wald’s statistical decision function framework, producing a framework one might call *Machine Wald*.

5.2 Reduction Calculus

The resolution of minimax problems (6.11) require, at an abstract level, searching in the space of all possible functions of the data. By restricting models to the Bayesian class, the complete class theorem allows to limit this search to prior distributions on \mathcal{A} , i.e., to measure over spaces of measures and functions. To enable the computation of these models, it is therefore necessary to identify conditions under which Minimax problems over measures over spaces of measures and functions can be reduced to the manipulation of finite-dimensional objects and develop the associated reduction calculus. For min or max problems over measures over spaces of measures (and possibly functions), this calculus can take the form of a reduction to a nesting of optimization problems over measures (and possibly functions for the inner part) [109, 112, 113], which, in turn, can be reduced to searches over extreme points [51, 110, 114, 142].

5.3 Stopping Conditions

Many of these optimization problems will not be tractable. However even in the tractable case, which has rigorous guarantees on the amount of computation required to obtain an approximate optima, it will be useful to have stopping criteria for the specific algorithm and the specific problem instance under consideration, which can be used to guarantee when an approximate optima has been achieved. Although in the intractable case no such guarantee will exist in general, intelligent choices of algorithms may result in the attainment of approximate optima and such tests guarantee that fact. Ermoliev, Gaivoronski, and Nedeva [36] successfully develop such stopping criteria using Lagrangian duality and generalized Bender's decompositions by Geoffrion [46] for certain stochastic optimization problems which are also relevant here. In addition, the approximation of intractable problems by tractable ones will be important. Recently, Hanasusanto, Roitch, Kuhn, and Wiesemann [53] derive explicit conic reformulations for tractable problem classes and suggest efficiently computable conservative approximations for intractable ones.

5.4 On the Borel-Kolmogorov Paradox

An oftentimes overlooked difficulty with Bayesian estimators lies in the fact that for a prior $\pi \in \mathcal{M}(\mathcal{A})$, the posterior (6.12) is not a measurable function of d but a convex set $\Theta(\pi)$ of measurable functions θ of d that are almost surely equal to each other under the measure $\pi \cdot \mathbb{D}$ on \mathcal{D} .

A notorious pathological consequence is the Borel–Kolmogorov paradox (see Chapter 5 of [76] and Section 15.7 of [63]). Recall that in the formulation of this paradox, one considers the uniform distribution on the two-dimensional sphere and one is interested in obtaining the conditional distribution associated with a great circle of that sphere. If the problem is parameterized in spherical coordinates, then the resulting conditional distribution is uniform for the equator but nonuniform for the longitude corresponding to the prime meridian. The following theorem suggests that this paradox is generic and dissipates the idea that it could be limited to fabricated toy examples. See also Singpurwalla and Swift [132] for implications of this paradox in modeling and inference.

Recall that for $\pi \in \mathcal{M}(\mathcal{A})$, that $\Theta(\pi)$ is defined as the convex set of measurable functions which are equal to $\pi \cdot \mathbb{D}$ -everywhere to the regular conditional expectation (6.12). Despite this indeterminateness, it is comforting to know that

$$\mathcal{E}(\theta_2, \pi) = \mathcal{E}(\theta_1, \pi), \quad \theta_1, \theta_2 \in \Theta(\pi).$$

Moreover, it is also easy to see that if π^\dagger is absolutely continuous with respect to π , then $\theta_1(d) = \theta_2(d)$ with $\pi^\dagger \cdot \mathbb{D}$ probability one for all $\theta_1, \theta_2 \in \Theta(\pi)$, and consequently

$$\mathcal{E}(\theta_2, \pi^\dagger) = \mathcal{E}(\theta_1, \pi^\dagger), \quad \theta_1, \theta_2 \in \Theta(\pi), \quad \pi^\dagger \prec \pi,$$

where the notation $\pi^\dagger \prec \pi$ means that π^\dagger is absolutely continuous with respect to π . The following theorem shows that this requirement of absolute continuity is necessary for all versions of conditional expectations $\theta \in \Theta(\pi)$ to share the same risk. See Sect. 6 for its proof.

Theorem 2. *Assume that $V(x) = x^2$ and that the image $\Phi(\mathcal{A})$ is a nontrivial interval. If π^\dagger is not absolutely continuous with respect to π then*

$$\frac{1}{4} \leq \frac{\sup_{\theta_1, \theta_2 \in \Theta(\pi)} (\mathcal{E}(\theta_2, \pi^\dagger) - \mathcal{E}(\theta_1, \pi^\dagger))}{(\mathcal{U}(\mathcal{A}) - \mathcal{L}(\mathcal{A}))^2 \sup_{B \in \mathcal{B}(\mathcal{D}): (\pi \cdot \mathbb{D})[B] = 0} (\pi^\dagger \cdot \mathbb{D})[B]} \leq 1 \quad (6.19)$$

where $\mathcal{U}(\mathcal{A})$ and $\mathcal{L}(\mathcal{A})$ are defined by (6.2) and (6.3).

Remark 3. If moreover $\pi^\dagger \cdot \mathbb{D}$ is orthogonal to $\pi \cdot \mathbb{D}$, that is, there exists a set $B \in \mathcal{B}(\mathcal{D})$ such that $(\pi \cdot \mathbb{D})[B] = 0$ and $(\pi^\dagger \cdot \mathbb{D})[B] = 1$, then Theorem 2 implies that $\sup_{\theta_1, \theta_2 \in \Theta(\pi)} (\mathcal{E}(\theta_2, \pi^\dagger) - \mathcal{E}(\theta_1, \pi^\dagger))$ is larger than the statistical error of the midpoint estimator

$$\theta := \frac{\mathcal{L}(\mathcal{A}) + \mathcal{U}(\mathcal{A})}{2}.$$

As a remedy, one can try (see [144, 145] and [117]) constructing conditional expectations as disintegration or derivation limits defined as

$$\mathbb{E}_{\pi \odot \mathbb{D}} [\Phi(f, \mu) | D = d] = \lim_{B \downarrow \{d\}} \mathbb{E}_{\pi \odot \mathbb{D}} [\Phi(f, \mu) | D \in B] \quad (6.20)$$

where the limit $B \downarrow \{d\}$ is taken over a net of open neighborhoods of d . But as shown in [66], the limit generally depends on the net $B \downarrow \{d\}$ and the resulting conditional expectations can be distinctly different for different nets. Furthermore the limit (6.20) may exist/not exist on subsets of \mathcal{D} of $(\pi \cdot \mathbb{D})$ -measure zero (which, as shown above, can lead to the inconsistency of the estimator). A related important issue is that conditional probabilities can in general not be computed [2]. Observe that if the limit (6.20) does not exist, then Bayesian estimation of $\Phi(f, \mu)$ may have significant oscillations as the precise measurement of d becomes sharper.

5.5 On Bayesian Robustness/Brittleness

As much as classical numerical analysis shows that there are stable and unstable ways to discretize a partial differential equation, positive [13, 23, 28, 75, 80, 140, 152] and negative results [6, 27, 42, 43, 65, 84, 108, 109, 112, 113] are forming an emerging understanding of stable and unstable ways to apply Bayes' rule in practice. One

aspect of stability concerns the sensitivity of posterior conclusions with respect to the underlying models and prior beliefs.

Most statisticians would acknowledge that an analysis is not complete unless the sensitivity of the conclusions to the assumptions is investigated. Yet, in practice, such sensitivity analyses are rarely used. This is because sensitivity analyses involve difficult computations that must often be tailored to the specific problem. This is especially true in Bayesian inference where the computations are already quite difficult. [165]

Another aspect concerns situations where Bayes' rule is applied iteratively and posterior values become prior values for the next iteration. Observe in particular that when posterior distributions (which are later on used as prior distributions) are only approximated (e.g., via MCMC methods), stability requires the convergence of the MCMC method in the same metric used to quantify the sensitivity of posterior with respect to the prior distributions.

In the context of the framework being developed here, recent results [108, 109, 112, 113] on the extreme sensitivity (brittleness) of Bayesian inference in the TV and Prokhorov metrics appear to suggest that robust inference, in a continuous world under finite-information, should perhaps be done with reduced/coarse models rather than highly sophisticated/complex models (with a level of coarseness/reduction depending on the available finite information) [113].

5.6 Information-Based Complexity

From the point of view of practical applications, it is clear that the set of possible models entering in the minimax problem 6.11 must be restricted by introducing constraints on computational complexity. For example, finding optimal models of materials in extreme environments is not the correct objective when these models require full quantum mechanics calculations. A more productive approach is to search for computationally tractable optimal models in a given complexity class. Here one may wonder if Bayesian models remain a complete class for the resulting complexity constrained minimax problems. It is also clear that computationally tractable optimal models may not use all the available information, for instance, a material model of bounded complexity should not use the state of every atom. The idea that fast computation requires computation with partial information forms the core of information-based complexity, the branch of computational complexity that studies the complexity of approximating continuous mathematical operations with discrete and finite ones up to a specified level of accuracy [101, 115, 146, 171, 172], where it is also augmented by concepts of contaminated and priced information associated with, for example, truncation errors and the cost of numerical operations. Recent results [107] suggest that decision theory concepts could be used, not only to identify reduced models but also algorithms of near-optimal complexity by reformulating the process of computing with partial information and limited resources as that of playing underlying hierarchies of adversarial information games.

6 Conclusion

Although uncertainty quantification is still in its formative stage, much like the state of probability theory before its rigorous formulation by Kolmogorov in the 1930s, it has the potential to have an impact on the process of scientific discovery that is similar to the advent of scientific computing. Its emergence remains sustained by the persistent need to make critical decisions with partial information and limited resources. There are many paths to its development, but one such path appears to be the incorporation of notions of computation and complexity in a generalization of Wald's decision framework built on Von Neumann's theory of adversarial games.

Appendix

Construction of $\pi \odot \mathbb{D}$

The below construction works when $\mathcal{A} \subseteq \mathcal{G} \times \mathcal{M}(\mathcal{X})$ for some Polish subset $\mathcal{G} \subset \mathcal{F}(\mathcal{X})$ and \mathcal{X} is Polish. Observe that since \mathcal{D} is metrizable, it follows from [4, Thm. 15.13], that, for any $B \in \mathcal{B}(\mathcal{D})$, the evaluation $v \mapsto v(B)$, $v \in \mathcal{M}(\mathcal{D})$, is measurable. Consequently, the measurability of \mathbb{D} implies that the mapping

$$\widehat{\mathbb{D}}: \mathcal{A} \times \mathcal{B}(\mathcal{D}) \rightarrow R$$

defined by

$$\widehat{\mathbb{D}}((f, \mu), B) := \mathbb{D}(f, \mu)[B], \quad \text{for } (f, \mu) \in \mathcal{A}, B \in \mathcal{B}(\mathcal{D})$$

is a transition function in the sense that, for fixed $(f, \mu) \in \mathcal{A}$, $\widehat{\mathbb{D}}((f, \mu), \cdot)$ is a probability measure, and, for fixed $B \in \mathcal{B}(\mathcal{D})$, $\widehat{\mathbb{D}}(\cdot, B)$ is Borel measurable. Therefore, by [18, Thm. 10.7.2], any $\pi \in \mathcal{M}(\mathcal{A})$ defines a probability measure

$$\pi \odot \mathbb{D} \in \mathcal{M}(\mathcal{B}(\mathcal{A}) \times \mathcal{B}(\mathcal{D}))$$

through

$$\pi \odot \mathbb{D}[A \times B] := \mathbb{E}_{(f, \mu) \sim \pi} [\mathbb{1}_A(f, \mu) \mathbb{D}(f, \mu)[B]], \quad \text{for } A \in \mathcal{B}(\mathcal{A}), B \in \mathcal{B}(\mathcal{D}), \quad (6.21)$$

where $\mathbb{1}_A$ is the indicator function of the set A :

$$\mathbb{1}_A(f, \mu) := \begin{cases} 1, & \text{if } (f, \mu) \in A, \\ 0, & \text{if } (f, \mu) \notin A. \end{cases}$$

It is easy to see that π is the \mathcal{A} -marginal of $\pi \odot \mathbb{D}$. Moreover, when \mathcal{X} is Polish, [4, Thm. 15.15] implies that $\mathcal{M}(\mathcal{X})$ is Polish, and when \mathcal{G} is Polish, it follows that $\mathcal{A} \subseteq \mathcal{G} \times \mathcal{M}(\mathcal{X})$ is second countable. Consequently, since \mathcal{D} is Suslin and hence second countable, it follows from [32, Prop. 4.1.7] that

$$\mathcal{B}(\mathcal{A} \times \mathcal{D}) = \mathcal{B}(\mathcal{A}) \times \mathcal{B}(\mathcal{D})$$

and hence $\pi \odot \mathbb{D}$ is a probability measure on $\mathcal{A} \times \mathcal{D}$. That is,

$$\pi \odot \mathbb{D} \in \mathcal{M}(\mathcal{A} \times \mathcal{D}).$$

Henceforth denote $\pi \cdot \mathbb{D}$ the corresponding Bayes' sampling distribution defined by the \mathcal{D} -marginal of $\pi \odot \mathbb{D}$, and note that by (6.21), one has

$$\pi \cdot \mathbb{D}[B] := \mathbb{E}_{(f,\mu) \sim \pi} [\mathbb{D}(f, \mu)[B]], \quad \text{for } B \in \mathcal{B}(\mathcal{D}).$$

Since both \mathcal{D} and \mathcal{A} are Suslin, it follows that the product $\mathcal{A} \times \mathcal{D}$ is Suslin. Consequently, [18, Cor. 10.4.6] asserts that regular conditional probabilities exist for any sub- σ -algebra of $\mathcal{B}(\mathcal{A} \times \mathcal{D})$. In particular, the product theorem of [18, Thm. 10.4.11] asserts that product regular conditional probabilities

$$(\pi \odot \mathbb{D})|_d \in \mathcal{M}(\mathcal{A}), \quad \text{for } d \in \mathcal{D}$$

exist and that they are $\pi \cdot \mathbb{D}$ -a.e. unique.

Proof of Theorem 2

If $\pi^\dagger \cdot \mathbb{D}$ is not absolutely continuous with respect to $\pi \cdot \mathbb{D}$, then there exists $B \in \mathcal{B}(\mathcal{D})$ such that $(\pi \cdot \mathbb{D})[B] = 0$ and $(\pi^\dagger \cdot \mathbb{D})[B] > 0$. Let $\theta \in \Theta(\pi)$. Define

$$\theta_y(d) := \theta(d)1_{B^c}(d) + y1_B(d) \tag{6.22}$$

Then it is easy to see that if y is in the range of Φ , then $\theta_y \in \Theta(\pi)$. Now observe that for $y, z \in \text{Image}(\Phi)$,

$$\mathcal{E}(\theta_y, \pi^\dagger) - \mathcal{E}(\theta_z, \pi^\dagger) = \mathbb{E}_{(f,\mu,d) \sim \pi^\dagger \odot \mathbb{D}} \left[1_B(d) \left(V(y - \Phi(f, \mu)) - V(z - \Phi(f, \mu)) \right) \right]$$

Hence, for $V(x) = x^2$, it holds true that

$$\mathcal{E}(\theta_y, \pi^\dagger) - \mathcal{E}(\theta_z, \pi^\dagger) = [(y - \gamma)^2 - (z - \gamma)^2](\pi^\dagger \cdot \mathbb{D})[B]$$

with

$$\gamma := \mathbb{E}_{\pi^\dagger \odot \mathbb{D}}[\Phi | D \in B]$$

which proves

$$\begin{aligned} \sup_{\theta_2 \in \Theta(\pi)} \mathcal{E}(\theta_2, \pi^\dagger) - \inf_{\theta_1 \in \Theta(\pi)} \mathcal{E}(\theta_1, \pi^\dagger) &\geq \sup_{B \in \mathcal{B}(\mathcal{D}) : (\pi \cdot \mathbb{D})[B] = 0, y, z \in \text{Image}(\Phi)} \\ &\quad \left[(y - \mathbb{E}_{\pi^\dagger \odot \mathbb{D}}[\Phi | D \in B])^2 - (z - \mathbb{E}_{\pi^\dagger \odot \mathbb{D}}[\Phi | D \in B])^2 \right] (\pi^\dagger \cdot \mathbb{D})[B], \end{aligned}$$

and,

$$\sup_{\theta_2 \in \Theta(\pi)} \mathcal{E}(\theta_2, \pi^\dagger) - \inf_{\theta_1 \in \Theta(\pi)} \mathcal{E}(\theta_1, \pi^\dagger) \leq (\mathcal{U}(\mathcal{A}) - \mathcal{L}(\mathcal{A}))^2 \sup_{B \in \mathcal{B}(\mathcal{D}) : (\pi \cdot \mathbb{D})[B] = 0} (\pi^\dagger \cdot \mathbb{D})[B].$$

To obtain the right hand side of (6.19) observe that (see for instance [29, Sec. 5]) there exists $B^* \in \mathcal{B}(\mathcal{D})$ such that

$$(\pi^\dagger \cdot \mathbb{D})[B^*] = \sup_{B \in \mathcal{B}(\mathcal{D}) : (\pi \cdot \mathbb{D})[B] = 0} (\pi^\dagger \cdot \mathbb{D})[B]$$

and (since $\theta_2 = \theta_1$ on the complement of B^*)

$$\begin{aligned} \sup_{\theta_1, \theta_2 \in \Theta(\pi)} (\mathcal{E}(\theta_2, \pi^\dagger) - \mathcal{E}(\theta_1, \pi^\dagger)) \\ = \sup_{\theta_1, \theta_2 \in \Theta(\pi)} \mathbb{E}_{(f, \mu, d) \sim \pi^\dagger \odot \mathbb{D}} \left[1_{B^*}(d) \left(V(\theta_2 - \Phi(f, \mu)) - V(\theta_1 - \Phi(f, \mu)) \right) \right]. \end{aligned}$$

We conclude by observing that for $V(x) = x^2$,

$$\sup_{\theta_1, \theta_2 \in \Theta(\pi)} \left(V(\theta_2 - \Phi(f, \mu)) - V(\theta_1 - \Phi(f, \mu)) \right) \leq (\mathcal{U}(\mathcal{A}) - \mathcal{L}(\mathcal{A}))^2.$$

Conditional Expectation as an Orthogonal Projection

It easily follows from Tonelli's Theorem that

$$\mathbb{E}_{\pi \cdot \mathbb{D}}[h^2] = \mathbb{E}_{\pi \odot \mathbb{D}}[h^2] = \mathbb{E}_{(f, \mu) \sim \pi} \mathbb{E}_{\mathbb{D}(f, \mu)}[h^2].$$

By considering the sub σ -algebra $\mathcal{A} \times \mathcal{B}(\mathcal{D}) \subset \mathcal{B}(\mathcal{A} \times \mathcal{D}) = \mathcal{B}(\mathcal{A}) \times \mathcal{B}(\mathcal{D})$, it follows from, e.g., Theorem 10.2.9 of [32], that $L^2_{\pi \cdot \mathbb{D}}(\mathcal{D})$ is a closed Hilbert subspace of the Hilbert space $L^2_{\pi \odot \mathbb{D}}(\mathcal{A} \times \mathcal{D})$ and the conditional expectation of Φ given the random variable D is the orthogonal projection from $L^2_{\pi \odot \mathbb{D}}(\mathcal{A} \times \mathcal{D})$ to $L^2_{\pi \cdot \mathbb{D}}(\mathcal{D})$.

Hierarchical Models for Uncertainty Quantification: An Overview

7

Christopher K. Wikle

Abstract

Analyses of complex processes should account for the uncertainty in the data, the processes that generated the data, and the models that are used to represent the processes and data. Accounting for these uncertainties can be daunting in traditional statistical analyses. In recent years, hierarchical statistical models have provided a coherent probabilistic framework that can accommodate these multiple sources of quantifiable uncertainty. This overview describes a science-based hierarchical statistical modeling approach and the associated Bayesian inference. In addition, given that many complex processes involve the dynamical evolution of spatial processes, an overview of hierarchical dynamical spatio-temporal models is also presented. The hierarchical and spatio-temporal modeling frameworks are illustrated with a problem concerned with assimilating ocean vector wind observations from satellite and weather center analyses.

1 Introduction

Scientists and engineers are increasingly aware of the importance of accurately characterizing various sources of uncertainty when trying to understand complex systems. When performing statistical modeling on complex phenomena, the goal is typically either inference, prediction, or forecasting. To accomplish these goals through modeling, one must synthesize information. This information can come from a variety of sources, including direct (*in situ*) observations, indirect (remotely sensed) observations, surrogate observations, previous empirical results, expert opinion, and scientific principles. In order to make inferential or predictive decisions with a statistical model, one must consider these sources of information in a coherent manner that accounts adequately for the various sources of uncertainty that are present. That is, there may be measurement error, model representativeness error, error associated with differing levels of support between observations and process, parameterization error, and parameter uncertainty. Over the last 20 years or so, one of the most useful statistical paradigms in which to consider complex models in the presence of uncertainty is *hierarchical modeling* (HM). The purpose of this overview is to outline the general principles of science-based statistical HM and its utility to a wide class of processes.

Hierarchical modeling is, at its core, just a system of coherently linked probability relationships. In this sense, it is certainly not a new idea, and from a modeling perspective, such ideas have been at the core of fundamental statistical methods such as mixed models, structural equation models, spatial models, directed acyclic graph models, among others. This class of models might be referred to as “little h” hierarchical models. That is, one is either focused on a data model (i.e., “likelihood”) and parameters, with the process considered a nuisance, or a data model and process model, with the parameters considered a nuisance. The perspective presented in this overview follows more closely the perspective originally outlined by Mark Berliner [4] in a somewhat obscure conference proceedings paper written while he was the director of the Geophysical Statistics Project at the National Center for Atmospheric Research (NCAR) in Boulder, Colorado, USA. In this seminal paper, Berliner presents a simple, yet fundamentally important, way to think about partitioning uncertainty associated with data, processes, and parameters in complex

systems. As described below, the basic tenet of this modeling paradigm is to characterize uncertainty in the joint model of data, process, and parameters in terms of component conditional and marginal distributions, which is often facilitated by the inclusion of scientific information. The advent of this formulation coincided with the so-called computational Bayesian revolution, specifically in terms of Markov chain Monte Carlo (MCMC) methods that were facilitated by the classic paper of [10]. This understanding provided the practical tools necessary to implement these models in the Bayesian context. One of the key components of thinking about models from this perspective is that one deliberately pushes complexity into the conditional mean, in which case subprocesses and parameters are often modeled with fairly complex dependence structures. This [4] hierarchical modeling paradigm might be referred to as a “big H” hierarchical model (HM), to emphasize that the conditional structure and parameter models are fundamental to the HM, not just a nuisance, and that scientific/mechanistic information is included in the various components of the HM.

The chapter begins with a general overview of hierarchical modeling and its Bayesian implementation. This is then followed by an overview of discrete-time spatio-temporal dynamical processes, given their importance as component models in many complex hierarchical modeling applications. A discussion of process and parameter space reduction is included in this overview of spatio-temporal processes. A simple illustrative example based on blending different sources of information for ocean surface vector winds is presented to highlight some of the important components of hierarchical modeling. Finally, a brief conclusion is presented that outlines the trade-offs one has to consider when building complex BHMs.

2 Hierarchical Modeling in the Presence of Uncertainty

This section presents a broad overview of statistical hierarchical modeling. The focus of this presentation is on the role of conditional models and, specifically, the separation of the joint model into coherently linked models for data, process, and parameters. This discussion follows similar discussions in [7, 8, 38], and [43].

To motivate the discussion of HMs, consider a problem in which one has observations of near-surface winds over the ocean from a satellite scatterometer and wishes to “predict” the distribution of complete spatial fields of the true wind across time. That is, there are satellite observations of east-west and north-south wind components that occur at a fairly fine spatial resolution, but are incomplete spatially due to the polar orbit of the satellite, and the goal is to interpolate the observations to form complete spatial fields for a regular sequence of times. In this case, the “process” corresponds to the wind components and, potentially, other relevant atmospheric state variables (e.g., sea-level pressure). In addition to the satellite observations, there is additional information from weather center “analysis” fields (i.e., model output from operational data assimilation systems that combine worldwide weather observations and deterministic weather forecasting models).

It is reasonable to assume that the satellite-derived scatterometer observations have not been used to produce the weather center data assimilation products.

For purposes of this general exposition, let the wind observations (data) be denoted by D . One possible approach to solving the aforementioned interpolation problem is to apply some deterministic curve-fitting interpolation algorithm $\hat{D} = f(D)$ (e.g., linear, polynomial, or spline interpolation). However, such approaches do not account for the uncertainty associated with the observations and, more importantly, do not utilize scientific knowledge to help fill in the data gaps in a physically plausible manner.

A more traditional statistical modeling alternative to this curve-fitting interpolation approach might consider a distribution for the data conditioned on some parameters, say θ_o , which is denoted by $[D | \theta_o]$. Note the use of a bracket notation for distribution, “[],” which is common in the hierarchical modeling literature, where the vertical bar, “|,” denotes conditioning, $[A, B]$ represents the joint distribution of A and B , and $[A | B]$ represents the conditional distribution of A “given” B . In the traditional statistical model, one would seek the parameters, θ_o , that maximize the likelihood of observing the data D . Of course, this assumes that the distributional assumption adequately captures all of the variability (spatial, temporal, multivariate, etc.) in the data, subject to the correct specification of the parameters. Although this is very much a reasonable paradigm in many traditional statistical modeling problems, it is extremely tenuous in the example considered here (and, indeed, most complex physical, biological, or engineering problems) because it is typically not possible to adequately represent the complexity in the data via a single distributional assumption. In particular, this approach does not consider the fact that much of the complexity of the data arises from the scientific *process* (e.g., the atmospheric state variables in the wind example).

2.1 Basic Hierarchical Structure

A scientific modeling approach considers a model for the process of interest, say W here for “wind.” Recognizing the fact that one’s understanding of such scientific processes is always limited, this uncertainty is accounted for via a stochastic representation, denoted by the distribution $[W | \theta_W]$, where θ_W are parameters. The traditional statistical approach described above does not explicitly account for this uncertainty nor the uncertainty about the relationship between D and W . To see this more clearly, one might decompose the joint distribution of the data and the process given the associated parameters as

$$[D, W | \theta_D, \theta_W] = [D | W, \theta_D][W | \theta_W], \quad (7.1)$$

where the parameters in the conditional distribution of D given the process W are denoted by θ_D , which are different than the parameters θ_o for the marginal distribution of the data described above. That is, integrating out the process, W , from (7.1), gives $[D | \theta_o = \{\theta_D, \theta_W\}]$, which implies that the complexity associated

with the process W is present in the marginal form of this data distribution and the associated parameters. Typically, this integration cannot be done analytically, and so one does not know the actual form of this marginal data likelihood nor could one generally account for the complicated multivariate spatio-temporal dependence in such a parameterization for real-world processes (e.g., nonlinearity, nonstationarity, non-Gaussianity). Even in the rare situation where one can do the integration analytically (e.g., Gaussian data and process models), the marginal dependence structure is typically more complicated than can be captured by traditional spatio-temporal parameterizations, that is, the dependence is some complicated function of the parameters θ_D and θ_W . Perhaps more importantly, in the motivating application considered here, the interest is with W , so one does not want to integrate it out of (7.1). Indeed, one typically wants to predict this process distribution. This separation between the data model conditional on the process and the process model is exactly the paradigm in traditional state-space models in engineering and time-series applications [e.g., 29]. More generally, the trade-off between considering a statistical model from the marginal perspective, in which the random process (parameters) are integrated out, and the conditional perspective, in which complicated dependence structures must be parameterized, is just the well-known trade-off that occurs in traditional mixed-model analysis in statistics [e.g., 31].

The decomposition given in (7.1) above is powerful in the sense that it separates the uncertainty associated with the process and the uncertainty associated with the observation of the process. However, it does not factor in the uncertainty associated with the parameters themselves. Utilizing basic probability, one can always decompose a joint distribution into a sequence of conditional and marginal distributions. For example, $[A, B, C] = [A | B, C][B | C][C]$. Thus, the hierarchical decomposition can be written as

$$[D, W, \theta] = [D | W, \theta][W | \theta][\theta], \quad (7.2)$$

where $\theta = \{\theta_D, \theta_W\}$. This hierarchical decomposition is not unique, e.g., it is equally valid probabilistically to write $[A, B, C] = [C | B, A][A | B][B]$, but the decomposition in (7.2) is meaningful scientifically as it implies causality in the sense that the parameters drive the process and the process generates the data, etc. In addition, note that the distributions on the right-hand side (RHS) of (7.2) could be simplified such that $[D | W, \theta] = [D | W, \theta_D]$ and $[W | \theta_W]$, that is, it might be reasonable to assume conditional independence in the parameter decomposition. This is a modeling choice, but it is reasonable in this case based on how the individual data and process distributions were specified above. More generally, it is helpful to consider the following schematic representation of [4] when partitioning uncertainty in hierarchical decompositions as it provides a framework for building probabilistically consistent models:

$$\begin{aligned} [\text{data, process, parameters}] &= [\text{data} | \text{process, parameters}] \\ &\times [\text{process} | \text{parameters}] \times [\text{parameters}]. \end{aligned} \quad (7.3)$$

2.2 Data Models

Each of the stages of the hierarchy given in (7.3) can be decomposed into products of distributions or submodels. For example, say there are three datasets for the near-ocean surface wind process (W) denoted by $D^{(1)}$, $D^{(2)}$, and $D^{(3)}$. These might correspond to the satellite scatterometer data mentioned previously, ocean buoy data, and the weather center analysis data product. These observations need not be coincident nor even of the same spatial or temporal support as the other data nor the process. In this case, the data model might be represented as

$$[D^{(1)}, D^{(2)}, D^{(3)} | W, \theta_D] = [D^{(1)} | W, \theta_D^{(1)}][D^{(2)} | W, \theta_D^{(2)}][D^{(3)} | W, \theta_D^{(3)}], \quad (7.4)$$

where the parameters for each submodel are given by $\theta_D = \{\theta_D^{(1)}, \theta_D^{(2)}, \theta_D^{(3)}\}$. The RHS of (7.4) makes use of the assumption that the three datasets are all conditionally independent given the true process. This is not to say that the data are independent marginally, as they surely are not. Yet, the assumption of conditional independence is a powerful simplifying modeling assumption that is often reasonable in complex systems, but must be justified in practice. It is important to emphasize that the specific forms of the component distributions on the RHS of (7.4) can be quite different from each other, accounting for the differing support and measurement properties associated with the specific dataset. For example, satellite scatterometer wind observations have fairly well-known measurement-error properties and are associated with fairly small areal “footprints” (depending on the specific instrument), but wind observations from an ocean buoy are best considered point-level support with well-calibrated measurement-error properties.

2.3 Process Models

Typically, the process model in the hierarchical decomposition can also be further decomposed into component distributions. For example, in the case of the wind example described here, the wind process is a vector composed of two components, speed and direction or, equivalently, north-south and east-west components that depend on pressure. That is, one might write

$$[W^{(1)}, W^{(2)}, W^{(3)} | \theta_W] = [W^{(1)}, W^{(2)} | W^{(3)}, \theta_W^{(1,2)}][W^{(3)} | \theta_W^{(3)}], \quad (7.5)$$

where $W^{(1)}$ and $W^{(2)}$ correspond to the east-west and north-south wind components (typically denoted by u and v , respectively) and $W^{(3)}$ corresponds to the near-surface atmospheric pressure (typically denoted P). The decomposition in (7.5) is not unique, but is sensible in this case because there is strong scientific justification for conditioning the wind on the pressure [e.g., 14]. The process parameters are again decomposed into those components associated with each distribution, $\theta_W = \{\theta_W^{(1,2)}, \theta_W^{(3)}\}$. The decomposition in (7.5) simplifies the joint dependence structure

between the various process components by utilizing simplifying assumptions based on scientific input. It is important to recognize that these components are still distributions, so that the uncertainties in the relationships (say, between wind and pressure) can be accommodated through appropriate modeling components (e.g., bias and error terms).

Other types of joint interactions in the process can also be simplified through such conditional probability relationships. For example, given that the wind process is time varying, one might be able to make Markov assumptions in time. For example, if W_t corresponds to the wind process at time t for $t = 0, \dots, T$, then

$$[W_0, W_1, \dots, W_T | \theta_W] = \prod_{t=1}^T [W_t | W_{t-1}, \theta_W][W_0], \quad (7.6)$$

represents a first-order Markov assumption, that is, the process is independent of the past if conditioned on the most recent past. This is a significant simplifying assumption, and must be justified in practice, but such assumptions are often very realistic for real-world time-varying processes. Similar sorts of conditioning arguments can be made for networks, spatial processes (e.g., Markov random fields), and spatio-temporal processes (e.g., spatio-temporal dynamical models) as described in [7].

2.4 Parameter Models

An important consequence of the hierarchical modeling paradigm described above is the recognition that additional complexity can be accommodated by allowing the parameters to be random and endowing them with dependence structures (e.g., multivariate, spatial, temporal, etc.). That is, the parameter models can themselves be quite complex and can incorporate additional information, whether that be through exogenous data sources (e.g., a sea-surface temperature index corresponding to the El Niño/La Niña phenomenon) or scientific knowledge (e.g., spatial turbulent scaling relationships). For example, one might write $[\theta_W | X, \theta_X]$, where X is some exogenous covariate and θ_X are parameters. It can be very difficult, if not impossible, to account for such complex parameter dependence structures in the classical modeling approach discussed above.

Now, one must decide how to account for the uncertainty in X and θ_X , which often leads to yet another data or parameter level of the model hierarchy. Typically, at some point, there is no more information that can assist the specification of these distributions, and one either assigns some sort of non-informative distribution to the parameters or, in some cases, estimates them through some other means.

It is apparent that the distinction between “process” and “parameter” may not always be precise. This can be the case in some applications, but the strength of the hierachal paradigm is that it is the complete sequence of the hierarchical decomposition that is important, *not* what one calls “process” or “parameter.”

This suggests that one requires a flexible inferential paradigm that allows one to perform inference and prediction on both process and parameters and even their joint interaction.

2.5 Bayesian Formulation

The Bayesian paradigm fits naturally with hierarchical models because the posterior distribution is proportional to the product distributions in the hierarchical decomposition. For example, in the schematic representation of [4] given in (7.3), the posterior distribution can be written via Bayes' rule as

$$\begin{aligned} [\text{process, parameters} | \text{data}] &\propto [\text{data} | \text{process, parameters}] \\ &\quad \times [\text{process} | \text{parameters}] \times [\text{parameters}], \end{aligned} \quad (7.7)$$

where the normalizing constant is the integral (in the case of continuous distributions) of (7.3) with respect to the process and parameters (i.e., the marginal distribution of the data). In the context of the wind example, the posterior distribution can be written

$$[W, \theta_W, \theta_D | D] \propto [D | W, \theta_D][W | \theta_W][\theta_D, \theta_W]. \quad (7.8)$$

In practice, it is not typically possible to calculate the normalizing constant ($1/[D]$) analytically. With the understanding that Markov chain Monte Carlo (MCMC) methods could be used generally for such purposes (i.e., after the seminal paper of [10]), this has not been a serious limitation.

MCMC methods seek to draw simulation samples from a distribution that coincides with the posterior distribution of interest. In particular, a Markov chain is constructed algorithmically such that samples from the stationary distribution of the Markov chain correspond to samples from the desired posterior distribution. Details of the implementation of such algorithms are beyond the scope of this overview, but they can be found in references such as [25] and [6]. Alternatively, approximate solutions can sometimes be found with less computational burden, such as with variational methods, approximate Bayesian computation (ABC), and integrated nested Laplace approximations (INLA) [e.g., 21, 27, 30]. In general, one must find trade-offs between model complexity and computational complexity when building complex statistical models in the presence of uncertainty (see the Conclusion of this chapter).

In some simpler modeling situations (e.g., state-space models), one might be content with assuming the parameters are fixed but unknown rather than assign them distributions. In that case, one could write (7.8) as

$$[W | D, \theta_W, \theta_D] \propto [D | W, \theta_D][W | \theta_W]. \quad (7.9)$$

In applications where the component models are not too complex, these parameters can be estimated using classical statistical approaches, and then the parameters are used in a “plug-in” fashion in the model. For example, in state-space modeling, one might estimate the parameters through an E-M algorithm and then evaluate the process distributions through a Kalman filter/smooth [e.g., 29]. Such an approach is sometimes called “empirical Bayes” or, in the context of hierarchical models, empirical hierarchical modeling (EHM) [e.g., 7]. A potential concern using such an approach is accounting for the uncertainty in the parameter estimation. In some cases, this uncertainty can be accounted for by Taylor approximations or bootstrap resampling methods [e.g., 29]. Typically, in complex models, the BHM framework provides a more sensible approach to uncertainty quantification than EHM approaches.

3 Dynamical Spatio-temporal Process Models

The motivating wind example discussed above can be thought of as a data assimilation (DA) problem. [33] characterize DA as a set of methods that blend observations with prior system knowledge in an optimal way in order to obtain a distributional summary of a process of interest. In this context, “system knowledge” can correspond to deterministic models, scientific/mechanistic relationships, model output, and expert opinion. As summarized in [33], there is a large literature in the physical sciences dedicated to various methods for DA. In many ways, this is just a type of inverse modeling, and many different solution approaches are possible. However, if DA is considered from a BHM perspective, then one can gain a more comprehensive characterization of the uncertainty associated with the data, process, and parameters. From a statistical perspective, these methods typically require a dynamical spatio-temporal model (DSTM) of some sort. Hence, this section gives a brief overview of hierarchical DSTMs. More complete details can be found in [7] and [40]. This overview considers only DSTMs from a discrete-time perspective for the sake of brevity. However, it should be noted that many science-oriented process models are specified from a continuous time perspective (e.g., differential equations) and these can be used either to motivate HMs or can be implemented directly within the HM framework (e.g., [4]).

The data model in a general DSTM can be written

$$Z_t(\cdot) = \mathcal{H}(Y_t(\cdot), \theta_d(t), \epsilon_t(\cdot)), \quad t = 1, \dots, T,$$

where $Z_t(\cdot)$ corresponds to the data at time t and $Y_t(\cdot)$ is the corresponding latent process of interest, with a linear or nonlinear mapping function, $\mathcal{H}(\cdot)$, that relates the data to the latent process. The data model error is given by $\epsilon_t(\cdot)$, and data model parameters are represented by $\theta_d(t)$. These parameters may vary spatially and/or temporally in general. As discussed more generally above, an important assumption that is present here, and in many hierarchical representations of DSTMs, is that the data $Z_t(\cdot)$ are independent in time when conditioned on the true process, $Y_t(\cdot)$

and parameters $\boldsymbol{\theta}_d(t)$. Thus, the observations conditioned on the true process and parameters can be represented

$$\prod_{t=1}^T [Z_t(\cdot) \mid Y_t(\cdot), \boldsymbol{\theta}_d(t)].$$

The key component of the DSTM is the dynamical process model. As discussed above, one can simplify this by making use of conditional independence through Markov assumptions. For example, a first-order Markov process can be written as

$$[Y_t(\cdot) | Y_{t-1}(\cdot), \dots, Y_0(\cdot), \{\boldsymbol{\theta}_p(t), t = 0, \dots, T\}] = [Y_t(\cdot) | Y_{t-1}(\cdot), \boldsymbol{\theta}_p(t)],$$

for $t = 1, 2, \dots$ so that

$$\begin{aligned} [Y_0(\cdot), Y_1(\cdot), \dots, Y_T(\cdot) | \{\boldsymbol{\theta}_p(t), t = 0, \dots, T\}] &= \prod_{t=1}^T [Y_t(\cdot) | Y_{t-1}(\cdot), \boldsymbol{\theta}_p(t)] \\ &\quad \times [Y_0(\cdot) | \boldsymbol{\theta}_p(0)]. \end{aligned} \quad (7.10)$$

Higher-order Markov assumptions could be considered if warranted by the specific problem of interest. Such relationships are critical for real-world spatio-temporal processes because they follow the etiology of process development.

Now, the modeling focus is on the component Markov models in (7.10). For example, a first-order process can be written generally as

$$Y_t(\cdot) = \mathcal{M}(Y_{t-1}(\cdot), \boldsymbol{\theta}_p(t), \eta_t(\cdot)), \quad t = 1, 2, \dots, \quad (7.11)$$

where $\mathcal{M}(\cdot)$ is the evolution operator (linear or nonlinear), $\eta_t(\cdot)$ is the noise (error) process, and $\boldsymbol{\theta}_p(t)$ are process model parameters that may vary with time and/or space. Typically, one would also specify a distribution for the initial state, $[Y_0(\cdot) | \boldsymbol{\theta}_p(0)]$.

The hierarchical model then requires distributions to be assigned to the parameters $\{\boldsymbol{\theta}_d(t), \boldsymbol{\theta}_p(t), t = 0, \dots, T\}$. Specific distributional forms for the parameters (e.g., spatially or temporally varying, dependence on auxiliary covariate information, etc.) depend strongly on the problem of interest. Indeed, as mentioned above, one of the most critical aspects of complex hierarchical modeling is the specification of these distributions. This is illustrated below with regard to linear and nonlinear DSTMs.

3.1 Linear DSTM Process Models

In the case where one has a discrete set of spatial locations $D_s = \{\mathbf{s}_1, \mathbf{s}_2, \dots, \mathbf{s}_n\}$ of interest (e.g., a lattice or grid), the first-order evolution process model (7.11) can be written as

$$Y_t(\mathbf{s}_i) = \sum_{j=1}^n m_{ij}(\boldsymbol{\theta}_m) Y_{t-1}(\mathbf{s}_j) + \eta_t(\mathbf{s}_i), \quad (7.12)$$

for $t = 1, 2, \dots$, with redistribution (transition) components $m_{ij}(\boldsymbol{\theta}_m)$ that depend on parameters $\boldsymbol{\theta}_m$. If interest is in continuous space and discrete time, one can also write this in terms of an *integro-difference equation (IDE)*

$$Y_t(\mathbf{s}) = \int_{D_s} m(\mathbf{s}, \mathbf{x}; \boldsymbol{\theta}_m) Y_{t-1}(\mathbf{x}) d\mathbf{x} + \eta_t(\mathbf{s}), \quad \mathbf{s}, \mathbf{x} \in D_s, \quad (7.13)$$

for $t = 1, 2, \dots$, where $m(\mathbf{s}, \mathbf{x}; \boldsymbol{\theta}_m)$ is a *transition kernel* that gives redistribution weights for process at the previous time and $\eta_t(\mathbf{s})$ is a time-varying (continuous) spatial error process. Analogous stochastic partial differential equation models could be specified for continuous time and space.

Now, denoting the process vector $\mathbf{Y}_t \equiv (Y_t(\mathbf{s}_1), \dots, Y_t(\mathbf{s}_n))'$, (7.12) can be written in vector/matrix form as a first-order vector autoregression (VAR(1)) DSTM

$$\mathbf{Y}_t = \mathbf{M}\mathbf{Y}_{t-1} + \boldsymbol{\eta}_t, \quad (7.14)$$

where the $n \times n$ transition matrix is given by \mathbf{M} with elements $\{m_{ij}\}$ with the associated time-varying spatial error process given by $\boldsymbol{\eta}_t \equiv (\eta_t(\mathbf{s}_1), \dots, \eta_t(\mathbf{s}_n))'$, which is typically specified to be zero mean and Gaussian, with spatial variance-covariance matrix \mathbf{C}_η . Usually, \mathbf{M} and \mathbf{C}_η are assumed to depend on parameters $\boldsymbol{\theta}_m$ and $\boldsymbol{\theta}_\eta$, respectively, to mitigate the curse of dimensionality that often occurs in spatio-temporal modeling. As discussed below, the parameterization of these matrices is one way that additional mechanistic information can be incorporated into the HM framework.

3.2 Nonlinear DSTM Process Models

Many mechanistic processes are best modeled nonlinearly, at least at some spatial and temporal scales of variability. A class of nonlinear statistical DSTMs can be specified to accommodate such processes with quadratic interactions. Such a *general quadratic nonlinear (GQN)* DSTM [35] can be written as

$$Y_t(\mathbf{s}_i) = \sum_{j=1}^n m_{ij} Y_{t-1}(\mathbf{s}_j) + \sum_{k=1}^n \sum_{\ell=1}^n b_{i,k\ell} Y_{t-1}(\mathbf{s}_k) g(Y_{t-1}(\mathbf{s}_\ell); \boldsymbol{\theta}_g) + \eta_t(\mathbf{s}_i), \quad (7.15)$$

where m_{ij} are the linear transition coefficients seen previously and quadratic interaction transition coefficients are denoted by $b_{i,k\ell}$. A transformation of one of the components of the quadratic interaction is specified through the function $g(\cdot)$, which can depend on parameters $\boldsymbol{\theta}_g$. This function $g(\cdot)$ is responsible for the “general” in GQN, and such transformations are critical for many processes such as density-dependent growth that one may see in an epidemic or invasive species

population process. The spatio-temporal error process is again typically assumed to be independent in time and Gaussian with mean zero and a spatial covariance matrix. Note that the conditional GQN model is Gaussian, but the marginal model will not in general be Gaussian because of the nonlinear interactions.

3.3 Multivariate DSTM Process Models

There are three primary approaches to modeling multivariate spatio-temporal dynamical processes in statistics. An obvious approach is to simply *augment* the process vector (e.g., concatenating the process vectors for a given time) and then using one of the univariate models (such as described above) to model the evolution of the process. That is, if there are J processes given by $\{\mathbf{Y}_t^{(j)}\}$, $j = 1, \dots, J$, then for time t one could write $\mathbf{W}_t \equiv (\mathbf{Y}_t^{(1)'}, \dots, \mathbf{Y}_t^{(J)'})'$ and then evolve \mathbf{W}_t as above. The simplicity of this approach is appealing, but it is often more difficult to incorporate scientific information into the process evolution. Perhaps more critically, this often leads to very high-dimensional process vectors, which compounds the curse of dimensionality issue that is endemic in spatio-temporal statistical modeling.

As discussed generally above, multivariate processes can be modeled hierarchically by using the law of total probability and applying some conditional independence assumptions. As a simple example, consider $J = 3$ processes for the component conditional distribution for time t given time $t - 1$ might be written as

$$\begin{aligned} [\mathbf{Y}_t^{(1)}, \mathbf{Y}_t^{(2)}, \mathbf{Y}_t^{(3)} | \mathbf{Y}_{t-1}^{(1)}, \mathbf{Y}_{t-1}^{(2)}, \mathbf{Y}_{t-1}^{(3)}] &= [\mathbf{Y}_t^{(1)} | \mathbf{Y}_t^{(3)}, \mathbf{Y}_{t-1}^{(1)}, \mathbf{Y}_{t-1}^{(2)}] \\ &\quad \times [\mathbf{Y}_t^{(2)} | \mathbf{Y}_t^{(3)}, \mathbf{Y}_{t-1}^{(1)}, \mathbf{Y}_{t-1}^{(2)}] [\mathbf{Y}_t^{(3)} | \mathbf{Y}_{t-1}^{(3)}]. \end{aligned}$$

That is, processes 1 and 2 are conditionally independent at time t given process 3 at time t and previous values of processes 1 and 2 at time $t - 1$, and process 3 at time t is conditionally independent of the others given its previous values. Such a model formulation has the advantage of being able to match up to mechanistic knowledge about the processes and their interactions. However, if such knowledge is not available, this conditional formulation is arbitrary (or there is no basis for the conditional independence assumptions), and such an approach is not recommended.

The third primary approach for modeling multivariate dynamical spatio-temporal processes is to condition the J processes on one or more latent processes, much like what is done in multivariate factor analysis. For a set of $K \leq J$ common latent dynamical processes, $\{\alpha_{\ell,t}^{(k)}\}$, which may or may not be spatially referenced, consider

$$Y_t^{(j)}(\mathbf{s}_t) = \sum_{\ell=1}^{n_\alpha} \sum_{k=1}^K h_{i,\ell}^{(jk)} \alpha_{\ell,t}^{(k)} + \eta_t^{(j)}(\mathbf{s}_t), \quad (7.16)$$

for $i = 1, \dots, n$, $j = 1, \dots, J$, where $h_{i,\ell}^{(jk)}$ are interaction coefficients that account for how the ℓ th element of the k th latent process influences the j th process at

location i . This is a powerful modeling framework, but the curse of dimensionality in parameter space can easily make this impractical. In addition, care must be taken when modeling the latent processes, which is typically done at the next level of the model hierarchy, as there are identifiability problems between the h parameters at this level and potential dynamical evolution parameters for the α processes at the next level [see 7, Section 7.4.2, for more discussion].

3.4 Process and Parameter Reduction

As mentioned above, one of the greatest challenges when considering DSTMs in hierarchical settings is the curse of dimensionality associated with the process and parameter space. For the fairly common situation where the number of spatial locations (n) is much larger than the number of time replicates (T), even the fairly simple linear VAR(1) model (7.14) is problematic as there are on order n^2 parameters to estimate. This is compounded for the GQN model (7.15), which has on order n^3 free parameters and similarly for the multivariate model. To proceed, one must reduce the number of free parameters to be estimated in the model and/or reduce the dimension of the dynamical process. These two approaches are discussed briefly below.

3.4.1 Parameter Reduction

Very seldom would one estimate the full variance/covariance matrix (\mathbf{C}_η) in the DSTM. Rather, given that these are spatial covariance matrices, one would either use one of the common spatial covariance function representations (e.g., Matérn, conditional autoregressive, etc.; see Cressie and Wikle [7, Chapter 4]) or a spatial random effect representation (see the “Process Reduction” section below). Generally, the transition parameters in the DSTM require the most care. For example, in the case of the simple VAR model (7.14), one could parameterize the transition matrix \mathbf{M} simply as a random walk (i.e., $\mathbf{M} = \mathbf{I}$), a spatially homogeneous autoregressive process (i.e., $\mathbf{M} = \theta \mathbf{I}$), or a spatially varying autoregressive process ($\mathbf{M} = \text{diag}(\theta_m)$). The first two parameterizations are somewhat unrealistic for most real-world dynamical processes, and the latter, although able to accommodate non-separable spatio-temporal dependence, does not account for interactions dynamically across space and time. Although in the context of evolving a spectral latent process (see below), such models can be very effective.

More mechanistically realistic dynamical parameterizations in the context of physical space representations recognize that spatio-temporal interactions are crucial for dynamical propagation. For example, in the linear case, the asymmetry and rate of decay of the transition parameters relative to a location (say, \mathbf{s}_i) control propagation (linear advection) and spread (diffusion). This suggests that a simple *lagged-nearest-neighbor* parameterization can be quite effective. For example,

$$Y_t(\mathbf{s}_i) = \sum_{j \in \mathcal{N}_i} m_{ij} Y_{t-1}(\mathbf{s}_j) + \eta_t(\mathbf{s}_i), \quad (7.17)$$

where \mathcal{N}_i corresponds to a prespecified neighborhood of location $s_i, i = 1, \dots, n$ and $m_{ij} = 0$ for all $s_j \notin \mathcal{N}_i$. Such a parameterization reduces the number of parameters from $O(n^2)$ to $O(n)$. It can be shown that such a parameterization can be motivated by many mechanistic models, such as those suggested by standard discretization of differential equations (e.g., finite difference, Galerkin, spectral) [e.g., see 7, 35]. In these cases, the m_{ij} parameters in (7.17) can be parameterized in terms of other mechanistically motivated knowledge, such as spatially varying diffusion or advection coefficients [e.g., 16, 17, 32, 37, 45]. Mechanistically motivated parameterizations can also be applied to nonlinear and multivariate processes [35].

3.4.2 Process Rank Reduction

Useful process reductions can be formulated with the realization that the essential dynamics for spatio-temporal processes typically exist on a relatively low-dimensional manifold [e.g., 41]. This is helpful because instead of having to model the evolution of the n -dimensional process $\{\mathbf{Y}_t\}$, one can model the evolution of a much lower-dimensional (n_α) process $\{\boldsymbol{\alpha}_t\}$, where $n_\alpha \ll n$. Thus, consider a decomposition of \mathbf{Y}_t [36] such that

$$\mathbf{Y}_t = \boldsymbol{\mu}_t + \boldsymbol{\Phi}\boldsymbol{\alpha}_t + \boldsymbol{\Psi}\boldsymbol{\xi}_t + \boldsymbol{\nu}_t, \quad (7.18)$$

where $\boldsymbol{\mu}_t$ is an n -dimensional time-varying (potentially) spatial mean corresponding to large-scale non-dynamic features and/or covariate effects; $\boldsymbol{\Phi}$ is an $n \times n_\alpha$ matrix of basis vectors corresponding to the latent dynamical expansion coefficient process, $\{\boldsymbol{\alpha}_t\}$; and $\boldsymbol{\Psi}$ can either be an $n \times n_\xi$ basis function matrix corresponding to the latent process, $\{\boldsymbol{\xi}_t\}$, which typically is assumed to have different dynamical characteristics than $\{\boldsymbol{\alpha}_t\}$ or this component might account for non-dynamical spatial variability. The error process $\{\boldsymbol{\nu}_t\}$ is typically Gaussian and assumed to be mean zero with simple dependence structure. Note that a continuous space representation of this decomposition can be expressed in terms of IDEs [e.g., see 7, Section 7.1.3].

The evolution of the latent $\boldsymbol{\alpha}_t$ process can proceed according to the basic linear or nonlinear models described above. Even in this low-dimensional context, parameter space reduction may still be necessary, particularly the case in nonlinear models (e.g., there are on the order of n_α^3 free parameters to estimate in the GQN model). Mechanistic knowledge can again be used to motivate such parameterizations in some cases [11, 36], and/or model selection approaches can be used to reduce the parameter space, such as stochastic search variable selection [e.g., 34].

There are many choices for the basis vectors that make up $\boldsymbol{\Phi}$ and $\boldsymbol{\Psi}$. It has become quite common in recent years to represent spatial processes in terms of basis decompositions, and there are many choices for these, such as orthogonal polynomials, empirical spectral decompositions (i.e., empirical orthogonal functions (EOFs)), stochastic optimals, balanced truncations, wavelets, splines, bisquare bases, Wendland bases, Moran's I bases, kernel convolution and “predictive process” bases, and dynamic factor bases [e.g., see the discussion in 7, 39]. Each has its proponents, although it does not seem to matter too much in the spatial context which basis is used, so long as it can accommodate the appropriate variability. In the

context of DSTMs, it can make more of a difference because it is important that interactions across spatial scales be allowed [e.g., 40]. This is more difficult to do in the standard “knot-based” representations (e.g., splines, kernel convolutions, predictive processes) in which case the α_t coefficients are spatially referenced, but not necessarily multi-resolution. Most of the other basis representations are in some sense multi-scale, and the associated expansion coefficients α_t are not indexed in space. However, the product of the basis times the expansion coefficients is spatially referenced, and more importantly, dynamical evolution in the DSTM can accommodate scale interactions. Note that the coefficients ξ_t associated with the matrix Ψ are typically specified to have much-simpler dynamical structure (if at all) as the assumption is that the controlling dynamics are associated with α_t . In general, the ξ_t coefficient portion of the expansion is used to accommodate extra-dynamical spatial variability and/or exogenous effects.

The projection of the process $\{\mathbf{Y}_t\}$ to the lower-dimensional manifold need not be linear as shown in (7.18). There are a bewildering number of choices for nonlinear dimension reduction, and some of them could potentially represent the dynamics more realistically (e.g., Laplacian eigenmaps [2], kernel principal components [e.g., 44], etc.). However, these methods are somewhat limited by a lack of uniqueness in the back projection of the expansion coefficients into physical space, which requires either some sort of ad hoc procedure or an additional modeling component in the HM.

In some cases, the process is so complicated that it might be very difficult to specify an adequate process model. If deterministic simulation models are available, it can sometimes be easier to incorporate the mechanistic information through a surrogate model or statistical emulator. That is, much like the design and analysis of computer modeling experiment literature [e.g., 12, 18, 28], one builds a statistical model for the fairly rich simulation output (in terms of spatio-temporal behavior) and uses that either as a black box [e.g., 15, 22] or to inform prior distributions for simpler mechanistically motivated DSTMs [e.g., 19]. In other cases, one can build simpler lower-dimensional emulators and link them together hierarchically to represent the dynamical process [e.g., 20]. It is important to note that emulators in the context of dynamical spatio-temporal processes typically are built from what [15] call the “first-order” perspective. That is, process evolution is accounted for explicitly in the conditional mean structure, following the etiology of the real-world process. This is unlike the design and analysis of computer modeling literature, which typically considers so-called “second-order” emulators, in which the focus is on the covariance structure. Such an approach is well suited for the model calibration problem.

4 Example: Near-Surface Winds Over the Ocean

To illustrate many of the HM concepts described above, consider the motivating example of prediction of complete near-surface wind fields from a blend of weather center analysis winds and satellite scatterometer winds (so-called *surface vector*

winds (SVW)). Some relevant background on the problem is presented, followed by a fairly simple BHM illustration applied to this problem.

4.1 Surface Vector Wind Background

Near-surface ocean winds are a critical component of the atmosphere/ocean interface as they are directly responsible for the transfer momentum to the ocean and the wind speed modulates the exchanges of heat and freshwater to and from the upper ocean. The advent of spaceborne scatterometer instruments in the 1990s provided the first global wind fields, on daily timescales, from observations. Prior to these scatterometer instruments, ocean winds were largely inferred from global weather forecast models (so-called *analyses*). These analyses depend on sparse global network of in situ wind observations from buoys and ships of opportunity and blend them with a mechanistic model of the atmosphere. The practical spatial resolution of such winds is limited to the relatively large spatial and temporal scales of variability.

Scatterometer SVW observations are not direct measures of the wind [see [23](#), for a more detailed description]. The winds are derived from complicated (“geophysical model function”) relationships concerning the roughness imparted on the ocean by surface capillary waves in response to the shear stress vector at the air-sea interface. Depending on the specific sensor, SVW estimates from scatterometers are accurate to within at least 2 ms^{-1} in speed and 30° in direction, and resolutions are on the order of 12.5–50 km for up to 90% global coverage on daily timescales. The SVW retrievals occur in swaths along the polar-orbiting satellite ground track, with varying swath widths depending on the instrument system. For the purposes of predicting complete spatial fields, it is important to note that because of the polar orbit (approximately 14 polar orbits per day), the swaths overlap at high latitudes and are separated by gaps in coverage at low latitudes. So, although there are gaps over a day, areas in which there are SVWs exhibit much finer spatial resolution of atmospheric wind features than the analysis wind products from the same period, which are complete in space but have much lower effective spatial feature resolution in general (i.e., an unrealistic kinetic energy spatial spectrum). The goal of a statistical data assimilation is then to blend the complete, but energy-deficient, weather center analyses with the incomplete, yet energy-realistic, SVW in order to provide spatially complete wind fields at sub-daily intervals while managing the uncertainties associated with the different data sources and the blending procedure.

Uncertainty management via BHM with process dynamics motivated by mechanistic models (i.e., leading order terms and/or approximations of the primitive equations) has been shown to be a very effective approach for this wind data assimilation problem [e.g., see the sequence of papers: [5](#), [13](#), [23](#), [24](#), [26](#), [36](#), [42](#)]. In particular, these methods have been shown to be quite useful in the context of providing inputs to ocean forecasting systems such as the Mediterranean Forecast System (MFS) [[23](#), [24](#)].

The MFS produces 10-day forecasts for upper ocean fields every day. This forecast model resolves medium-scale (in time and space) features (e.g., *synoptic scale*) in the upper ocean, and the most uncertain parts of the forecast fields correspond to so-called *mesoscales* (i.e., hourly and 10–50 km scales). These are the primary scales of the upper ocean hydrodynamic instabilities driven by the surface wind. Thus, modeling uncertainty in the surface wind field can be an important means of quantifying uncertainty in the MFS ocean forecasts on the scales that are most important to daily users.

4.2 Ocean SVW BHM

[23] describe the details of a SVW BHM for the MFS, and [24] discuss the impacts of the resulting BHM SVW fields in an ensemble forecast methodology built around realizations from the posterior distribution for SVW from the BHM. The process model in [23] involves the leading-order terms in a Rayleigh friction equation (RFE) approximation at synoptic scales, with extra-spatial variability added to account for turbulent scaling relationships in the wind field. A critical component of the [23] model is that it is multivariate in terms of modeling the east-west (u) and north-south (v) wind components and surface pressure (all of which are spatio-temporal processes) such that the wind components are independently conditioned on the pressure, which is a reasonable and justifiable assumption to first order. However, higher-order interactions of wind components are most likely important even after conditioning on the pressure field, so the model presented here considers a multivariate low-rank representation of the residual wind components after accounting for potential pressure gradient effects as suggested by the RFE. The data, process, and parameter models are described below.

4.2.1 Data Models

Two sources of wind data are considered, along with sea-level pressure data. In particular, there are satellite wind observations from the QuikSCAT scatterometer and surface winds and pressures from an analysis by the European Centre for Medium-Range Weather Forecasts (ECMWF). In this simple illustrative application, the pressure will be considered “known,” and only the wind components are modeled as a process, i.e., the pressure is used as an exogenous variable here. The wind data models are then:

$$\mathbf{d}_t^{Q_u} | \mathbf{u}_t, \sigma_Q^2 \sim \text{ind. Gau}(\mathbf{H}_t^Q \mathbf{u}_t, \sigma_Q^2 \mathbf{I}),$$

$$\mathbf{d}_t^{Q_v} | \mathbf{v}_t, \sigma_Q^2 \sim \text{ind. Gau}(\mathbf{H}_t^Q \mathbf{v}_t, \sigma_Q^2 \mathbf{I}),$$

$$\mathbf{d}_t^{E_u} | \mathbf{u}_t, \sigma_E^2 \sim \text{ind. Gau}(\mathbf{H}_t^E \mathbf{u}_t, \sigma_E^2 \mathbf{I}),$$

$$\mathbf{d}_t^{E_v} | \mathbf{v}_t, \sigma_E^2 \sim \text{ind. Gau}(\mathbf{H}_t^E \mathbf{v}_t, \sigma_E^2 \mathbf{I}),$$

where $\mathbf{d}_t^{Q_u}$ and $\mathbf{d}_t^{Q_v}$ are m_t -dimensional vectors of scatterometer u -wind and v -wind observations, respectively, within a specified time window indexed by t ; and $\mathbf{d}_t^{E_u}$ and $\mathbf{d}_t^{E_v}$ are ECMWF u -wind and v -wind component observations, respectively, within the same window. The spatially vectorized true wind process components are given by the n -dimensional vectors \mathbf{u}_t , \mathbf{v}_t . The mapping matrices for the scatterometer and ECMWF observations are given by \mathbf{H}_t^Q and \mathbf{H}_t^E , respectively. In this case, these are just incidence matrices that map the observations to the nearest process grid location [see 7, Chapter 7 for details]. The measurement errors are assumed to have Gaussian distributions that are independent in space and time, conditioned upon the true process values. The measurement-error variances, σ_Q^2 and σ_E^2 , correspond to scatterometer and ECMWF wind components, respectively. The conditional independence of these data models follows from the more general discussion above concerning the relative ease of incorporating multiple data sources in the BHM framework.

The wind data for February 2, 2005, are shown in Figs. 7.1 and 7.2. These plots show the QuikSCAT scatterometer and ECMWF analysis observations available within a window of ± 3 h of $t = 00:00, 06:00, 12:00$, and $18:00$ UTC (“Coordinated Universal Time”). The ECMWF analysis winds and pressures are specified on a $0.5^\circ \times 0.5^\circ$ spatial grid, and they are available at each time period for all locations. This grid is also used for the process vectors, \mathbf{u}_t and \mathbf{v}_t . As described above, the QuikSCAT observations are available intermittently in space due to the polar orbit of the satellite, but at much higher spatial resolution (25 km) when they are available. Thus, the mapping matrices for the scatterometer data, \mathbf{H}_t^Q , are defined as incidence matrices such that all scatterometer observations within 0.25° of a process grid point, and within 3 h of time t , are associated with the wind process at that grid point and time.

4.2.2 Process Model

The wind component process models are specified as

$$\mathbf{u}_t \equiv \mathbf{D}_x \mathbf{p}_t \theta_{ux} + \mathbf{D}_y \mathbf{p}_t \theta_{uy} + \boldsymbol{\Phi}_u \boldsymbol{\alpha}_t \quad (7.19)$$

$$\mathbf{v}_t \equiv \mathbf{D}_x \mathbf{p}_t \theta_{vx} + \mathbf{D}_y \mathbf{p}_t \theta_{vy} + \boldsymbol{\Phi}_v \boldsymbol{\alpha}_t, \quad (7.20)$$

where \mathbf{D}_x and \mathbf{D}_y are matrix operators that give the x -direction- and y -direction-centered differences of the spatial field vector on which they operate, respectively, and \mathbf{p}_t is the vectorized gridded ECMWF pressure data (assumed known here). In the context of the process rank reduction decomposition given in (7.18), $\boldsymbol{\Phi}_u$ and $\boldsymbol{\Phi}_v$ correspond to $n \times n_\alpha$ matrices of basis functions for the u - and v -wind components, respectively, with the common random reduced-rank latent process expansion coefficients, $\boldsymbol{\alpha}_t$. In addition, relative to (7.18), let $\boldsymbol{\mu}_{u,t} \equiv \mathbf{D}_x \mathbf{p}_t \theta_{ux} + \mathbf{D}_y \mathbf{p}_t \theta_{uy}$ and $\boldsymbol{\mu}_{v,t} \equiv \mathbf{D}_x \mathbf{p}_t \theta_{vx} + \mathbf{D}_y \mathbf{p}_t \theta_{vy}$, where these terms represent the importance of winds on the gradient of pressure, as controlled by the parameters $\boldsymbol{\theta} \equiv \{\theta_{ux}, \theta_{uy}, \theta_{vx}, \theta_{vy}\}$. This particular formulation does not include a separate small-scale spatial variability component (e.g., $\boldsymbol{\Psi} \boldsymbol{\beta}_t$ in (7.18)) for simplicity. [36] and [23] include such a term

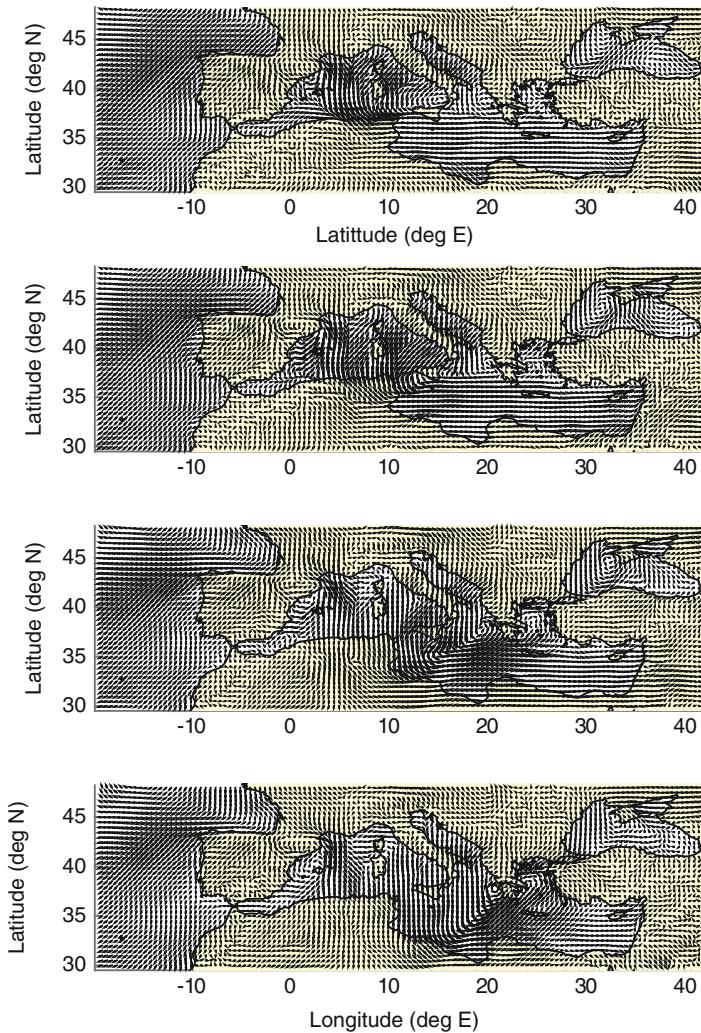

Fig. 7.1 Wind observations from February 2, 2005. From *top* to *bottom*, the panels correspond to the available data at 00:00, 06:00, 12:00, and 18:00 UTC (Universal Coordinated Time). The panels correspond to the ECMWF analysis winds on a $0.5^\circ \times 0.5^\circ$ grid. The length of the wind quiver (arrow) corresponds to speed, where the smallest is 0.06 m/s and the largest is 17.7 m/s.

and parameterize it in terms of two-dimensional spatial wavelet basis functions to account for the turbulent scaling relationships that are inherent in the SVW.

Note that the basis function matrices, Φ_u and Φ_v , are constructed from multivariate empirical orthogonal functions (EOFs) of the joint ECMWF u - and v -wind components [see 7, for an overview of EOF basis functions]. The advantage of such bases in this context is that they are constructed multivariately, so that the joint dependence of the wind components is considered in their construction. In

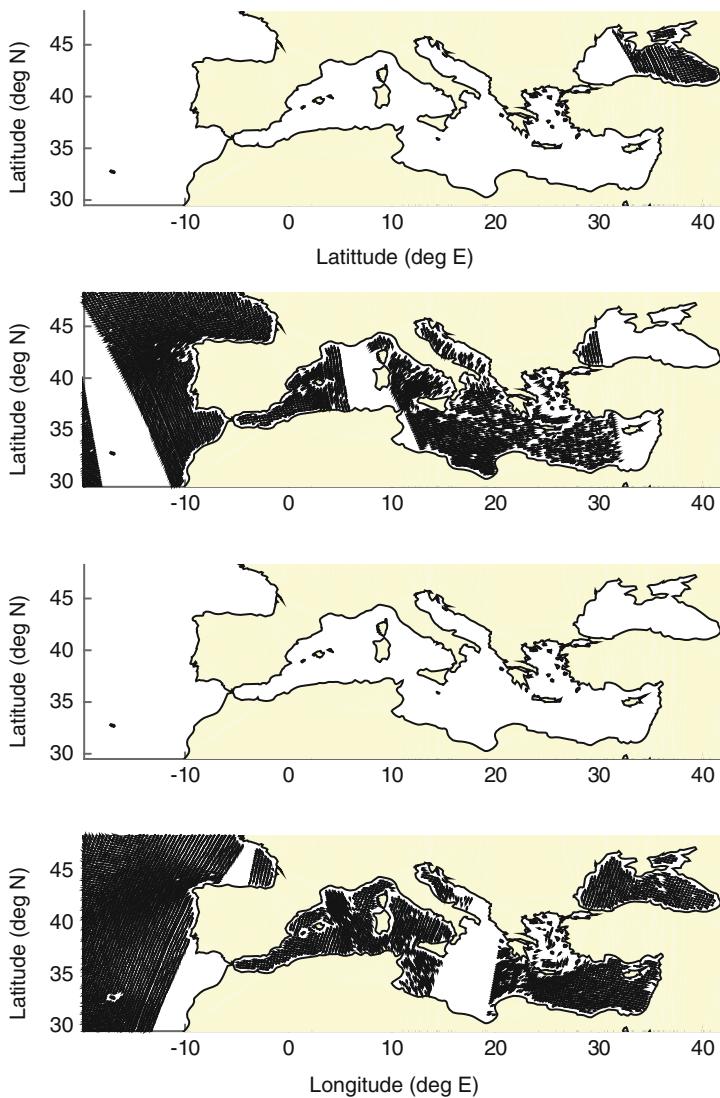

Fig. 7.2 Wind observations from February 2, 2005. From *top* to *bottom*, the panels correspond to the available data at 00:00, 06:00, 12:00, and 18:00 UTC (Universal Coordinated Time). The panels correspond to the high-resolution (25 km), but spatially intermittent, QuickSCAT scatterometer wind retrievals. The length of the wind quiver (arrow) corresponds to speed, where the smallest is 0.2 m/s and the largest is 21.3 m/s.

addition, EOFs generally are useful for dynamical reduced-rank modeling because the dimension reduction is quite significant (in the case here, $n = 4096$ and $n_\alpha = 32$, which accounts for approximately 98% of the variability in the ECMWF wind data). Although they can be quite useful for DSTM rank reduction, given

that EOFs are essentially spatial principal component loadings, they are optimal for variance reduction but not typically for dynamical propagation. Regarding the notions of inclusion of mechanistic information in BHMs, note that by conditioning the wind components on common processes \mathbf{p}_t and $\boldsymbol{\alpha}_t$, the process decomposition in (7.19) and (7.20) allows a reasonable mechanistic-based approach for building in the conditional independence between the wind components.

The dynamical evolution of the common latent process coefficients is specified fairly simply in this illustrative example as

$$\boldsymbol{\alpha}_t = \text{diag}(\mathbf{m}_\alpha) \boldsymbol{\alpha}_{t-1} + \boldsymbol{\eta}_t, \quad \boldsymbol{\eta}_t \sim Gau(\mathbf{0}, \mathbf{C}_\eta), \quad (7.21)$$

for $t = 1, \dots, T$, where $\text{diag}(\mathbf{m}_\alpha)$ corresponds to an n_α -dimensional diagonal matrix with \mathbf{m}_α on the main diagonal and zeros elsewhere. The initial condition is specified as $\boldsymbol{\alpha}_0 \sim Gau(\mathbf{0}, \mathbf{C}_0)$. Note that this fairly simple dynamical structure is motivated by the components of the RFE described in [23] that do not depend on pressure. Marginal dependence between the elements that make up $\boldsymbol{\alpha}_t$ is accommodated by a non-diagonal variance-covariance matrix, \mathbf{C}_η .

4.2.3 Parameter Models

To facilitate computation for this simple illustrative example, the parameters in the previous stages are given conjugate prior distributions. In particular, specify $\theta_k \sim N(\mu_i, \sigma_i^2)$ for $i = \{ux, uy, vx, vy\}$, $\mathbf{m}_\alpha \sim N(\boldsymbol{\mu}_\alpha, \mathbf{C}_\alpha)$, and $\mathbf{C}_\eta^{-1} \sim W((d_\eta \mathbf{S}_\eta)^{-1}, d_\eta)$, where $W(\cdot)$ corresponds to a Wishart distribution. The remaining parameters and hyperparameters are fixed at scientifically plausible values (e.g., σ_Q^2 , σ_E^2 , μ_i , and $\boldsymbol{\mu}_\alpha$ as described in [23]) or given values to suggest vague (non-informative) priors (e.g., \mathbf{C}_0 , \mathbf{S}_η , d_η , σ_i^2 , \mathbf{C}_α).

4.3 Implementation

The posterior distribution for the random components of the model is given by

$$\begin{aligned} [\{\boldsymbol{\alpha}_t\}_{t=0}^T, \boldsymbol{\theta}, \mathbf{m}_\alpha, \mathbf{C}_\eta \mid \{\mathbf{d}_t^{Q_u}\}_{t=1}^T, \{\mathbf{d}_t^{Q_v}\}_{t=1}^T, \{\mathbf{d}_t^{E_u}\}_{t=1}^T, \{\mathbf{d}_t^{E_v}\}_{t=1}^T] &\propto \\ &\prod_{t=1}^T [\mathbf{d}_t^{Q_u} \mid \boldsymbol{\alpha}_t, \boldsymbol{\theta}] \prod_{t=1}^T [\mathbf{d}_t^{Q_v} \mid \boldsymbol{\alpha}_t, \boldsymbol{\theta}] \\ &\times \prod_{t=1}^T [\mathbf{d}_t^{E_u} \mid \boldsymbol{\alpha}_t, \boldsymbol{\theta}] \prod_{t=1}^T [\mathbf{d}_t^{E_v} \mid \boldsymbol{\alpha}_t, \boldsymbol{\theta}] \\ &\times \prod_{t=1}^T [\boldsymbol{\alpha}_t \mid \boldsymbol{\alpha}_{t-1}, \mathbf{m}_\alpha, \mathbf{C}_\eta][\boldsymbol{\alpha}_0][\mathbf{m}_\alpha][\mathbf{C}_\eta][\boldsymbol{\theta}]. \end{aligned}$$

Although an analytical posterior distribution is not available in this case, given the conjugate distributional forms, the required full-conditional distributions for a Gibbs sampler can all be derived analytically [e.g., see 7, for the details of a similar DSTM example]. In the example given here, the spatial grid sizes are $n = 4096$ and $T = 57$ times and were considered corresponding to the period from 12:00 UTC January 25, 2005, through 12:00 UTC February 8, 2005, at 6-h intervals. The reduced-rank vectors were of dimension $n_\alpha = 32$. The MCMC was run for 100,000 iterations after a 20,000-iteration burn-in period. The algorithm is quite efficient given the number of prediction locations 4096×57 and large amount of data (e.g., the MCMC was run in less than 4 h on a standard 2014 vintage laptop computer).

4.4 Results

The posterior mean wind fields for 12:00 UTC on February 2, 2005, are shown in Fig. 7.3. In addition, Fig. 7.4 shows a portion of the prediction domain, in which ten samples widely separated in the MCMC chain are plotted. One can see from this plot that the uncertainty associated with the spatial prediction of the wind fields is not homogeneous in the domain. For example, the strong flow off the south coast of France into the Gulf of Lion (so-called mistral winds) shows more variability in wind direction than areas over land. Note that this area of increased posterior variability is over a fairly small spatial region, which is important when one is using winds to force an ocean model such as with the MFS. That is, the small-scale variations in the wind forcing can lead to similar-scale uncertainties in the ocean state variables, which can make a substantial difference in ocean forecasts [see 24, for an in-depth discussion].

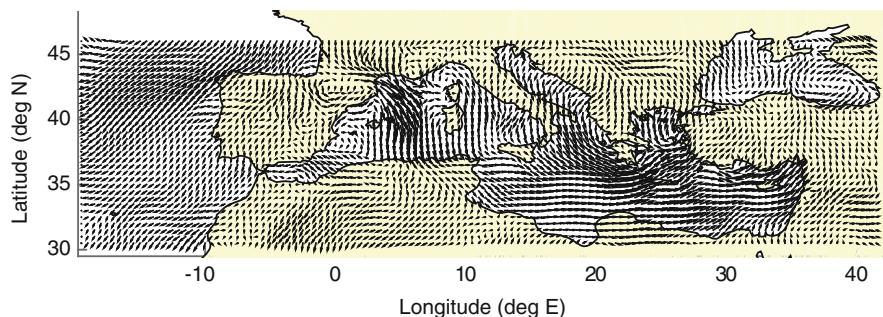

Fig. 7.3 Posterior mean wind vectors for 12:00 UTC on February 2, 2005, on the prediction grid. Wind speed is proportional to the length of the vectors, with the direction of wind toward the “arrowhead” on the wind quiver. The length of the wind quiver corresponds to speed, where the smallest is 0.0 m/s and the largest is 18.0 m/s.

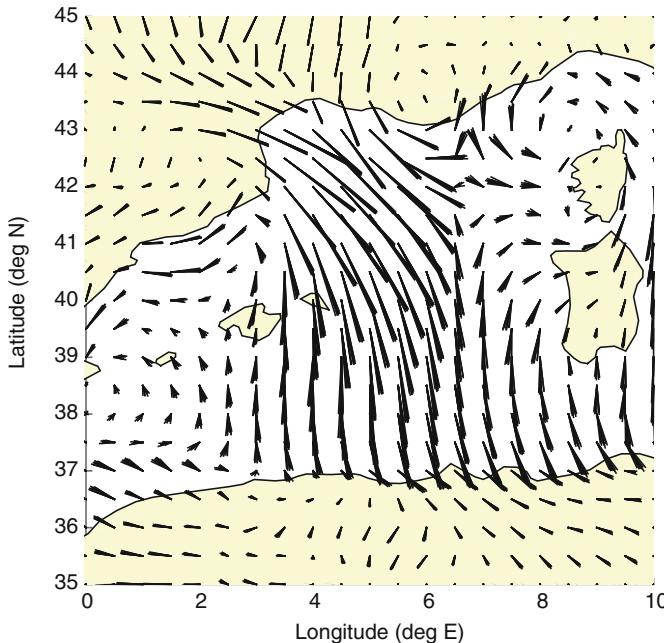

Fig. 7.4 Ten samples of wind vectors taken from the posterior distribution for 12:00 UTC on February 2, 2005, over the western Mediterranean basins. Wind speed is proportional to the length of the vectors. The direction of the vector is away from the vertex at the center of its grid cell. In this case, the “arrowhead” on the wind quivers is suppressed so that the variability in the wind corresponds to the width of the downwind portion of the vector.

5 Conclusion

This chapter has presented a brief summary of hierarchical modeling in the context of complex processes, typically those with mechanistically motivated spatio-temporal dependence. When modeling the complex processes one sees in many science and engineering applications, hierarchical modeling is a coherent approach to accommodate uncertainty in the observations (measurement error and sampling error), in the process specification, and in the knowledge of the parameters and potential additional forcings. The approach is very flexible, but with that flexibility comes potentially significant challenges and compromises when it comes to implementation.

Consider what [7] call the “data/model compromise.” Even for complicated spatio-temporal processes, if one has *enough* (whatever that may be) high-quality observations, then the model can be fairly simple since the complex dependence structure is already contained in the observations and, presumably, can be “learned” by the statistical model. In many respects, this was the case with the SVW example

presented above. There are a lot of observations from two different observation sources in this example, so the wind component process model is actually fairly simple relative to a mechanistic model that would be used with little or no data. In other SVW implementations, more sophisticated process models may have to be used depending on the data coverage and complexity of the dynamic environment [e.g., 36]. On the other hand, if one specifies a very complex mechanistic process model, but has very little data, there may not be enough information in the data to inform the posterior distributions associated with the parameters and process [e.g., 9]. That is, when the data are not rich enough to learn about the process and parameters, then one effectively has a practical lack of identifiability that may inhibit fitting the BHM. In practice, one tries to strike a balance between these two competing data/model trade-offs.

Perhaps the greatest challenge with implementing complex BHMs is recognizing the need to trade the complexity of the model for computational simplicity or what [7] call the “computing/model compromise.” Despite the ever-advancing state of statistical computation for HMs, the algorithms can still be difficult to implement, both in terms of time required to code and the effort required to tune the algorithm. Software packages to implement BHMs are increasing in number and quality, but it is still often difficult to implement very complex BHMs with these packages. Thus, one is often faced with the dilemma of either simplifying the model and sacrificing some realism or utilizing an approximate estimation/inference approach (e.g., ABC, INLA, variational Bayes, etc.) and either limiting the sorts of inference that can be accomplished or accepting some inaccuracy relative to the true posterior distribution of interest. Thus, when implementing a complex BHM, one must always consider the difference between what one *wants* to do and what one *can* do and whether it is best for the particular problem at hand to sacrifice model complexity or computational efficiency. Regardless, the BHM paradigm still remains one of the most powerful frameworks in which to quantify uncertainty.

This chapter is concerned with science-based hierarchical modeling, in which one has mechanistic information available to inform the model components (either data, model, or parameters). In recent years, alternative hierarchical modeling approaches have been developed from the statistical learning perspective [e.g., see the review outlined in 3], which typically do not make use of scientific/mechanistic information, but seek to build multilayer models (e.g., “deep learning”) through nonparametric approaches. These approaches can sometimes be useful in situations where subject-matter knowledge is not readily available yet can overfit in situations with complex spatial and temporal dependencies. In both the science-based and statistical learning-based HM approaches, much more work remains to be done on the theoretical properties of the estimators and predictors under various amounts of uncertainty in observations, process models and parameter structure, as well as data volume. Promising approaches are being developed [e.g., 1], but to date, these approaches have not been able to speak to the multilevel-dependent parameter structures common in the science-based BHM setting.

Random Matrix Models and Nonparametric Method for Uncertainty Quantification

8

Christian Soize

Abstract

This chapter deals with the fundamental mathematical tools and the associated computational aspects for constructing the stochastic models of random matrices that appear in the nonparametric method of uncertainties and in the random constitutive equations for multiscale stochastic modeling of heterogeneous materials. The explicit construction of ensembles of random matrices but also the presentation of numerical tools for constructing general ensembles of random matrices are presented and can be used for high stochastic dimension. The developments presented are illustrated for the nonparametric method for multiscale stochastic modeling of heterogeneous linear elastic materials and for the nonparametric stochastic models of uncertainties in computational structural dynamics.

Keywords

Random matrix • Symmetric random matrix • Positive-definite random matrix • Nonparametric uncertainty • Nonparametric method for uncertainty quantification • Random vector • Maximum entropy principle • Non-Gaussian • Generator • Random elastic medium • Uncertainty quantification in linear structural dynamics • Uncertainty quantification in nonlinear structural dynamics • Parametric-nonparametric uncertainties • Identification • Inverse problem • Statistical inverse problem

1 Introduction

It is well known that the parametric method for uncertainty quantification consists in constructing stochastic models of the uncertain physical parameters of a computational model that results from the discretization of a boundary value problem. The parametric method is efficient for taking into account the variabilities of physical parameters, but has not the capability to take into account the model uncertainties induced by modeling errors that are introduced during the construction of the computational model. The nonparametric method for the uncertainty quantification is a way for constructing a stochastic model of the model uncertainties induced by the modeling errors. It is also an approach for constructing stochastic models of constitutive equations of materials involving some non-Gaussian tensor-valued random fields, such as in the framework of elasticity, thermoelasticity, electromagnetism, etc. The random matrix theory is a fundamental tool that is really efficient for performing stochastic modeling of matrices that appear in the nonparametric method of uncertainties and in the random constitutive equations for multiscale stochastic

modeling of heterogeneous materials. The applications of the nonparametric stochastic modeling of uncertainties and of the random matrix theory presented in this chapter have been developed and validated for many fields of computational sciences and engineering, in particular for dynamical systems encountered in aeronautics and aerospace engineering [7, 20, 78, 88, 91, 94], in biomechanics [30, 31], in environment [32], in nuclear engineering [9, 12, 13, 29], in soil-structure interaction and for the wave propagations in soils [4, 5, 26, 27], in rotor dynamics [79, 80, 82] and vibration of turbomachines [18, 19, 22, 70], in vibroacoustics of automotive vehicles [3, 38–40, 61], but also, in continuum mechanics for multiscale stochastic modeling of heterogeneous materials [48, 49, 51–53], for the heat transfer in complex composites and for their nonlinear thermomechanic analyses [97, 98].

The chapter is organized as follows:

- Notions on random matrices and on the nonparametric method for uncertainty quantification: What is a random matrix and what is the nonparametric method for uncertainty quantification?
- Brief history concerning the random matrix theory and the nonparametric method for UQ and its connection with the random matrix theory.
- Overview and mathematical notations used in the chapter.
- Maximum entropy principle (MaxEnt) for constructing random matrices.
- Fundamental ensemble for the symmetric real random matrices with a unit mean value.
- Fundamental ensembles for positive-definite symmetric real random matrices.
- Ensembles of random matrices for the nonparametric method in uncertainty quantification.
- The MaxEnt as a numerical tool for constructing ensembles of random matrices.
- The MaxEnt for constructing the pdf of a random vector.
- Nonparametric stochastic model for constitutive equation in linear elasticity.
- Nonparametric stochastic model of uncertainties in computational linear structural dynamics.
- Parametric-nonparametric uncertainties in computational nonlinear structural dynamics.
- Some key research findings and applications.

2 Notions on Random Matrices and on the Nonparametric Method for Uncertainty Quantification

2.1 What Is a Random Matrix?

A real (or complex) *matrix* is a rectangular or a square array of real (or complex) numbers, arranged in rows and columns. The individual items in a matrix are called its elements or its entries.

A real (or complex) *random matrix* is a matrix-valued random variable, which means that its entries are real (or complex) random variables. The *random matrix*

theory is related to the fundamental mathematical methods required for constructing the probability distribution of such a random matrix, for constructing a generator of independent realizations, for analyzing some algebraic properties and some spectral properties, etc.

Let us give an example for illustrating the types of problems related to the random matrix theory. Let us consider a random matrix $[A]$, defined on a probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in a set \mathbb{S}_n of matrices, which is a subset of the set $\mathbb{M}_n^S(\mathbb{R})$ of all the symmetric $(n \times n)$ real matrices. Thus, for θ in Θ , the realization $[A](\theta)$ is a deterministic matrix in $\mathbb{S}_n \subset \mathbb{M}_n^S(\mathbb{R})$. Fundamental questions are related to the definition and to the construction of the probability distribution $P_{[A]}$ of such a random matrix $[A]$. If this probability distribution is defined by a probability density function (pdf) with respect a volume element $d^S A$, which is a mapping $[A] \mapsto p_{[A]}([A])$ from $\mathbb{M}_n^S(\mathbb{R})$ into $\mathbb{R}^+ = [0, +\infty[$, for which its support is \mathbb{S}_n (which implies that $p_{[A]}([A]) = 0$ if $[A] \notin \mathbb{S}_n$), then how must the volume element $d^S A$ be defined, how is the integration over $\mathbb{M}_n^S(\mathbb{R})$ defined, and what are the methods and tools for constructing pdf $p_{[A]}$ and its generator of independent realizations? For instance, such a pdf cannot simply be defined in giving the pdf of every entry $[A]_{jk}$ for many reasons among the following ones. As random matrix $[A]$ is symmetric, all the entries are not algebraically independent, and therefore, only the $n(n + 1)/2$ random variables $\{[A]_{1 \leq j \leq k \leq n}\}$ must be considered. In addition, if \mathbb{S}_n is the subset $\mathbb{M}_n^+(\mathbb{R})$ of all the positive-definite symmetric $(n \times n)$ real matrices, then there is an algebraic constraint that relates the random variables $\{[A]_{1 \leq j \leq k \leq n}\}$ in order that $[A]$ be with values in $\mathbb{M}_n^+(\mathbb{R})$, and such an algebraic constraint implies that all the random variables $\{[A]_{1 \leq j \leq k \leq n}\}$ are statistically dependent.

2.2 What Is the Nonparametric Method for Uncertainty Quantification?

The *parametric method* for uncertainty quantification consists in constructing stochastic models of the uncertain physical parameters (geometry, boundary conditions, material properties, etc) of a computational model that results from the discretization of a boundary value problem. The parametric method, which introduces prior and posterior stochastic models of the uncertain physical parameters of the computational model, has not the capability to take into account *model uncertainties* induced by *modeling errors* that are introduced during the construction of the computational model.

The *nonparametric method* for uncertainty quantification consists in constructing a stochastic model of both the uncertain physical parameters and the model uncertainties induced by the modeling errors, without separating the effects of the two types of uncertainties. Such an approach consists in directly constructing stochastic models of matrices representing operators of the problem considered and not in using the parametric method for the uncertain physical parameters whose matrices depend. Initially developed for uncertainty quantification in computational structural dynamics, the use of the nonparametric method has been extended for

constructing stochastic models of matrices of computational models, such as the nonparametric stochastic model for constitutive equation in linear elasticity.

The *parametric-nonparametric method* for uncertainty quantification consists in using simultaneously in a computational model, the parametric method for constructing stochastic models of certain of its uncertain physical parameters, and the nonparametric method for constructing a stochastic model of both, the other uncertain physical parameters and the model uncertainties induced by the modeling errors, in separating the effects of the two types of uncertainties.

Consequently, the nonparametric method for uncertainty quantification uses the random matrix theory.

3 A Brief History

3.1 Random Matrix Theory (RMT)

The *random matrix theory* (RMT) were introduced and developed in mathematical statistics by Wishart and others in the 1930s and was intensively studied by physicists and mathematicians in the context of nuclear physics. These works began with Wigner [125] in the 1950s and received an important effort in the 1960s by Dyson, Mehta, Wigner [36, 37, 126], and others. In 1965, Porter [92] published a volume of important papers in this field, followed, in 1967, by the first edition of the Mehta book [72] whose second edition [73] published in 1991 gives a synthesis of the random matrix theory. For applications in physics, an important ensemble of the random matrix theory is the Gaussian orthogonal ensemble (GOE) for which the elements are constituted of real symmetric random matrices with statistically independent entries and which are invariant under orthogonal linear transformations (this ensemble can be viewed as a generalization of a Gaussian real-valued random variable to a symmetric real square random matrix).

For an introduction to multivariate statistical analysis, we refer the reader to [2], for an overview on explicit probability distributions of ensembles of random matrices and their properties, to [55] and, for analytical mathematical methods devoted to the random matrix theory, to [74].

RMT has been used in other domains than nuclear physics. In 1984 and 1986, Bohigas et al. [14, 15] found that the level fluctuations of the quantum Sinai's billiard were able to predict with the GOE of random matrices. In 1989, Weaver [124] showed that the higher frequencies of an elastodynamic structure constituted of a small aluminum block had the behavior of the eigenvalues of a matrix belonging to the GOE. Then, Bohigas, Legrand, Schmidt, and Sornette [16, 65, 66, 99] studied the high-frequency spectral statistics with the GOE for elastodynamics and vibration problems in the high-frequency range. Langley [64] showed that, in the high-frequency range, the system of natural frequencies of linear uncertain dynamic systems is a non-Poisson point process. These results have been validated for the high-frequency range in elastodynamics. A synthesis of theses aspects related to

quantum chaos and random matrix theory, devoted to linear acoustics and vibration, can be found in the book edited by Wright and Weaver [127].

3.2 Nonparametric Method for UQ and Its Connection with the RMT

The nonparametric method was initially be introduced by Soize [106, 107] in 1999–2000 for uncertainty quantification in computational linear structural dynamics in order to take into account the model uncertainties induced by the modeling errors that could not be addressed by the parametric method. The concept of the nonparametric method then consisted in modeling the generalized matrices of the reduced-order model of the computational model by random matrices. It should be noted that the terminology “nonparametric” is not at all connected to the “nonparametric statistics” but was introduced to show the differences between the well-known parametric method consisting in constructing a stochastic model of uncertain physical parameters of the computational model, and the new proposed nonparametric method that consisted in modeling the generalized matrices of the reduced-order model by random matrices, related to the operators of the problem. Later, the parametric-nonparametric method has been introduced [113].

Early in the development of the concept of the nonparametric method, a problem has occurred in the choice of ensembles of random matrices. Indeed the ensembles of random matrices coming from the RMT were not adapted to stochastic modeling required by the nonparametric method. For instance, the GOE of random matrices could not be used for the generalized mass matrix, which must be positive definite, what is not the case for a random matrix belonging to GOE. Consequently, new ensembles of random matrices have had to be developed [76, 107, 108, 110, 115], using the maximum entropy (MaxEnt) principle, for implementing the concept of the nonparametric method for various computational models in mechanics, for which the matrices must verify various algebraic properties. In addition, parameterizations of the new ensembles of random matrices have been introduced in the different constructions in order to be in capability to quantify simply the level of uncertainties. These ensembles of random matrices have been constructed with a parameterization exhibiting a small number of hyperparameters, what allows for identifying the hyperparameters in using experimental data, solving a statistical inverse problems for random matrices that are, in general, in very high dimension. In these constructions, for certain types of available information, an explicit solution of the MaxEnt principle has been obtained, giving an explicit description of the ensembles of random matrices and of the corresponding generators of realizations. Nevertheless, for other cases of available information coming from computational models, there is no explicit solution of the MaxEnt, and therefore, a numerical tool adapted to the high dimension has had to be developed [112].

Finally, during these last 15 years the nonparametric method has extensively been used and extended, with experimental validations, to many problems in linear and nonlinear structural dynamics, in fluid-structure interaction and in vibroacoustics,

in unsteady aeroelasticity, in soil-structure interaction, in continuum mechanics of solids for the nonparametric stochastic modeling of the constitutive equations in linear and nonlinear elasticity, in thermoelasticity, etc. A brief overview on all the experimental validations and applications in different fields is given in the last Sect. 15.

4 Overview

This chapter is constituted of two main parts:

- The first one is devoted to the presentation of ensembles of random matrices that are explicitly described and also deals with an efficient numerical tool for constructing ensembles of random matrices when an explicit construction cannot be obtained. The presentation is focused to the fundamental results and to the fundamental tools related to ensembles of random matrices that are useful for constructing nonparametric stochastic models for uncertainty quantification in computational mechanics and in computational science and engineering, in such a framework, for the construction of nonparametric stochastic models of the random tensors or the tensor-valued random fields and also for the nonparametric stochastic models of uncertainties in linear and nonlinear structural dynamics.

All the ensembles of random matrices, which have been developed for the nonparametric method of uncertainties in computational sciences and engineering, are given hereinafter using a unified presentation based on the use of the MaxEnt principle, what allow us, not only to learn about the useful ensembles of random matrices for which the probability distributions and the associated generators of independent realizations are explicitly known but also to present a general tool for constructing any ensemble of random matrices, possibly using computation in high dimension.

- The second part deals with the nonparametric method for uncertainty quantification, which uses the new ensembles of random matrices that have been constructed in the context of the development of the nonparametric method and that are detailed in the first part. The presentation is limited to the nonparametric stochastic model for constitutive equation in linear elasticity, to the nonparametric stochastic model of uncertainties in computational linear structural dynamics for damped elastic structures but also for viscoelastic structures, and to the parametric-nonparametric uncertainties in computational nonlinear structural dynamics. In the last Sect. 15 brief bibliographical analysis is given concerning the propagation of uncertainties using nonparametric or parametric-nonparametric stochastic models of uncertainties, some additional ingredients useful for the nonparametric stochastic modeling of uncertainties, some experimental validations of the nonparametric method of uncertainties,

and finally some applications of the nonparametric stochastic modeling of uncertainties in different fields of computational sciences and engineering.

5 Notations

The following algebraic notations are used through all the developments devoted to this chapter.

5.1 Euclidean and Hermitian Spaces

Let $\mathbf{x} = (x_1, \dots, x_n)$ be a vector in \mathbb{K}^n with $\mathbb{K} = \mathbb{R}$ (the set of all the real numbers) or $\mathbb{K} = \mathbb{C}$ (the set of all the complex numbers). The Euclidean space \mathbb{R}^n (or the Hermitian space \mathbb{C}^n) is equipped with the usual inner product $\langle \mathbf{x}, \mathbf{y} \rangle = \sum_{j=1}^n x_j \bar{y}_j$ and the associated norm $\|\mathbf{x}\| = \sqrt{\langle \mathbf{x}, \mathbf{x} \rangle}$ in which \bar{y}_j is the complex conjugate of the complex number y_j and where $\bar{y}_j = y_j$ when y_j is a real number.

5.2 Sets of Matrices

$\mathbb{M}_{n,m}(\mathbb{R})$ be the set of all the $(n \times m)$ real matrices.

$\mathbb{M}_n(\mathbb{R}) = \mathbb{M}_{n,n}(\mathbb{R})$ the square matrices.

$\mathbb{M}_n(\mathbb{C})$ be the set of all the $(n \times m)$ complex matrices.

$\mathbb{M}_n^S(\mathbb{R})$ be the set of all the symmetric $(n \times n)$ real matrices.

$\mathbb{M}_n^{+0}(\mathbb{R})$ be the set of all the semipositive-definite symmetric $(n \times n)$ real matrices.

$\mathbb{M}_n^+(\mathbb{R})$ be the set of all the positive-definite symmetric $(n \times n)$ real matrices.

The ensembles of real matrices are such that

$$\mathbb{M}_n^+(\mathbb{R}) \subset \mathbb{M}_n^{+0}(\mathbb{R}) \subset \mathbb{M}_n^S(\mathbb{R}) \subset \mathbb{M}_n(\mathbb{R}).$$

5.3 Kronecker Symbol, Unit Matrix, and Indicator Function

The Kronecker symbol is denoted as δ_{jk} and is such that $\delta_{jk} = 0$ if $j \neq k$ and $\delta_{jj} = 1$. The unit (or identity) matrix in $\mathbb{M}_n(\mathbb{R})$ is denoted as $[I_n]$ and is such that $[I_n]_{jk} = \delta_{jk}$. Let \mathbb{S} be any subset of any set \mathbb{M} , possibly with $\mathbb{S} = \mathbb{M}$. The indicator function $M \mapsto \mathbb{1}_{\mathbb{S}}(M)$ defined on set \mathbb{M} is such that $\mathbb{1}_{\mathbb{S}}(M) = 1$ if $M \in \mathbb{S} \subset \mathbb{M}$ and $\mathbb{1}_{\mathbb{S}}(M) = 0$ if $M \notin \mathbb{S}$.

5.4 Norms and Usual Operators

- (i) The determinant of a matrix $[G]$ in $\mathbb{M}_n(\mathbb{R})$ is denoted as $\det[G]$, and its trace is denoted as $\text{tr}[G] = \sum_{j=1}^n G_{jj}$.

- (ii) The transpose of a matrix $[G]$ in $\mathbb{M}_{n,m}(\mathbb{R})$ is denoted as $[G]^T$, which is in $\mathbb{M}_{m,n}(\mathbb{R})$.
- (iii) The operator norm of a matrix $[G]$ in $\mathbb{M}_{n,m}(\mathbb{R})$ is denoted as $\|G\| = \sup_{\|\mathbf{x}\| \leq 1} \| [G] \mathbf{x} \|$ for all \mathbf{x} in \mathbb{R}^m , which is such that $\| [G] \mathbf{x} \| \leq \|G\| \|\mathbf{x}\|$ for all \mathbf{x} in \mathbb{R}^m .
- (iv) For $[G]$ and $[H]$ in $\mathbb{M}_{n,m}(\mathbb{R})$, we denote $\ll [G], [H] \gg = \text{tr}\{[G]^T [H]\}$ and the Frobenius norm (or Hilbert-Schmidt norm) $\|G\|_F$ of $[G]$ is such that $\|G\|_F^2 = \ll [G], [G] \gg = \text{tr}\{[G]^T [G]\} = \sum_{j=1}^n \sum_{k=1}^m G_{jk}^2$, which is such that $\|G\| \leq \|G\|_F \leq \sqrt{n} \|G\|$.

5.5 Order Relation in the Set of All the Positive-Definite Real Matrices

Let $[G]$ and $[H]$ be two matrices in $\mathbb{M}_n^+(\mathbb{R})$. The notation $[G] > [H]$ means that the matrix $[G] - [H]$ belongs to $\mathbb{M}_n^+(\mathbb{R})$.

5.6 Probability Space, Mathematical Expectation, and Space of Second-Order Random Vectors

The mathematical expectation relative to a probability space (Θ, \mathcal{T}, P) is denoted as E . The space of all the second-order random variables, defined on (Θ, \mathcal{T}, P) , with values in \mathbb{R}^n , equipped with the inner product $((\mathbf{X}, \mathbf{Y})) = E\{\langle \mathbf{X}, \mathbf{Y} \rangle\}$ and with the associated norm $\| \mathbf{X} \| = ((\mathbf{X}, \mathbf{X}))^{1/2}$, is a Hilbert space denoted as \mathcal{L}_n^2 .

6 The MaxEnt for Constructing Random Matrices

The measure of uncertainties using the entropy of information has been introduced by Shannon [103] in the framework of the development of information theory. The maximum entropy (MaxEnt) principle (that is to say, the maximization of the level of uncertainties) has been introduced by Jaynes [58] and allows a prior probability model of any random variables to be constructed, under the constraints defined by the available information. This principle appears as a major tool to construct the prior probability models. All the ensembles of random matrices presented hereinafter (including the well-known Gaussian Orthogonal Ensemble) are constructed in the framework of a unified presentation using the MaxEnt. This means that the probability distributions of the random matrices belonging to these ensembles are constructed using the MaxEnt.

6.1 Volume Element and Probability Density Function (PDF)

This section deals with the definition of a probability density function (pdf) of a random matrix $[G]$ with values in the Euclidean space $\mathbb{M}_n^S(\mathbb{R})$ (set of all the

symmetric $(n \times n)$ real matrices, equipped with the inner product $\ll [G], [H] \gg = \text{tr}\{[G]^T [H]\}$. In order to correctly defined the integration on Euclidean space $\mathbb{M}_n^S(\mathbb{R})$, it is necessary to define the volume element on this space.

6.1.1 Volume Element on the Euclidean Space of Symmetric Real Matrices

In order to well understand the principle of the construction of the volume element on Euclidean space $\mathbb{M}_n^S(\mathbb{R})$, the construction of the volume element on Euclidean spaces \mathbb{R}^n and $\mathbb{M}_n(\mathbb{R})$ is first introduced.

- (i) *Volume element on Euclidean space \mathbb{R}^n .* Let $\{\mathbf{e}_1, \dots, \mathbf{e}_n\}$ be the orthonormal basis of \mathbb{R}^n such that $\mathbf{e}_j = (0, \dots, 1, \dots, 0)$ is the null vector with 1 in position j . Consequently, $\langle \mathbf{e}_j, \mathbf{e}_k \rangle = \delta_{jk}$. Any vector $\mathbf{x} = (x_1, \dots, x_n)$ in \mathbb{R}^n can then be written as $\mathbf{x} = \sum_{j=1}^n x_j \mathbf{e}_j$. This Euclidean structure on \mathbb{R}^n defines the volume element $d\mathbf{x}$ on \mathbb{R}^n such that $d\mathbf{x} = \prod_{j=1}^n dx_j$.
- (ii) *Volume element on Euclidean space $\mathbb{M}_n(\mathbb{R})$.* Similarly, let $\{[b_{jk}]\}_{jk}$ be the orthonormal basis of $\mathbb{M}_n(\mathbb{R})$ such that $[b_{jk}] = \mathbf{e}_j \mathbf{e}_k^T$. Consequently, we have $\ll [b_{jk}], [b_{j'k'}] \gg = \delta_{jj'} \delta_{kk'}$. Any matrix $[G]$ in $\mathbb{M}_n(\mathbb{R})$ can be written as $[G] = \sum_{j,k=1}^n G_{jk} [b_{jk}]$ in which $G_{jk} = [G]_{jk}$. This Euclidean structure on $\mathbb{M}_n(\mathbb{R})$ defines the volume element dG on $\mathbb{M}_n(\mathbb{R})$ such that $dG = \prod_{j,k=1}^n dG_{jk}$.
- (iii) *Volume element on Euclidean space $\mathbb{M}_n^S(\mathbb{R})$.* Let $\{[b_{jk}^S]\}, 1 \leq j \leq k \leq n$ be the orthonormal basis of $\mathbb{M}_n^S(\mathbb{R})$ such that $[b_{jj}^S] = \mathbf{e}_j \mathbf{e}_j^T$ and $[b_{jk}^S] = (\mathbf{e}_j \mathbf{e}_k^T + \mathbf{e}_k \mathbf{e}_j^T)/\sqrt{2}$ if $j < k$. We have $\ll [b_{jk}^S], [b_{j'k'}^S] \gg = \delta_{jj'} \delta_{kk'}$ for $j \leq k$ and $j' \leq k'$. Any symmetric matrix $[G]$ in $\mathbb{M}_n^S(\mathbb{R})$ can be written as $[G] = \sum_{1 \leq j \leq k \leq n} G_{jk}^S [b_{jk}^S]$ in which $G_{jj}^S = G_{jj}$ and $G_{jk}^S = \sqrt{2} G_{jk}$ if $j < k$. This Euclidean structure on $\mathbb{M}_n^S(\mathbb{R})$ defines the volume element $d^S G$ on $\mathbb{M}_n^S(\mathbb{R})$ such that $d^S G = \prod_{1 \leq j \leq k \leq n} dG_{jk}^S$. The volume element is then defined by

$$d^S G = 2^{n(n-1)/4} \prod_{1 \leq j \leq k \leq n} dG_{jk}. \quad (8.1)$$

6.1.2 Probability Density Function of a Symmetric Real Random Matrix

Let $[G]$ be a random matrix, defined on a probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in $\mathbb{M}_n^S(\mathbb{R})$ whose probability distribution $P_{[G]} = p_{[G]}([G])$ $d^S G$ is defined by a pdf $[G] \mapsto p_{[G]}([G])$ from $\mathbb{M}_n^S(\mathbb{R})$ into $\mathbb{R}^+ = [0, +\infty[$ with respect to the volume element $d^S G$ on $\mathbb{M}_n^S(\mathbb{R})$. This pdf verifies the normalization condition,

$$\int_{\mathbb{M}_n^S(\mathbb{R})} p_{[G]}([G]) d^S G = 1, \quad (8.2)$$

in which the volume element $d^S G$ is defined by Eq. (8.1).

6.1.3 Support of the Probability Density Function

The support of pdf $p_{[G]}$, denoted as $\text{supp } p_{[G]}$, is any subset \mathbb{S}_n of $\mathbb{M}_n^S(\mathbb{R})$, possibly with $\mathbb{S}_n = \mathbb{M}_n^S(\mathbb{R})$. For instance, we can have $\mathbb{S}_n = \mathbb{M}_n^+(\mathbb{R}) \subset \mathbb{M}_n^S(\mathbb{R})$, which means that $[G]$ is a random matrix with values in the positive-definite symmetric $(n \times n)$ real matrices. Thus, $p_{[G]}([G]) = 0$ for $[G]$ not in \mathbb{S}_n , and Eq.(8.2) can be rewritten as

$$\int_{\mathbb{S}_n} p_{[G]}([G]) d^S G = 1. \quad (8.3)$$

It should be noted that, in the context of the construction of the unknown pdf $p_{[G]}$, it is assumed that support \mathbb{S}_n is a given (known) set.

6.2 The Shannon Entropy as a Measure of Uncertainties

The Shannon measure [103] of uncertainties of random matrix $[G]$ is defined by the entropy of information (*Shannon's entropy*), $\mathcal{E}(p_{[G]})$, of pdf $p_{[G]}$ whose support is $\mathbb{S}_n \subset \mathbb{M}_n^S(\mathbb{R})$, such that

$$\mathcal{E}(p_{[G]}) = - \int_{\mathbb{S}_n} p_{[G]}([G]) \log(p_{[G]}([G])) d^S G, \quad (8.4)$$

which can be rewritten as $\mathcal{E}(p_{[G]}) = -E\{\log(p_{[G]}([G]))\}$. For any pdf $p_{[G]}$ defined on $\mathbb{M}_n^S(\mathbb{R})$ and with support \mathbb{S}_n , entropy $\mathcal{E}(p_{[G]})$ is a real number. The uncertainty increases when the Shannon entropy increases. More the Shannon entropy is small and more the level of uncertainties is small. If $\mathcal{E}(p_{[G]})$ goes to $-\infty$, then the level of uncertainties goes to zero, and random matrix $[G]$ goes to a deterministic matrix for the convergence in probability distribution (in probability law).

6.3 The MaxEnt Principle

As explained before, the use of the MaxEnt principle requires to correctly defined the available information related to random matrix $[G]$ for which pdf $p_{[G]}$ (that is unknown with a given support \mathbb{S}_n) has to be constructed.

6.3.1 Available Information

It is assumed that the available information related to random matrix $[G]$ is represented by the following equation on \mathbb{R}^μ , where μ is a finite positive integer,

$$\mathbf{h}(p_{[G]}) = \mathbf{0}, \quad (8.5)$$

in which $p_{[G]} \mapsto \mathbf{h}(p_{[G]}) = (h_1(p_{[G]}), \dots, h_\mu(p_{[G]}))$ is a given functional of $p_{[G]}$, with values in \mathbb{R}^μ . For instance, if the mean value $E\{[G]\} = [\underline{G}]$ of $[G]$ is a

given matrix in \mathbb{S}_n , and if this mean value $[\underline{G}]$ corresponds to the only available information, then $h_\alpha(p_{[G]}) = \int_{\mathbb{S}_n} G_{jk} p_{[G]}([G]) d^S G - \underline{G}_{jk}$, in which $\alpha = 1, \dots, \mu$ is associated with the couple of indices (j, k) such as $1 \leq j \leq k \leq n$ and where $\mu = n(n + 1)/2$.

6.3.2 The Admissible Sets for the pdf

The following admissible sets $\mathcal{C}_{\text{free}}$ and \mathcal{C}_{ad} are introduced for defining the optimization problem resulting from the use of the MaxEnt principle in order to construct the pdf of random matrix $[G]$. The set $\mathcal{C}_{\text{free}}$ is made up of all the pdf $p : [G] \mapsto p([G])$, defined on $\mathbb{M}_n^S(\mathbb{R})$, with support $\mathbb{S}_n \subset \mathbb{M}_n^S(\mathbb{R})$,

$$\mathcal{C}_{\text{free}} = \{[G] \mapsto p([G]) : \mathbb{M}_n^S(\mathbb{R}) \rightarrow \mathbb{R}^+, \text{supp } p = \mathbb{S}_n, \int_{\mathbb{S}_n} p([G]) d^S G = 1\}. \quad (8.6)$$

The set \mathcal{C}_{ad} is the subset of $\mathcal{C}_{\text{free}}$ for which all the pdf p in $\mathcal{C}_{\text{free}}$ satisfy the constraint defined by

$$\mathcal{C}_{\text{ad}} = \{p \in \mathcal{C}_{\text{free}}, \mathbf{h}(p) = \mathbf{0}\}. \quad (8.7)$$

6.3.3 Optimization Problem for Constructing the pdf

The use of the MaxEnt principle for constructing the pdf $p_{[G]}$ of random matrix $[G]$ yields the following optimization problem:

$$p_{[G]} = \arg \max_{p \in \mathcal{C}_{\text{ad}}} \mathcal{E}(p). \quad (8.8)$$

The optimization problem defined by Eq. (8.8) on set \mathcal{C}_{ad} is transformed in an optimization problem on $\mathcal{C}_{\text{free}}$ in introducing the Lagrange multipliers associated with the constraints defined by Eqs. (8.5) [58, 60, 107]. This type of construction and the analysis of the existence and the uniqueness of a solution of the optimization problem defined by Eq. (8.8) are detailed in Sect. 10.

7 A Fundamental Ensemble for the Symmetric Real Random Matrices with a Unit Mean Value

A fundamental ensemble for the symmetric real random matrices is the Gaussian orthogonal ensemble (GOE) that is an ensemble of random matrices $[G]$, defined on a probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in $\mathbb{M}_n^S(\mathbb{R})$, defined by a pdf $p_{[G]}$ on $\mathbb{M}_n^S(\mathbb{R})$ with respect to the volume element $d^S G$, for which the support \mathbb{S}_n of $p_{[G]}$ is $\mathbb{M}_n^S(\mathbb{R})$, and satisfying the additional properties defined hereinafter.

7.1 Classical Definition [74]

The additional properties of a random matrix $[G]$ belonging to GOE are (i) invariance under any real orthogonal transformation, that is to say, for any orthogonal $(n \times n)$ real matrix $[R]$ such that $[R]^T [R] = [R] [R]^T = [I_n]$, the pdf (with respect

to $d^S G$) of the random matrix $[R]^T [\mathbf{G}] [R]$ is equal to pdf $p_{\mathbf{G}}$ of random matrix $[\mathbf{G}]$, and (ii) statistical independence of all the real random variables $\{\mathbf{G}_{jk}, 1 \leq j \leq k \leq n\}$.

7.2 Definition by the MaxEnt and Calculation of the pdf

Alternatively to the properties introduced in the classical definition, the additional properties of a random matrix $[\mathbf{G}]$ belonging to GOE are the following. For all $1 \leq j \leq k \leq n$,

$$E\{\mathbf{G}_{jk}\} = 0, \quad E\{\mathbf{G}_{jk}\mathbf{G}_{j'k'}\} = \delta_{jj'}\delta_{kk'}(1 + \delta_{jk}) \frac{\delta^2}{n+1}. \quad (8.9)$$

in which $\delta > 0$ is a given positive-valued hyperparameter whose interpretation is given after. The GOE is then defined using the MaxEnt principle for the available information given by Eq. (8.9), which defines mapping \mathbf{h} (see Eq. (8.5)). The corresponding ensemble is written as GOE_{δ} . In Eq. (8.9), the first equation means that the symmetric random matrix $[\mathbf{G}]$ is centered, and the second one means that its fourth-order covariance tensor is diagonal. Using the MaxEnt principle for random matrix $[\mathbf{G}]$ yields the following unique explicit expression for the pdf $p_{\mathbf{G}}$ with respect to the volume element $d^S G$:

$$p_{[\mathbf{G}]}([G]) = c_G \exp\left(-\frac{n+1}{4\delta^2} \text{tr}\{[G]^2\}\right), \quad G_{kj} = G_{jk}, \quad 1 \leq j \leq k \leq n, \quad (8.10)$$

in which c_G is the constant of normalization such that Eq. (8.2) is verified. It can then be deduced that $\{\mathbf{G}_{jk}, 1 \leq j \leq k \leq n\}$ are Gaussian independent real random variables such that Eq. (8.9) is verified. Consequently, for all $1 \leq j \leq k \leq n$, the pdf (with respect to dg on \mathbb{R}) of the Gaussian real random variable \mathbf{G}_{jk} is $p_{\mathbf{G}_{jk}}(g) = (\sqrt{2\pi}\sigma_{jk})^{-1} \exp\{-g^2/(2\sigma_{jk}^2)\}$ in which the variance of random variable \mathbf{G}_{jk} is $\sigma_{jk}^2 = (1 + \delta_{jk})\delta^2/(n+1)$.

7.3 Decentering and Interpretation of Hyperparameter δ

Let $[\mathbf{G}^{\text{GOE}}]$ be the random matrix with values in $\mathbb{M}_n^S(\mathbb{R})$ such that $[\mathbf{G}^{\text{GOE}}] = [I_n] + [\mathbf{G}]$ in which $[\mathbf{G}]$ is a random matrix belonging to the GOE_{δ} defined before. Therefore $[\mathbf{G}^{\text{GOE}}]$ is not centered and its mean value is $E\{[\mathbf{G}^{\text{GOE}}]\} = [I_n]$. The coefficient of variation of the random matrix $[\mathbf{G}^{\text{GOE}}]$ is defined [109] by

$$\delta_{\text{GOE}} = \left\{ \frac{E\{\|\mathbf{G}^{\text{GOE}} - E\{\mathbf{G}^{\text{GOE}}\}\|_F^2\}}{\|E\{\mathbf{G}^{\text{GOE}}\}\|_F^2} \right\}^{1/2} = \left\{ \frac{1}{n} E\{\|\mathbf{G}^{\text{GOE}} - I_n\|_F^2\} \right\}^{1/2}, \quad (8.11)$$

and $\delta_{\text{GOE}} = \delta$. The parameter $2\delta/\sqrt{n+1}$ can be used to specify a scale.

7.4 Generator of Realizations

For $\theta \in \Theta$, any realization $[\mathbf{G}^{\text{GOE}}(\theta)]$ is given by $[\mathbf{G}^{\text{GOE}}(\theta)] = [I_n] + [\mathbf{G}(\theta)]$ with, for $1 \leq j \leq k \leq n$, $\mathbf{G}_{kj}(\theta) = \mathbf{G}_{jk}(\theta)$ and $\mathbf{G}_{jk}(\theta) = \sigma_{jk} U_{jk}(\theta)$, in which $\{U_{jk}(\theta)\}_{1 \leq j \leq k \leq n}$ is the realization of $n(n+1)/2$ independent copies of a normalized (centered and unit variance) Gaussian real random variable.

7.5 Use of the GOE Ensemble in Uncertainty Quantification

The GOE can then be viewed as a generalization of the Gaussian real random variables to the Gaussian symmetric real random matrices. It can be seen that $[\mathbf{G}^{\text{GOE}}]$ is with values in $\mathbb{M}_n^S(\mathbb{R})$ but is not positive. In addition, for all fixed n ,

$$E\{\|[\mathbf{G}^{\text{GOE}}]^{-1}\|^2\} = +\infty. \quad (8.12)$$

- (i) It has been proved by Weaver [124] and others (see [127] and included references) that the GOE is well adapted for describing universal fluctuations of the eigenfrequencies for generic elastodynamical, acoustical, and elastoacoustical systems, in the high-frequency range corresponding to the asymptotic behavior of the largest eigenfrequencies.
- (ii) On the other hand, random matrix $[\mathbf{G}^{\text{GOE}}]$ cannot be used for stochastic modeling of a symmetric real matrix for which a positiveness property and an integrability of its inverse are required. Such a situation is similar to the following one that is well known for the scalar case. Let us consider the scalar equation in u : $(\underline{G} + G)u = v$ in which v is a given real number, \underline{G} is a given positive number, and G is a positive parameter. This equation has a unique solution $u = (\underline{G} + G)^{-1}v$. Let us assume that G is uncertain and is modeled by a centered random variable \mathbf{G} . We then obtain the random equation in U : $(\underline{G} + \mathbf{G})U = v$. If the random solution U must have finite statistical fluctuations, that is to say, U must be a second-order random variable (this is generally required due to physical considerations), then \mathbf{G} cannot be chosen as a Gaussian second-order centered real random variable, because with such a Gaussian stochastic modeling, the solution $U = (\underline{G} + \mathbf{G})^{-1}v$ is not a second-order random variable, because $E\{U^2\} = +\infty$ due to the non integrability of the function $G \mapsto (\underline{G} + G)^{-2}$ at point $G = -\underline{G}$.

8 Fundamental Ensembles for Positive-Definite Symmetric Real Random Matrices

In this section, we present fundamental ensembles of positive-definite symmetric real random matrices, SG_0^+ , SG_ε^+ , SG_b^+ , and SG_λ^+ , which have been developed and

analyzed for constructing other ensembles of random matrices used for the nonparametric stochastic modeling of matrices encountered in uncertainty quantification.

- The ensemble SG_0^+ is a subset of all the positive-definite symmetric real $(n \times n)$ random matrices for which the mean value is the unit matrix and for which the lower bound is the zero matrix. This ensemble has been introduced and analyzed in [107, 108] in the context of the development of the nonparametric method of model uncertainties induced by modeling errors in computational dynamics. This ensemble has later been used for constructing other ensembles of random matrices encountered in the nonparametric stochastic modeling of uncertainties [110].
- The ensemble SG_ε^+ is a subset of all the positive-definite symmetric real $(n \times n)$ random matrices for which the mean value is the unit matrix and for which there is an arbitrary lower bound that is a positive-definite matrix controlled by an arbitrary positive number ε that can be chosen as small as is desired [114]. In such an ensemble, the lower bound does not correspond to a given matrix that results from a physical model, but allows for assuring a uniform ellipticity for the stochastic modeling of elliptic operators encountered in uncertainty quantification of boundary value problems. The construction of this ensemble is directly derived from ensemble SG_0^+ ,
- The ensemble SG_b^+ is a subset of all the positive-definite random matrices for which the mean value is either not given or is equal to the unit matrix [28, 50] and for which a lower bound and an upper bound are given positive-definite matrices. In this ensemble, the lower bound and the upper bound are not arbitrary positive-definite matrices, but are given matrices that result from a physical model. The ensemble is interesting for the nonparametric stochastic modeling of tensors and tensor-valued random fields for describing uncertain physical properties in elasticity, poroelasticity, thermics, etc.
- The ensemble SG_λ^+ , introduced in [76], is a subset of all the positive-definite random matrices for which the mean value is the unit matrix, for which the lower bound is the zero matrix, and for which the second-order moments of diagonal entries are imposed. In the context of the nonparametric stochastic modeling of uncertainties, this ensemble allows for imposing the variances of certain random eigenvalues of stochastic generalized eigenvalue problems, such as the eigenfrequency problem in structural dynamics.

8.1 Ensemble SG_0^+ of Positive-Definite Random Matrices With a Unit Mean Value

8.1.1 Definition of SG_0^+ Using the MaxEnt and Expression of the pdf

The ensemble SG_0^+ of random matrices $[G_0]$, defined on the probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in the set $\mathbb{M}_n^+(\mathbb{R}) \subset \mathbb{M}_n^S(\mathbb{R})$, is constructed using the

MaxEnt with the following available information, which defines mapping \mathbf{h} (see Eq. (8.5)):

$$E\{\mathbf{G}_0\} = [I_n], \quad E\{\log(\det[\mathbf{G}_0])\} = v_{G_0}, \quad |v_{G_0}| < +\infty. \quad (8.13)$$

The support of the pdf is the subset $\mathbb{S}_n = \mathbb{M}_n^+(\mathbb{R})$ of $\mathbb{M}_n^S(\mathbb{R})$. This pdf $p_{[\mathbf{G}_0]}$ (with respect to the volume element $d^S G$ on the set $\mathbb{M}_n^S(\mathbb{R})$) verifies the normalization condition and is written as

$$p_{[\mathbf{G}_0]}([G]) = \mathbb{1}_{\mathbb{S}_n}([G]) c_{G_0} (\det[G])^{(n+1)\frac{(1-\delta^2)}{2\delta^2}} \exp(-\frac{n+1}{2\delta^2} \text{tr}[G]). \quad (8.14)$$

The positive parameter δ is such that $0 < \delta < (n+1)^{1/2}(n+5)^{-1/2}$, which allows the level of statistical fluctuations of random matrix $[\mathbf{G}_0]$ to be controlled and which is defined by

$$\delta = \left\{ \frac{E\{\|\mathbf{G}_0 - E\{\mathbf{G}_0\}\|_F^2\}}{\|E\{\mathbf{G}_0\}\|_F^2} \right\}^{1/2} = \left\{ \frac{1}{n} E\{\|\mathbf{G}_0 - [I_n]\|_F^2\} \right\}^{1/2}. \quad (8.15)$$

The normalization positive constant c_{G_0} is such that

$$c_{G_0} = (2\pi)^{-n(n-1)/4} \left(\frac{n+1}{2\delta^2} \right)^{n(n+1)(2\delta^2)^{-1}} \left\{ \prod_{j=1}^n \Gamma\left(\frac{n+1}{2\delta^2} + \frac{1-j}{2}\right) \right\}^{-1}, \quad (8.16)$$

where, for all $z > 0$, $\Gamma(z) = \int_0^{+\infty} t^{z-1} e^{-t} dt$. Note that $\{\mathbf{G}_0\}_{jk}$, $1 \leq j \leq k \leq n$ are dependent random variables. If $(n+1)/\delta^2$ is an integer, then this pdf coincides with the Wishart probability distribution [2, 107]. If $(n+1)/\delta^2$ is not an integer, then this probability density function can be viewed as a particular case of the Wishart distribution, in infinite dimension, for stochastic processes [104].

8.1.2 Second-Order Moments

Random matrix $[\mathbf{G}_0]$ is such that $E\{\|\mathbf{G}_0\|^2\} \leq E\{\|\mathbf{G}_0\|_F^2\} < +\infty$, which proves that $[\mathbf{G}_0]$ is a second-order random variable. The mean value of random matrix $[\mathbf{G}_0]$ is unit matrix $[I_n]$. The covariance $C_{jk,j'k'} = E\{[\mathbf{G}_0]_{jk} - [I_n]_{jk}\} ([\mathbf{G}_0]_{j'k'} - [I_n]_{j'k'})$ of the real-valued random variables $[\mathbf{G}_0]_{jk}$ and $[\mathbf{G}_0]_{j'k'}$ is $C_{jk,j'k'} = \delta^2(n+1)^{-1}\{\delta_{j'k} \delta_{jk'} + \delta_{jj'} \delta_{kk'}\}$. The variance of real-valued random variable $[\mathbf{G}_0]_{jk}$ is $\sigma_{jk}^2 = C_{jk,jk} = \delta^2(n+1)^{-1}(1 + \delta_{jk})$.

8.1.3 Invariance of Ensemble \mathbf{SG}_0^+ Under Real Orthogonal Transformations

Ensemble \mathbf{SG}_0^+ is invariant under real orthogonal transformations. This means that the pdf (with respect to $d^S G$) of the random matrix $[R]^T [\mathbf{G}_0] [R]$ is equal to the pdf

(with respect to $d^S G$) of random matrix $[G_0]$ for any real orthogonal matrix $[R]$ belonging to $\mathbb{M}_n(\mathbb{R})$.

8.1.4 Invertibility and Convergence Property When Dimension Goes to Infinity

Since $[G_0]$ is a positive-definite random matrix, $[G_0]$ is invertible almost surely, which means that for \mathcal{P} -almost θ in Θ , the inverse $[G_0(\theta)]^{-1}$ of the matrix $[G_0(\theta)]$ exists. This last property does not guarantee that $[G_0]^{-1}$ is a second-order random variable, that is to say, that $E\{\|[G_0]^{-1}\|_F^2\} = \int_{\Theta} \|[G_0(\theta)]^{-1}\|_F^2 d\mathcal{P}(\theta)$ is finite. However, it is proved [108] that

$$E\{\|[G_0]^{-1}\|_F^2\} \leq E\{\|[G_0]^{-1}\|_F^2\} < +\infty, \quad (8.17)$$

and that the following fundamental property holds:

$$\forall n \geq 2, \quad E\{\|[G_0]^{-1}\|_F^2\} \leq C_{\delta} < +\infty, \quad (8.18)$$

in which C_{δ} is a positive finite constant that is independent of n but that depends on δ . This means that $n \mapsto E\{\|[G_0]^{-1}\|_F^2\}$ is a bounded function from $\{n \geq 2\}$ into \mathbb{R}^+ .

It should be noted that the invertibility property defined by Eqs. (8.17) and (8.18) is due to the constraint $E\{\log(\det[G_0])\} = v_{G_0}$ with $|v_{G_0}| < +\infty$. This is the reason why the truncated Gaussian distribution restricted to $\mathbb{M}_n^+(\mathbb{R})$ does not satisfy this invertibility condition that is required for stochastic modeling in many cases.

8.1.5 Probability Density Function of the Random Eigenvalues

Let $\Lambda = (\Lambda_1, \dots, \Lambda_n)$ be the positive-valued random eigenvalues of the random matrix $[G_0]$ belonging to ensemble SG_0^+ , such that $[G_0] \Phi^j = \Lambda_j \Phi^j$ in which Φ^j is the random eigenvector associated with the random eigenvalue Λ_j . The joint probability density function $p_{\Lambda}(\lambda) = p_{\Lambda_1, \dots, \Lambda_n}(\lambda_1, \dots, \lambda_n)$ with respect to $d\lambda = d\lambda_1 \dots d\lambda_n$ of $\Lambda = (\Lambda_1, \dots, \Lambda_n)$ is written [107] as

$$p_{\Lambda}(\lambda) = \mathbb{1}_{[0, +\infty]^n}(\lambda) c_{\Lambda} \left\{ \prod_{j=1}^n \lambda_j^{(n+1)\frac{(1-\delta^2)}{2\delta^2}} \right\} \left\{ \prod_{\alpha < \beta} |\lambda_{\beta} - \lambda_{\alpha}| \right\} \exp \left\{ -\frac{(n+1)}{2\delta^2} \sum_{k=1}^n \lambda_k \right\}, \quad (8.19)$$

in which c_{Λ} is a constant of normalization defined by the equation $\int_0^{+\infty} \dots \int_0^{+\infty} p_{\Lambda}(\lambda) d\lambda = 1$. All the random eigenvalues Λ_j of random matrix $[G_0]$ in SG_0^+ are positive almost surely, while this assertion is not true for the random eigenvalues Λ_j^{GOE} of the random matrix $[G]^{\text{GOE}} = [I_n] + [G]$ in which $[G]$ is a random matrix belonging to the GOE_{δ} ensemble.

8.1.6 Algebraic Representation and Generator of Realizations

The generator of realizations of random matrix $[\mathbf{G}_0]$ whose pdf is defined by Eq. (8.14) is directly deduced from the following algebraic representation of $[\mathbf{G}_0]$ in SG_0^+ . Random matrix $[\mathbf{G}_0]$ is written as $[\mathbf{G}_0] = [\mathbf{L}]^T [\mathbf{L}]$ in which $[\mathbf{L}]$ is an upper triangular real $(n \times n)$ random matrix such that:

- (i) The random variables $\{[\mathbf{L}]_{jk}, j \leq k\}$ are independent;
- (ii) For $j < k$, the real-valued random variable $[\mathbf{L}]_{jk}$ is written as $[\mathbf{L}]_{jk} = \sigma_n U_{jk}$ in which $\sigma_n = \delta(n+1)^{-1/2}$ and where U_{jk} is a real-valued Gaussian random variable with zero mean and variance equal to 1;
- (iii) For $j = k$, the positive-valued random variable $[\mathbf{L}]_{jj}$ is written as $[\mathbf{L}]_{jj} = \sigma_n \sqrt{2V_j}$ in which σ_n is defined before and where V_j is a positive-valued gamma random variable whose pdf is $p_{V_j}(v) = \mathbb{1}_{\mathbb{R}^+}(v) \frac{1}{\Gamma(a_j)} v^{a_j-1} e^{-v}$, in which $a_j = \frac{n+1}{2\delta^2} + \frac{1-j}{2}$.

It should be noted that the set $\{\{U_{jk}\}_{1 \leq j < k \leq n}, \{V_j\}_{1 \leq j \leq n}\}$ of random variables are statistically independent, and the pdf of each diagonal element $[\mathbf{L}]_{jj}$ of random matrix $[\mathbf{L}]$ depends on the rank j of the entry.

For $\theta \in \Theta$, any realization $[\mathbf{G}_0(\theta)]$ is then deduced from the algebraic representation given before, using the realization $\{U_{jk}(\theta)\}_{1 \leq j < k \leq n}$ of $n(n-1)/2$ independent copies of a normalized (zero mean and unit variance) Gaussian real random variable and using the realization $\{V_j(\theta)\}_{1 \leq j \leq n}$ of the n independent positive-valued gamma random variable V_j with parameter a_j .

8.2 Ensemble SG_ε^+ of Positive-Definite Random Matrices with a Unit Mean Value and an Arbitrary Positive-Definite Lower Bound

The ensemble SG_ε^+ is a subset of all the positive-definite random matrices for which the mean value is the unit matrix and for which there is an arbitrary lower bound that is a positive-definite matrix controlled by an arbitrary positive number ε that can be chosen as small as is desired. In this ensemble, the lower bound does not correspond to a given matrix that results from a physical model.

Ensemble SG_ε^+ is the set of the random matrices $[\mathbf{G}]$ with values in $\mathbb{M}_n^+(\mathbb{R})$, which are written as

$$[\mathbf{G}] = \frac{1}{1+\varepsilon} \{[\mathbf{G}_0] + \varepsilon [I_n]\}, \quad (8.20)$$

in which $[\mathbf{G}_0]$ is a random matrix in SG_0^+ , with mean value $E\{[\mathbf{G}_0]\} = [I_n]$, and for which the level of statistical fluctuations is controlled by the hyperparameter δ defined by Eq. (8.15) and where ε is any positive number (note that for $\varepsilon = 0$, $\text{SG}_\varepsilon^+ = \text{SG}_0^+$ and then $[\mathbf{G}] = [\mathbf{G}_0]$). This definition shows that, almost surely,

$$[\mathbf{G}] - [G_\ell] = \frac{1}{1+\varepsilon} [\mathbf{G}_0] > 0, \quad (8.21)$$

in which the lower bound is the positive-definite matrix $[G_\ell] = c_\varepsilon[I_n]$ with $c_\varepsilon = \varepsilon/(1 + \varepsilon)$. For all $\varepsilon > 0$, we have

$$E\{[\mathbf{G}]\} = [I_n], \quad E\{\log(\det([\mathbf{G}] - [G_\ell]))\} = v_{G_\varepsilon}, \quad |v_{G_\varepsilon}| < +\infty, \quad (8.22)$$

with $v_{G_\varepsilon} = v_{G_0} - n \log(1 + \varepsilon)$. The coefficient of variation δ_G of random matrix $[\mathbf{G}]$, defined by

$$\delta_G = \left\{ \frac{E\{\|\mathbf{G} - E\{\mathbf{G}\}\|_F^2\}}{\|E\{\mathbf{G}\}\|_F^2} \right\}^{1/2} = \left\{ \frac{1}{n} E\{\|\mathbf{G} - [I_n]\|_F^2\} \right\}^{1/2}, \quad (8.23)$$

is such that

$$\delta_G = \frac{\delta}{1 + \varepsilon}, \quad (8.24)$$

where δ is the hyperparameter defined by Eq. (8.15).

8.2.1 Generator of Realizations

For $\theta \in \Theta$, any realization $[\mathbf{G}(\theta)]$ of $[\mathbf{G}]$ is given by $[\mathbf{G}(\theta)] = \frac{1}{1+\varepsilon}\{[\mathbf{G}_0(\theta)] + \varepsilon[I_n]\}$ in which $[\mathbf{G}_0(\theta)]$ is a realization of random matrix $[\mathbf{G}_0]$ constructed as explained before.

8.2.2 Lower Bound and Invertibility

For all $\varepsilon > 0$, the bilinear form $b(\mathbf{X}, \mathbf{Y}) = (([\mathbf{G}]\mathbf{X}, \mathbf{Y}))$ on $\mathcal{L}_n^2 \times \mathcal{L}_n^2$ is such that

$$b(\mathbf{X}, \mathbf{X}) \geq c_\varepsilon \|\mathbf{X}\|^2. \quad (8.25)$$

Random matrix $[\mathbf{G}]$ is invertible almost surely and its inverse $[\mathbf{G}]^{-1}$ is a second-order random variable, $E\{\|[\mathbf{G}]^{-1}\|_F^2\} < +\infty$.

8.3 Ensemble SG_b^+ of Positive-Definite Random Matrices with Given Lower and Upper Bounds and with or without Given Mean Value

The ensemble SG_b^+ is a subset of all the positive-definite random matrices for which the mean value is either the unit matrix or is not given and for which a lower bound and an upper bound are given positive-definite matrices. In this ensemble, the lower bound and the upper bound are not arbitrary positive-definite matrices, but are given matrices that result from a physical model.

The ensemble SG_b^+ is constituted of random matrices $[\mathbf{G}_b]$, defined on the probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in the set $\mathbb{M}_n^+(\mathbb{R}) \subset \mathbb{M}_n^S(\mathbb{R})$, such that

$$[0] < [G_\ell] < [\mathbf{G}_b] < [G_u], \quad (8.26)$$

in which the lower bound $[G_\ell]$ and the upper bound $[G_u]$ are given matrices in $\mathbb{M}_n^+(\mathbb{R})$ such that $[G_\ell] < [G_u]$. The support of the pdf $p_{[\mathbf{G}_b]}$ (with respect to the volume element $d^S G$ on $\mathbb{M}_n^S(\mathbb{R})$) of random matrix $[\mathbf{G}_b]$ is the subset \mathbb{S}_n of $\mathbb{M}_n^+(\mathbb{R}) \subset \mathbb{M}_n^S(\mathbb{R})$ such that

$$\mathbb{S}_n = \{ [G] \in \mathbb{M}_n^+(\mathbb{R}) \mid [G_\ell] < [G] < [G_u] \}. \quad (8.27)$$

The available information associated with the presence of the lower and upper bounds is defined by

$$E\{\log(\det([\mathbf{G}_b] - [G_\ell]))\} = v_\ell, \quad E\{\log(\det([G_u] - [\mathbf{G}_b]))\} = v_u, \quad (8.28)$$

in which v_ℓ and v_u are two constants such that $|v_\ell| < +\infty$ and $|v_u| < +\infty$. The mean value $[\underline{G}_b] = E\{[\mathbf{G}_b]\}$ is given by

$$[\underline{G}_b] = \int_{\mathbb{S}_n} [G] p_{[\mathbf{G}_b]}([G]) d^S G. \quad (8.29)$$

The positive parameter δ_b , which allows the level of statistical fluctuations of random matrix $[\mathbf{G}_b]$ to be controlled, is defined by

$$\delta_b = \left\{ \frac{E\{\|\mathbf{G}_b - \underline{G}_b\|_F^2\}}{\|\underline{G}_b\|_F^2} \right\}^{1/2}. \quad (8.30)$$

8.3.1 Definition of SG_b^+ for a Non-given Mean Value Using the MaxEnt

The mean value $[\underline{G}_b]$ of random matrix $[\mathbf{G}_b]$ is not given and therefore does not constitute an available information. In this case, the ensemble SG_b^+ is constructed using the MaxEnt with the available information given by Eq. (8.28) (that defines mapping \mathbf{h} introduced in Eq. (8.5) and rewritten for $p_{[\mathbf{G}_b]}$). The pdf $p_{[\mathbf{G}_b]}$ is the generalized matrix-variate beta-type I pdf [55]:

$$p_{[\mathbf{G}_b]}([G]) = \mathbb{1}_{\mathbb{S}_n}([G]) c_{G_b} (\det[G - G_\ell])^{\alpha-(n+1)/2} (\det[G_u - G])^{\beta-(n+1)/2}, \quad (8.31)$$

in which c_{G_b} is the normalization constant and where $\alpha > (n-1)/2$ and $\beta > (n-1)/2$ are two real parameters that are unknown and that depend on the two unknown constants v_ℓ and v_u . The mean value $[\underline{G}_b]$ must be calculated using Eqs. (8.29) and (8.31), and the hyperparameter δ_b , which characterizes the level of statistical fluctuations, must be calculated using Eqs. (8.30) and (8.31). Consequently, $[\underline{G}_b]$ and δ_b depend on α and β . It can be seen that, for $n \geq 2$, the two scalar parameters α and β are not sufficient for identifying the mean value $[\underline{G}_b]$ that is in \mathbb{S}_n and the hyperparameter δ_b . An efficient algorithm for generating realizations of $[\mathbf{G}_b]$ can be found in [28].

8.3.2 Definition of SG_b^+ for a Given Mean Value Using the MaxEnt

The mean value $[\underline{G}_b]$ of random matrix $[\mathbf{G}_b]$ is given such that $[G_\ell] < [\underline{G}_b] < [G_u]$. In this case, the ensemble SG_b^+ is constructed using the MaxEnt with the available information given by Eqs. (8.28) and (8.29) that defines mapping \mathbf{h} introduced in Eq. (8.5). Following the construction proposed in [50], the following change of variable is introduced:

$$[\mathbf{A}_0] = ([\mathbf{G}_b] - [G_\ell])^{-1} - [G_{\ell u}]^{-1}, \quad [G_{\ell u}] = [G_u] - [G_\ell] \in \mathbb{M}_n^+(\mathbb{R}). \quad (8.32)$$

This equation shows that the random matrix $[\mathbf{A}_0]$ is with values in $\mathbb{M}_n^+(\mathbb{R})$. Introducing the mean value $[\underline{\mathbf{A}}_0] = E\{[\mathbf{A}_0]\}$ that belongs to $\mathbb{M}_n^+(\mathbb{R})$ and is Cholesky factorization $[\underline{\mathbf{A}}_0] = [\underline{\mathbf{L}}_0]^T [\underline{\mathbf{L}}_0]$ in which $[\underline{\mathbf{L}}_0]$ is an upper triangular real $(n \times n)$ matrix, random matrix $[\mathbf{A}_0]$ can be written as $[\mathbf{A}_0] = [\underline{\mathbf{L}}_0]^T [\mathbf{G}_0] [\underline{\mathbf{L}}_0]$ with $[\mathbf{G}_0]$ that belongs to ensemble SG_0^+ depending on the hyperparameter δ defined by Eq. (8.15). The inversion of Eq. (8.32) yields

$$[\mathbf{G}_b] = [G_\ell] + ([\underline{\mathbf{L}}_0]^T [\mathbf{G}_0] [\underline{\mathbf{L}}_0] + [G_{\ell u}]^{-1})^{-1}. \quad (8.33)$$

It can then be seen that for any arbitrary small $\varepsilon_0 > 0$ (for instance, $\varepsilon_0 = 10^{-6}$), we have

$$\|E\{([\mathbf{A}_0] + [G_{\ell u}]^{-1})^{-1}\} + [G_\ell] - [\underline{G}_b]\|_F \leq \varepsilon_0 \|\underline{G}_b\|_F. \quad (8.34)$$

For δ and $[\underline{\mathbf{L}}_0]$ fixed, for θ in Θ , the realization $[\mathbf{G}_0(\theta)]$ of random matrix $[\mathbf{G}_0]$ in SG_0^+ is constructed using the generator of $[\mathbf{G}_0]$, which has been detailed before. The mean value $E\{[\mathbf{G}_b]\}$ and the hyperparameter δ_b defined by Eq. (8.30) are estimated with the corresponding realization $[\mathbf{G}_b(\theta)] = [G_\ell] + ([\underline{\mathbf{L}}_0]^T [\mathbf{G}_0(\theta)] [\underline{\mathbf{L}}_0] + [G_{\ell u}]^{-1})^{-1}$ of random matrix $[\mathbf{G}_b]$. Let \mathcal{U}_L be the set of all the upper triangular real $(n \times n)$ matrices $[\underline{\mathbf{L}}_0]$ with positive diagonal entries. For a fixed value of δ , and for a given target value of $[\underline{G}_b]$, the value $[\underline{\mathbf{L}}_0^{\text{opt}}]$ of $[\underline{\mathbf{L}}_0]$ is calculated in solving the optimization problem

$$[\underline{\mathbf{L}}_0^{\text{opt}}] = \arg \min_{[\underline{\mathbf{L}}_0] \in \mathcal{U}_L} \mathcal{F}([\underline{\mathbf{L}}_0]), \quad (8.35)$$

in which the cost function \mathcal{F} is deduced from Eq. (8.34) and is written as

$$\mathcal{F}([\underline{\mathbf{L}}_0]) = \|E\{([\underline{\mathbf{L}}_0]^T [\mathbf{G}_0] [\underline{\mathbf{L}}_0] + [G_{\ell u}]^{-1})^{-1}\} + [G_\ell] - [\underline{G}_b]\|_F / \|\underline{G}_b\|_F. \quad (8.36)$$

8.4 Ensemble \mathbf{SG}_λ^+ of Positive-Definite Random Matrices with a Unit Mean Value and Imposed Second-Order Moments

The ensemble \mathbf{SG}_λ^+ is a subset of all the positive-definite random matrices for which the mean value is the unit matrix, for which the lower bound is the zero matrix, and for which the second-order moments of diagonal entries are imposed. In the context of nonparametric stochastic modeling of uncertainties, this ensemble allows for imposing the variances of certain random eigenvalues of stochastic generalized eigenvalue problems.

8.4.1 Definition of \mathbf{SG}_λ^+ Using the MaxEnt and Expression of the pdf

The ensemble \mathbf{SG}_λ^+ of random matrices $[\mathbf{G}_\lambda]$, defined on the probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in the set $\mathbb{M}_n^+(\mathbb{R}) \subset \mathbb{M}_n^S(\mathbb{R})$, is constructed using the MaxEnt with the following available information, which defines mapping \mathbf{h} (see Eq. (8.5)):

$$E\{[\mathbf{G}_\lambda]\} = [I_n], \quad E\{\log(\det[\mathbf{G}_\lambda])\} = v_{G_\lambda}, \quad E\{[\mathbf{G}_\lambda]_{jj}^2\} = s_j^2, \quad j = 1, \dots, m, \quad (8.37)$$

in which $|v_{G_\lambda}| < +\infty$, with $m < n$, and where s_1^2, \dots, s_m^2 are m given positive constants. The pdf $p_{[\mathbf{G}_\lambda]}$ (with respect to the volume element $d^S G$ on the set $\mathbb{M}_n^S(\mathbb{R})$) has a support that is $\mathbb{S}_n = \mathbb{M}_n^+(\mathbb{R}) \subset \mathbb{M}_n^S(\mathbb{R})$ of $\mathbb{M}_n^S(\mathbb{R})$. The pdf verifies the normalization condition and is written [76] as

$$p_{[\mathbf{G}_\lambda]}([G]) = \mathbb{1}_{\mathbb{S}_n}([G]) \times C_{G_\lambda} \times (\det[G])^{\alpha-1} \times \exp\{-\text{tr}\{[\mu]^T[G]\} - \sum_{j=1}^m \tau_j G_{jj}^2\}, \quad (8.38)$$

in which C_{G_λ} is the normalization constant and α is a parameter such that $n + 2\alpha - 1 > 0$, where $[\mu]$ is a diagonal real $(n \times n)$ matrix such that $\mu_{jj} = (n + 2\alpha - 1)/2$ for $j > m$ and where $\mu_{11}, \dots, \mu_{mm}$ and τ_1, \dots, τ_m are $2m$ positive parameters, which are expressed as a function of α and s_1^2, \dots, s_m^2 . The level of statistical fluctuations of random matrix $[\mathbf{G}_\lambda]$ is controlled by the positive hyperparameter δ that is defined by

$$\delta = \left\{ \frac{E\{\|\mathbf{G}_\lambda - E\{\mathbf{G}_\lambda\}\|_F^2\}}{\|E\{\mathbf{G}_\lambda\}\|_F^2} \right\}^{1/2} = \left\{ \frac{1}{n} E\{\|\mathbf{G}_\lambda - [I_n]\|_F^2\} \right\}^{1/2}, \quad (8.39)$$

and where δ is such that

$$\delta^2 = \frac{1}{n} \sum_{j=1}^m s_j^2 + \frac{n + 1 - (m/n)(n + 2\alpha - 1)}{n + 2\alpha - 1}. \quad (8.40)$$

8.4.2 Generator of Realizations

For given $m < n$, δ , and s_1^2, \dots, s_m^2 , the explicit generator of realizations of random matrix $[\mathbf{G}_\lambda]$ whose pdf is defined by Eq. (8.38) is detailed in [76].

9 Ensembles of Random Matrices for the Nonparametric Method in Uncertainty Quantification

In this section, we present the ensembles SE_0^+ , SE_ε^+ , SE^{+0} , SE^{rect} , and SE^{HT} of random matrices which result from some transformations of the fundamental ensembles introduced before. These ensembles of random matrices are useful for performing the nonparametric stochastic modeling of matrices encountered in uncertainty quantification of computational models in structural dynamics, acoustics, vibroacoustics, fluid-structure interaction, unsteady aeroelasticity, soil-structure interaction, etc., but also in solid mechanics (elasticity tensors of random elastic continuous media, matrix-valued random fields for heterogeneous microstructures of materials), thermic (thermal conductivity tensor), electromagnetism (dielectric tensor), etc.

The ensembles of random matrices, devoted to the construction of nonparametric stochastic models of matrices encountered in uncertainty quantification, are briefly summarized below and then are mathematically detailed:

- The ensemble SE_0^+ is a subset of all the positive-definite random matrices for which the mean values are given and differ from the unit matrix (unlike to ensemble SG_0^+) and for which the lower bound is the zero matrix. This ensemble is constructed as a transformation of ensemble SG_0^+ in keeping all the mathematical properties of ensemble SG_0^+ such as the positiveness.
- The ensemble SE_ε^+ is a subset of all the positive-definite random matrices for which the mean value is a given positive-definite matrix and for which there is an arbitrary lower bound that is a positive-definite matrix controlled by an arbitrary positive number ε that can be chosen as small as is desired. In this ensemble, the lower bound does not correspond to a given matrix that results from a physical model. This ensemble is constructed as a transformation of ensemble SG_ε^+ and has the same area of use than ensemble SE_0^+ for stochastic modeling in uncertainty quantification but for which a lower bound is required in the stochastic modeling for mathematical reasons.
- The ensemble SE^{+0} is similar to ensemble SG_0^+ but is constituted of semipositive-definite ($m \times m$) real random matrices for which the mean value is a given semipositive-definite matrix. This ensemble is constructed as a transformation of positive-definite ($n \times n$) real random matrices belonging to ensemble SG_0^+ , with $n < m$, in which the dimension of the null space is $m - n$. Such an ensemble is useful for the nonparametric stochastic modeling of uncertainties such as those encountered in structural dynamics in presence of rigid body displacements.

- The ensemble SE^{rect} is an ensemble of rectangular random matrices for which the mean value is a given rectangular matrix and which is constructed using ensemble SE_ε^+ . This ensemble is useful for the nonparametric stochastic modeling of some uncertain coupling operators encountered, for instance, in fluid-structure interaction and in vibroacoustics.
- The ensemble SE^{HT} is a set of random functions with values in the set of the complex matrices such that the real part and the imaginary part are positive-definite random matrices that are constrained by an underlying Hilbert transform induced by a causality property. This ensemble allows for a nonparametric stochastic modeling in uncertainty quantification encountered, for instance, in linear viscoelasticity.

9.1 Ensemble SE_0^+ of Positive-Definite Random Matrices with a Given Mean Value

The ensemble SE_0^+ is a subset of all the positive-definite random matrices for which the mean values are given and differ from the unit matrix (unlike to ensemble SG_0^+). This ensemble is constructed as a transformation of ensemble SG_0^+ in keeping all the mathematical properties of ensemble SG_0^+ such as the positiveness [107].

9.1.1 Definition of Ensemble SE_0^+

Any random matrix $[\mathbf{A}_0]$ in ensemble SE_0^+ is defined on the probability space $(\Theta, \mathcal{T}, \mathcal{P})$, is with values in $\mathbb{M}_n^+(\mathbb{R}) \subset \mathbb{M}_n^S(\mathbb{R})$, and is such that

$$E\{[\mathbf{A}_0]\} = [A], \quad E\{\log(\det[\mathbf{A}_0])\} = v_{A_0}, \quad |v_{A_0}| < +\infty, \quad (8.41)$$

in which the mean value $[A]$ is a given matrix in $\mathbb{M}_n^+(\mathbb{R})$.

9.1.2 Expression of $[\mathbf{A}_0]$ as a Transformation of $[\mathbf{G}_0]$ and Generator of Realizations

Positive-definite mean matrix $[A]$ is factorized (Cholesky) as

$$[A] = [L_A]^T [L_A], \quad (8.42)$$

in which $[L_A]$ is an upper triangular matrix in $\mathbb{M}_n(\mathbb{R})$. Taking into account Eq. (8.41) and the definition of ensemble SG_0^+ , any random matrix $[\mathbf{A}_0]$ in ensemble SE_0^+ is written as

$$[\mathbf{A}_0] = [L_A]^T [\mathbf{G}_0] [L_A], \quad (8.43)$$

in which the random matrix $[\mathbf{G}_0]$ belongs to ensemble SG_0^+ , with mean value $E\{[\mathbf{G}_0]\} = [I_n]$, and for which the level of statistical fluctuations is controlled by the hyperparameter δ defined by Eq. (8.15).

Generator of realizations. For all θ in Θ , the realization $[\mathbf{G}_0(\theta)]$ of $[\mathbf{G}_0]$ is constructed as explained before. The realization $[\mathbf{A}_0(\theta)]$ of random matrix $[\mathbf{A}_0]$ is calculated by $[\mathbf{A}_0(\theta)] = [L_A]^T [\mathbf{G}_0(\theta)] [L_A]$.

Remark 1. It should be noted that the mean matrix $[A]$ could also been written as $[A] = [A]^{1/2} [A]^{1/2}$ in which $[A]^{1/2}$ is the square root of $[A]$ in $\mathbb{M}_n^+(\mathbb{R})$ and the random matrix $[\mathbf{A}_0]$ could then be written as $[\mathbf{A}_0] = [A]^{1/2} [\mathbf{G}_0] [A]^{1/2}$.

9.1.3 Properties of Random Matrix $[\mathbf{A}_0]$

Any random matrix $[\mathbf{A}_0]$ in ensemble SE_0^+ is a second-order random variable,

$$E\{\|\mathbf{A}_0\|^2\} \leq E\{\|\mathbf{A}_0\|_F^2\} < +\infty, \quad (8.44)$$

and its inverse $[\mathbf{A}_0]^{-1}$ exists almost surely and is a second-order random variable,

$$E\{\|[\mathbf{A}_0]^{-1}\|^2\} \leq E\{\|[\mathbf{A}_0]^{-1}\|_F^2\} < +\infty. \quad (8.45)$$

9.1.4 Covariance Tensor and Coefficient of Variation of Random Matrix $[\mathbf{A}_0]$

The covariance $C_{jk,j'k'} = E\{([\mathbf{A}_0]_{jk} - A_{jk})([\mathbf{A}_0]_{j'k'} - A_{j'k'})\}$ of random variables $[\mathbf{A}_0]_{jk}$ and $[\mathbf{A}_0]_{j'k'}$ is written as

$$C_{jk,j'k'} = \frac{\delta^2}{n+1} \{A_{j'k} A_{jk'} + A_{jj'} A_{kk'}\}, \quad (8.46)$$

and the variance $\sigma_{jk}^2 = C_{jk,jk}$ of random variable $[\mathbf{A}_0]_{jk}$ is

$$\sigma_{jk}^2 = \frac{\delta^2}{n+1} \{A_{jk}^2 + A_{jj} A_{kk}\}. \quad (8.47)$$

The coefficient of variation δ_{A_0} of random matrix $[\mathbf{A}_0]$ is defined by

$$\delta_{A_0} = \left\{ \frac{E\{\|\mathbf{A}_0 - A\|_F^2\}}{\|A\|_F^2} \right\}^{1/2}. \quad (8.48)$$

Since $E\{\|\mathbf{A}_0 - A\|_F^2\} = \sum_{j=1}^n \sum_{k=1}^n \sigma_{jk}^2$, we have

$$\delta_{A_0} = \frac{\delta}{\sqrt{n+1}} \left\{ 1 + \frac{(\text{tr}[A])^2}{\|A\|_F^2} \right\}^{1/2}. \quad (8.49)$$

9.2 Ensemble SE_ϵ^+ of Positive-Definite Random Matrices with a Given Mean Value and an Arbitrary Positive-Definite Lower Bound

The ensemble SE_ϵ^+ is a set of positive-definite random matrices for which the mean value is a given positive-definite matrix and for which there is an arbitrary lower

bound that is a positive-definite matrix controlled by an arbitrary positive number ε that can be chosen as small as is desired. In this ensemble, the lower bound does not correspond to a given matrix that results from a physical model. This ensemble is then constructed as a transformation of ensemble SG_ε^+ and has the same area of use than ensemble SE_0^+ for stochastic modeling in uncertainty quantification, but for which a lower bound is required in the stochastic modeling for mathematical reasons.

9.2.1 Definition of Ensemble SE_ε^+

For a fixed positive value of parameter ε (generally chosen very small, as 10^{-6}), any random matrix $[\mathbf{A}]$ in ensemble SE_ε^+ is defined on probability space $(\Theta, \mathcal{T}, \mathcal{P})$, is with values in $\mathbb{M}_n^+(\mathbb{R}) \subset \mathbb{M}_n^S(\mathbb{R})$, and is such that

$$[\mathbf{A}] = [L_A]^T [\mathbf{G}] [L_A], \quad (8.50)$$

in which $[L_A]$ is the upper triangular matrix in $\mathbb{M}_n(\mathbb{R})$ corresponding by the Cholesky factorization $[L_A]^T [L_A] = [A]$ of the positive-definite mean matrix $[A] = E\{[\mathbf{A}]\}$ of random matrix $[\mathbf{A}]$, and where the random matrix $[\mathbf{G}]$ belongs to ensemble SG_ε^+ , with mean value $E\{[\mathbf{G}]\} = [I_n]$ and for which the coefficient of variation δ_G is defined by Eq. (8.24) as a function of the hyperparameter δ defined by Eq. (8.15), which allows the level of statistical fluctuations to be controlled. It should be noted that for $\varepsilon = 0$, $[\mathbf{G}] = [\mathbf{G}_0]$ that yields $[\mathbf{A}] = [\mathbf{A}_0]$, and consequently, the ensemble SE_ε^+ coincides with SE_0^+ (if $\varepsilon = 0$).

Generator of realizations. For all θ in Θ , the realization $[\mathbf{G}(\theta)]$ of $[\mathbf{G}]$ is constructed as explained before. The realization $[\mathbf{A}(\theta)]$ of random matrix $[\mathbf{A}]$ is calculated by $[\mathbf{A}(\theta)] = [L_A]^T [\mathbf{G}(\theta)] [L_A]$.

9.2.2 Properties of Random Matrix $[\mathbf{A}]$

Almost surely, we have

$$[\mathbf{A}] - [A_\ell] = \frac{1}{1 + \varepsilon} [\mathbf{A}_0] > 0, \quad (8.51)$$

in which $[\mathbf{A}_0]$ is defined by Eq. (8.43) and where the lower bound is the positive-definite matrix $[A_\ell] = c_\varepsilon [A]$ with $c_\varepsilon = \varepsilon/(1 + \varepsilon)$, and we have the following properties:

$$E\{[\mathbf{A}]\} = [A], \quad E\{\log(\det([\mathbf{A}] - [A_\ell]))\} = v_A, \quad |v_A| < +\infty, \quad (8.52)$$

with $v_A = v_{A_0} - n \log(1 + \varepsilon)$. For all $\varepsilon > 0$, random matrix $[\mathbf{A}]$ in ensemble SE_ε^+ is a second-order random variable,

$$E\{\|\mathbf{A}\|^2\} \leq E\{\|\mathbf{A}\|_F^2\} < +\infty, \quad (8.53)$$

and the bilinear form $b_A(\mathbf{X}, \mathbf{Y}) = (([\mathbf{A}] \mathbf{X}, \mathbf{Y}))$ on $\mathcal{L}_n^2 \times \mathcal{L}_n^2$ is such that

$$b_A(\mathbf{X}, \mathbf{X}) \geq c_\varepsilon (([\mathbf{A}] \mathbf{X}, \mathbf{X})) = c_\varepsilon \|\| [L_A] \mathbf{X} \||^2. \quad (8.54)$$

Random matrix $[\mathbf{A}]$ is invertible almost surely and its inverse $[\mathbf{A}]^{-1}$ is a second-order random variable,

$$E\{\|[\mathbf{A}]^{-1}\|^2\} \leq E\{\|[\mathbf{A}]^{-1}\|_F^2\} < +\infty. \quad (8.55)$$

The coefficient of variation δ_A of random matrix $[\mathbf{A}]$, defined by

$$\delta_A = \left\{ \frac{E\{\|\mathbf{A} - A\|_F^2\}}{\|A\|_F^2} \right\}^{1/2}. \quad (8.56)$$

is such that

$$\delta_A = \frac{1}{1 + \varepsilon} \delta_{A_0}, \quad (8.57)$$

in which δ_{A_0} is defined by Eq. (8.49).

9.3 Ensemble SE^{+0} of Semipositive-Definite Random Matrices with a Given Semipositive-Definite Mean Value

The ensemble SE^{+0} is similar to ensemble SG_0^+ but is constituted of semipositive-definite ($m \times m$) real random matrices $[\mathbf{A}]$ for which the mean value is a given semipositive-definite matrix. This ensemble is constructed [110] as a transformation of positive-definite ($n \times n$) real random matrices $[\mathbf{G}_0]$ belonging to ensemble SG_0^+ , with $n < m$.

9.3.1 Algebraic Structure of the Random Matrices in SE^{+0}

The ensemble SE^{+0} is constituted of random matrix $[\mathbf{A}]$ with values in the set $\mathbb{M}_m^{+0}(\mathbb{R})$ such that the null space of $[\mathbf{A}]$, denoted as $\text{null}([\mathbf{A}])$, is deterministic and is a subspace of \mathbb{R}^m with a fixed dimension $\mu_{\text{null}} < m$. This deterministic null space is defined as the null space of the mean value $[A] = E\{[\mathbf{A}]\}$ that is given in $\mathbb{M}_m^{+0}(\mathbb{R})$. We then have

$$[A] \in \mathbb{M}_m^{+0}(\mathbb{R}), \quad \dim \text{null}([A]) = \mu_{\text{null}} < m, \quad \text{null}([\mathbf{A}]) = \text{null}([A]). \quad (8.58)$$

There is a rectangular matrix $[R_A]$ in $\mathbb{M}_{n,m}(\mathbb{R})$, with $n = m - \mu_{\text{null}}$, such that

$$[A] = [R_A]^T [R_A]. \quad (8.59)$$

Such a factorization is performed using classical algorithms [47].

9.3.2 Definition and Construction of Ensemble SE^{+0}

The ensemble SE^{+0} is then defined as the subset of all the second-order random matrices $[\mathbf{A}]$, defined on probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in the set $\mathbb{M}_m^{+0}(\mathbb{R})$, which are written as

$$[\mathbf{A}] = [R_A]^T [\mathbf{G}] [R_A], \quad (8.60)$$

in which $[\mathbf{G}]$ is a positive-definite symmetric $(n \times n)$ real random matrix belonging to ensemble SE_ε^+ , with mean value $E\{[\mathbf{G}]\} = [I_n]$ and for which the coefficient of variation δ_G is defined by Eq.(8.24) as a function of the hyperparameter δ defined by Eq.(8.15), which allows the level of statistical fluctuations to be controlled.

Generator of realizations. For all θ in Θ , the realization $[\mathbf{G}(\theta)]$ of $[\mathbf{G}]$ is constructed as explained before. The realization $[\mathbf{A}(\theta)]$ of random matrix $[\mathbf{A}]$ is calculated by $[\mathbf{A}(\theta)] = [R_A]^T [\mathbf{G}(\theta)] [R_A]$.

9.4 Ensemble SE^{rect} of Rectangular Random Matrices with a Given Mean Value

The ensemble SE^{rect} is an ensemble of rectangular random matrices for which the mean value is a given rectangular matrix and which is constructed with the MaxEnt. Such an ensemble depends on the available information and consequently, is not unique. We present hereinafter the construction proposed in [110], which is based on the use of a fundamental algebraic property for rectangular real matrices, which allows ensemble SE_ε^+ to be used.

9.4.1 Decomposition of a Rectangular Matrix

Let $[A]$ be a rectangular real matrix in $\mathbb{M}_{m,n}(\mathbb{R})$ for which its null space is reduced to $\{0\}$ ($[A] \mathbf{x} = \mathbf{0}$ yields $\mathbf{x} = \mathbf{0}$). Such a rectangular matrix $[A]$ can be written as

$$[A] = [U] [T], \quad (8.61)$$

in which the square matrix $[T]$ and the rectangular matrix $[U]$ are such that

$$[T] \in \mathbb{M}_n^+(\mathbb{R}) \quad \text{and} \quad [U] \in \mathbb{M}_{m,n}(\mathbb{R}) \quad \text{such that} \quad [U]^T [U] = [I_n]. \quad (8.62)$$

The construction of the decomposition defined by Eq.(8.61) can be performed, for instance, by using the singular value decomposition of $[A]$.

9.4.2 Definition of Ensemble SE^{rect}

Let $[A]$ be a given rectangular real matrix in $\mathbb{M}_{m,n}(\mathbb{R})$ with a null space reduced to $\{0\}$ and whose decomposition is given by Eqs.(8.61) and (8.62). Since symmetric real matrix $[T]$ is positive definite, there is an upper triangular matrix $[L_T]$ in $\mathbb{M}_n(\mathbb{R})$ such that $[T] = [L_T]^T [L_T]$ that corresponds to the Cholesky factorization of matrix $[T]$.

A random rectangular matrix $[\mathbf{A}]$ belonging to ensemble SE^{rect} is a second-order random matrix defined on probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in $\mathbb{M}_{m,n}(\mathbb{R})$, whose mean value is the rectangular matrix $[A] = E\{[\mathbf{A}]\}$, and which is written as

$$[\mathbf{A}] = [U] [\mathbf{T}], \quad (8.63)$$

in which the random $(n \times n)$ matrix $[\mathbf{T}]$ belongs to ensemble SE_ε^+ and is then written as

$$[\mathbf{T}] = [L_T]^T [\mathbf{G}] [L_T]. \quad (8.64)$$

The random matrix $[\mathbf{G}]$ belongs to ensemble SG_ε^+ in which $[\mathbf{G}]$ is a positive-definite symmetric $(n \times n)$ real random matrix belonging to ensemble SE_ε^+ , with mean value $E\{[\mathbf{G}]\} = [I_n]$ and for which the coefficient of variation δ_G is defined by Eq. (8.24) as a function of hyperparameter δ defined by Eq. (8.15), which allows the level of statistical fluctuations to be controlled.

Generator of realizations. For all θ in Θ , the realization $[\mathbf{G}(\theta)]$ of $[\mathbf{G}]$ is constructed as explained before. The realization $[\mathbf{A}(\theta)]$ of random matrix $[\mathbf{A}]$ is calculated by $[\mathbf{A}(\theta)] = [U][L_T]^T[\mathbf{G}(\theta)][L_T]$.

9.5 Ensemble SE^{HT} of a Pair of Positive-Definite Matrix-Valued Random Functions Related by a Hilbert Transform

The ensemble SE^{HT} is a set of random functions $\omega \mapsto [\mathbf{Z}(\omega)] = [\mathbf{K}(\omega)] + i\omega [\mathbf{D}(\omega)]$ indexed by \mathbb{R} with values in a subset of all the $(n \times n)$ complex matrices such that $[\mathbf{K}(\omega)]$ and $[\mathbf{D}(\omega)]$ are positive-definite random matrices that are constrained by an underlying Hilbert transform induced by a causality property [115].

9.5.1 Defining the Deterministic Matrix Problem

We consider a family of complex $(n \times n)$ matrices $[Z(\omega)]$ depending on a parameter ω in \mathbb{R} , such that $[Z(\omega)] = i\omega[D(\omega)] + [K(\omega)]$ where i is the pure imaginary complex number ($i = \sqrt{-1}$) and where, for all ω in \mathbb{R} ,

- (i) $[D(\omega)]$ and $[K(\omega)]$ belong to $\mathbb{M}_n^+(\mathbb{R})$.
- (ii) $[D(-\omega)] = [D(\omega)]$ and $[K(-\omega)] = [K(\omega)]$.
- (iii) Matrices $[D(\omega)]$ and $[K(\omega)]$ are such that

$$\omega[D(\omega)] = [\widehat{N}^I(\omega)], \quad [K(\omega)] = [K_0] + [\widehat{N}^R(\omega)]. \quad (8.65)$$

The real matrices $[\widehat{N}^R(\omega)]$ and $[\widehat{N}^I(\omega)]$ are the real part and the imaginary part of the $(n \times n)$ complex matrix $[\widehat{N}(\omega)] = \int_{\mathbb{R}} e^{-i\omega t} [N(t)] dt$ that is the Fourier transform of an integrable function $t \mapsto [N(t)]$ from \mathbb{R} into $\mathbb{M}_n(\mathbb{R})$ such that $[N(t)] = [0]$ for $t < 0$ (causal function). Consequently, $\omega \mapsto [\widehat{N}^R(\omega)]$ and $\omega \mapsto [\widehat{N}^I(\omega)]$ are continuous functions on \mathbb{R} , which goes to $[0]$ as $|\omega| \rightarrow +\infty$ and which are related by the Hilbert transform [90],

$$[\widehat{N}^R(\omega)] = \frac{1}{\pi} \text{p.v.} \int_{-\infty}^{+\infty} \frac{1}{\omega - \omega'} [\widehat{N}^I(\omega')] d\omega', \quad (8.66)$$

in which p.v. denotes the Cauchy principal value. The real matrix $[K_0]$ belongs to $\mathbb{M}_n^+(\mathbb{R})$ and can be written as

$$[K_0] = [K(0)] + \frac{2}{\pi} \int_0^{+\infty} [D(\omega)] d\omega = \lim_{|\omega| \rightarrow +\infty} [K(\omega)], \quad (8.67)$$

and consequently, we have the following equation:

$$[K(\omega)] = [K(0)] + \frac{\omega}{\pi} \text{p.v.} \int_{-\infty}^{+\infty} \frac{1}{\omega - \omega'} [D(\omega')] d\omega'. \quad (8.68)$$

9.5.2 Construction of a Nonparametric Stochastic Model

The construction of a nonparametric stochastic model then consists in modeling, for all real ω , the positive-definite symmetric $(n \times n)$ real matrices $[D(\omega)]$ and $[K(\omega)]$ by random matrices $[\mathbf{D}(\omega)]$ and $[\mathbf{K}(\omega)]$ such that

$$E\{[\mathbf{D}(\omega)]\} = [D(\omega)], \quad E\{[\mathbf{K}(\omega)]\} = [K(\omega)], \quad (8.69)$$

$$[\mathbf{D}(-\omega)] = [\mathbf{D}(\omega)], \quad [\mathbf{K}(-\omega)] = [\mathbf{K}(\omega)]. \quad (8.70)$$

For $\omega \geq 0$, the construction of the stochastic model of the family of random matrices $[\mathbf{D}(\omega)]$ and $[\mathbf{K}(\omega)]$ is carried out as follows:

- (i) Constructing the family $[\mathbf{D}(\omega)]$ of random matrices such that, for fixed ω , $[\mathbf{D}(\omega)] = [L_D(\omega)]^T [\mathbf{G}_D] [L_D(\omega)]$, where $[L_D(\omega)]$ is the upper triangular real $(n \times n)$ matrix resulting from the Cholesky decomposition of the positive-definite symmetric real matrix $[D(\omega)] = [L_D(\omega)]^T [L_D(\omega)]$ and where $[\mathbf{G}_D]$ is a $(n \times n)$ random matrix that belongs to ensemble SG_ε^+ , for which the hyperparameter δ is rewritten as δ_D . Hyperparameter δ_D allows the level of uncertainties to be controlled for random matrix $[\mathbf{D}(\omega)]$.
- (ii) Constructing the random matrix $[\mathbf{K}(0)] = [L_{K(0)}]^T [\mathbf{G}_{K(0)}] [L_{K(0)}]$ in which $[L_{K(0)}]$ is the upper triangular real $(n \times n)$ matrix resulting from the Cholesky decomposition of the positive-definite symmetric real matrix $[K(0)] = [L_{K(0)}]^T [L_{K(0)}]$ and where $[\mathbf{G}_{K(0)}]$ is a $(n \times n)$ random matrix that belongs to ensemble SG_ε^+ , for which the hyperparameter δ is rewritten as δ_K . Hyperparameter δ_K allows the level of uncertainties to be controlled for random matrix $[\mathbf{K}(0)]$.
- (iii) For fixed $\omega \geq 0$, constructing the random matrix $[\mathbf{K}(\omega)]$ using the equation,

$$[\mathbf{K}(\omega)] = [\mathbf{K}(0)] + \frac{\omega}{\pi} \text{p.v.} \int_{-\infty}^{+\infty} \frac{1}{\omega - \omega'} [\mathbf{D}(\omega')] d\omega', \quad (8.71)$$

or equivalently,

$$[\mathbf{K}(\omega)] = [\mathbf{K}(0)] + \frac{2\omega^2}{\pi} \text{p.v} \int_0^{+\infty} \frac{1}{\omega^2 - \omega'^2} [\mathbf{D}(\omega')] d\omega'. \quad (8.72)$$

The last equation can also be rewritten as the following equation recommended for computation (because the singularity in $u = 1$ is independent of ω):

$$\begin{aligned} [\mathbf{K}(\omega)] &= [\mathbf{K}(0)] + \frac{2\omega}{\pi} \text{p.v} \int_0^{+\infty} \frac{1}{1-u^2} [\mathbf{D}(\omega u)] du, \\ &= [\mathbf{K}(0)] + \frac{2\omega}{\pi} \lim_{\eta \rightarrow 0} \left\{ \int_0^{1-\eta} + \int_{1+\eta}^{+\infty} \right\}. \end{aligned} \quad (8.73)$$

- (iv) For fixed $\omega < 0$, $[\mathbf{K}(\omega)]$ is calculated using the even property, $[\mathbf{K}(\omega)] = [\mathbf{K}(-\omega)]$. With such a construction, it can be verified that, for all $\omega \geq 0$, $[\mathbf{K}(\omega)]$ is a positive-definite random matrix. The following sufficient condition is proved in [115]. If for all real vector $\mathbf{y} = (y_1, \dots, y_n)$, and if almost surely the random function $\omega \mapsto \langle [\mathbf{D}(\omega)] \mathbf{y}, \mathbf{y} \rangle$ is decreasing in ω for $\omega \geq 0$, then, for all $\omega \geq 0$, $[\mathbf{K}(\omega)]$ is a positive-definite random matrix.

10 MaxEnt as a Numerical Tool for Constructing Ensembles of Random Matrices

In the previous sections, we have presented fundamental ensembles of random matrices constructed with the MaxEnt principle. For these fundamental ensembles the optimization problem defined by Eq. (8.8) has been solved exactly, what has allowed us to explicitly construct the fundamental ensembles of random matrices and also to explicitly describe the generators of realizations. This was possible thanks to the type of the available information that was used to define the admissible set (see Eq. (8.7)). In many cases, the available information does not allow the Lagrange multipliers to be explicitly calculated and, thus, does not allow for solving explicitly the optimization problem defined by Eq. (8.8).

In this framework of the nonexistence of an explicit solution for constructing the pdf of random matrices using the MaxEnt principle under the constraints defined by the available information, the first difficulty consists of the computation of the Lagrange multipliers with an adapted algorithm that must be robust for the high dimension. In addition, the computation of the Lagrange multipliers requires the calculation of integrals in high dimension, which can be estimated only by the Monte Carlo method. Therefore a generator of realizations of the pdf, which is parameterized by the unknown Lagrange multipliers that are currently being calculated, must be constructed. This problem is particularly difficult for the high dimension. An advanced and efficient methodology is presented hereinafter for the case of the high dimension [112] (thus allows also for treating the cases of the small dimension and then for any dimension).

10.1 Available Information and Parameterization

Let $[A]$ be a random matrix defined on the probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in any subset \mathbb{S}_n of $\mathbb{M}_n^S(\mathbb{R})$, possibly with $\mathbb{S}_n = \mathbb{M}_n^S(\mathbb{R})$. For instance, \mathbb{S}_n can be $\mathbb{M}_n^+(\mathbb{R})$. Let $p_{[A]}$ be the pdf of $[A]$ with respect to the volume element $d^S A$ on $\mathbb{M}_n^S(\mathbb{R})$ (see Eq. (8.1)). The support, denoted as $\text{supp } p_{[A]}$ of pdf $[A]$, is \mathbb{S}_n . Thus, $p_{[A]}([A]) = 0$ for $[A]$ not in \mathbb{S}_n , and the normalization condition is written as

$$\int_{\mathbb{S}_n} p_{[A]}([A]) d^S A = 1. \quad (8.74)$$

The available information is defined by the following equation on \mathbb{R}^μ :

$$E\{\mathcal{G}([A])\} = \mathbf{f}, \quad (8.75)$$

in which $\mathbf{f} = (f_1, \dots, f_\mu)$ is a given vector in \mathbb{R}^μ with $\mu \geq 1$, where $[A] \mapsto \mathcal{G}([A]) = (\mathcal{G}_1([A]), \dots, \mathcal{G}_\mu([A]))$ is a given mapping from \mathbb{S}_n into \mathbb{R}^μ , and where E is the mathematical expectation. For instance, mapping \mathcal{G} can be defined by the mean value $E[A] = [A]$ in which $[A]$ is a given matrix in \mathbb{S}_n and by the condition $E\{\log(\det[A])\} = c_A$ in which $|c_A| < +\infty$. A parameterization of ensemble \mathbb{S}_n is introduced such that any matrix $[A]$ in \mathbb{S}_n is written as

$$[A] = [\mathcal{A}(\mathbf{y})], \quad (8.76)$$

in which $\mathbf{y} = (y_1, \dots, y_N)$ is a vector in \mathbb{R}^N and where $\mathbf{y} \mapsto [\mathcal{A}(\mathbf{y})]$ is a given mapping from \mathbb{R}^N into \mathbb{S}_n . Let $\mathbf{y} \mapsto \mathbf{g}(\mathbf{y}) = (g_1(\mathbf{y}), \dots, g_\mu(\mathbf{y}))$ be the mapping from \mathbb{R}^N into \mathbb{R}^μ such that

$$\mathbf{g}(\mathbf{y}) = \mathcal{G}([\mathcal{A}(\mathbf{y})]), \quad (8.77)$$

Let $\mathbf{Y} = (Y_1, \dots, Y_N)$ be a \mathbb{R}^N -valued second-order random variable for which the probability distribution on \mathbb{R}^N is represented by the pdf $\mathbf{y} \mapsto p_{\mathbf{Y}}(\mathbf{y})$ from \mathbb{R}^N into $\mathbb{R}^+ = [0, +\infty[$ with respect to $d\mathbf{y} = dy_1 \dots dy_N$. The support of function $p_{\mathbf{Y}}$ is \mathbb{R}^N . Function $p_{\mathbf{Y}}$ satisfies the normalization condition:

$$\int_{\mathbb{R}^N} p_{\mathbf{Y}}(\mathbf{y}) d\mathbf{y} = 1. \quad (8.78)$$

For random vector \mathbf{Y} , the available information is deduced from Eqs. (8.75) to (8.77) and is written as

$$E\{\mathbf{g}(\mathbf{Y})\} = \mathbf{f}. \quad (8.79)$$

10.1.1 Example of Parameterization

If $\mathbb{S}_n = \mathbb{M}_n^+(\mathbb{R})$, then the parameterization, $[A] = [\mathcal{A}(\mathbf{y})]$, of $[A]$ can be constructed in several ways. In order to obtain good properties for the random matrix $[A] = [\mathcal{A}(\mathbf{Y})]$ in which \mathbf{Y} is a \mathbb{R}^N -valued second-order random variable, deterministic matrix $[A]$ is written as

$$[A] = [L_{\underline{A}}]^T (\varepsilon[I_n] + [A_0]) [L_{\underline{A}}],$$

with $\varepsilon > 0$, where $[A_0]$ belongs to $\mathbb{M}_n^+(\mathbb{R})$ and where $[L_{\underline{A}}]$ is the upper triangular $(n \times n)$ real matrix corresponding to the Cholesky factorization $[L_{\underline{A}}]^T [L_{\underline{A}}] = [A]$ of the mean matrix $[A] = E\{\mathbf{A}\}$ that is given in $\mathbb{M}_n^+(\mathbb{R})$. Positive-definite matrix $[A_0]$ can be written in two different forms (inducing different properties for random matrix $[\mathbf{A}]$):

- (i) Exponential-type representation [54, 86]. Matrix $[A_0]$ is written as $[A_0] = \exp_{\mathbb{M}}([G])$ in which the matrix $[G]$ belongs to $\mathbb{M}_n^S(\mathbb{R})$ and where $\exp_{\mathbb{M}}$ denotes the exponential of the symmetric real matrices.
- (ii) Square-type representation [86, 111]. Matrix $[A_0]$ is written as $[A_0] = [L]^T [L]$ in which $[L]$ belongs to the set \mathcal{U}_L of all the upper triangular $(n \times n)$ real matrices with positive diagonal entries and where $[L] = \mathcal{L}([G])$ in which \mathcal{L} is a given mapping from $\mathbb{M}_n^S(\mathbb{R})$ into \mathcal{U}_L .

For this two representations, the parameterization is constructed in taking for \mathbf{y} , the $N = n(n + 1)/2$ independent entries $\{[G]_{jk}, 1 \leq j \leq k \leq n\}$ of symmetric real matrix $[G]$. Then for all \mathbf{y} in \mathbb{R}^N , $[A] = [\mathcal{A}(\mathbf{y})]$ is in \mathbb{S}_n , that is to say, is a positive-definite matrix.

10.2 Construction of the pdf of Random Vector \mathbf{Y} Using the MaxEnt

The unknown pdf $p_{\mathbf{Y}}$ with support \mathbb{R}^N , whose normalization condition is given by Eq. (8.78), is constructed using the MaxEnt principle for which the available information is defined by Eq. (8.79). This construction is detailed in the next Sect. 11.

11 MaxEnt for Constructing the pdf of a Random Vector

Let $\mathbf{Y} = (Y_1, \dots, Y_N)$ be a \mathbb{R}^N -valued second-order random variable for which the probability distribution $P_{\mathbf{Y}}(d\mathbf{y})$ on \mathbb{R}^N is represented by the pdf $\mathbf{y} \mapsto p_{\mathbf{Y}}(\mathbf{y})$ from \mathbb{R}^N into $\mathbb{R}^+ = [0, +\infty[$ with respect to $d\mathbf{y} = dy_1 \dots dy_N$. The support of function $p_{\mathbf{Y}}$ is \mathbb{R}^N . Function $p_{\mathbf{Y}}$ satisfies the normalization condition

$$\int_{\mathbb{R}^N} p_{\mathbf{Y}}(\mathbf{y}) d\mathbf{y} = 1. \quad (8.80)$$

The unknown pdf $p_{\mathbf{Y}}$ is constructed using the MaxEnt principle for which the available information is

$$E\{\mathbf{g}(\mathbf{Y})\} = \mathbf{f}, \quad (8.81)$$

in which $\mathbf{y} \mapsto \mathbf{g}(\mathbf{y}) = (g_1(\mathbf{y}), \dots, g_\mu(\mathbf{y}))$ is a given mapping from \mathbb{R}^N into \mathbb{R}^μ . Equation (8.81) is rewritten as

$$\int_{\mathbb{R}^N} \mathbf{g}(\mathbf{y}) p_{\mathbf{Y}}(\mathbf{y}) d\mathbf{y} = \mathbf{f}. \quad (8.82)$$

Let \mathcal{C}_p be the set of all the integrable positive-valued functions $\mathbf{y} \mapsto p(\mathbf{y})$ on \mathbb{R}^N , whose support is \mathbb{R}^N . Let \mathcal{C} be the set of all the functions p belonging to \mathcal{C}_p and satisfying the constraints defined by Eqs. (8.80) and (8.82),

$$\mathcal{C} = \left\{ p \in \mathcal{C}_p, \quad \int_{\mathbb{R}^N} p(\mathbf{y}) d\mathbf{y} = 1, \quad \int_{\mathbb{R}^N} \mathbf{g}(\mathbf{y}) p(\mathbf{y}) d\mathbf{y} = \mathbf{f} \right\}. \quad (8.83)$$

The maximum entropy principle [58] consists in constructing $p_{\mathbf{Y}}$ in \mathcal{C} such that

$$p_{\mathbf{Y}} = \arg \max_{p \in \mathcal{C}} \mathcal{E}(p), \quad (8.84)$$

in which the Shannon entropy $\mathcal{E}(p)$ of p is defined [103] by

$$\mathcal{E}(p) = - \int_{\mathbb{R}^N} p(\mathbf{y}) \log(p(\mathbf{y})) d\mathbf{y}, \quad (8.85)$$

where \log is the Neperian logarithm. In order to solve the optimization problem defined by Eq. (8.84), a Lagrange multiplier $\lambda_0 \in \mathbb{R}^+$ (associated with the constraint defined by Eq. (8.80)) and a Lagrange multiplier $\boldsymbol{\lambda} \in \mathcal{C}_{\boldsymbol{\lambda}} \subset \mathbb{R}^\mu$ (associated with the constraint defined by Eq. (8.82)) are introduced, in which the admissible set $\mathcal{C}_{\boldsymbol{\lambda}}$ is defined by

$$\mathcal{C}_{\boldsymbol{\lambda}} = \{\boldsymbol{\lambda} \in \mathbb{R}^\mu, \quad \int_{\mathbb{R}^N} \exp(-\langle \boldsymbol{\lambda}, \mathbf{g}(\mathbf{y}) \rangle) d\mathbf{y} < +\infty\}. \quad (8.86)$$

The solution of Eq. (8.84) can be written (see the proof in the next section) as

$$p_{\mathbf{Y}}(\mathbf{y}) = c_0^{\text{sol}} \exp(-\langle \boldsymbol{\lambda}^{\text{sol}}, \mathbf{g}(\mathbf{y}) \rangle), \quad \forall \mathbf{y} \in \mathbb{R}^N, \quad (8.87)$$

in which the normalization constant c_0^{sol} is written as $c_0^{\text{sol}} = \exp(-\lambda_0^{\text{sol}})$ and where the method for calculating $(\lambda_0^{\text{sol}}, \boldsymbol{\lambda}^{\text{sol}}) \in \mathbb{R}^+ \times \mathcal{C}_{\boldsymbol{\lambda}}$ is presented in the next two sections.

11.1 Existence and Uniqueness of a Solution to the MaxEnt

The introduction of the Lagrange multipliers λ_0 and $\boldsymbol{\lambda}$ and the analysis of existence and uniqueness of the solution of the MaxEnt corresponding to the solution of the optimization problem defined by Eq. (8.84) are presented hereafter [53].

- The first step of the proof consists in assuming that there exists a unique solution (denoted as p_Y) to the optimization problem defined by Eq. (8.84). The functionals

$$p \mapsto \int_{\mathbb{R}^N} p(\mathbf{y}) d\mathbf{y} - 1 \quad \text{and} \quad p \mapsto \int_{\mathbb{R}^N} \mathbf{g}(\mathbf{y}) p(\mathbf{y}) d\mathbf{y} - \mathbf{f}, \quad (8.88)$$

are continuously differentiable on \mathcal{C}_p and are assumed to be such that p_Y is a regular point (see p. 187 of [68]). The constraints appearing in set \mathcal{C} are taken into account by using the Lagrange multiplier method. Using the Lagrange multipliers $\lambda_0 \in \mathbb{R}^+$ and $\boldsymbol{\lambda} \in \mathcal{C}_{\lambda}$ defined by Eq. (8.86), the Lagrangian \mathcal{L} can be written, for all p in \mathcal{C}_p , as

$$\mathcal{L}(p; \lambda_0, \boldsymbol{\lambda}) = \mathcal{E}(p) - (\lambda_0 - 1) \left(\int_{\mathbb{R}^N} p(\mathbf{y}) d\mathbf{y} - 1 \right) - \langle \boldsymbol{\lambda}, \int_{\mathbb{R}^N} \mathbf{g}(\mathbf{y}) p(\mathbf{y}) d\mathbf{y} - \mathbf{f} \rangle. \quad (8.89)$$

From Theorem 2, p. 188, of [68], it can be deduced that there exists $(\lambda_0^{\text{sol}}, \boldsymbol{\lambda}^{\text{sol}})$ such that the functional $(p, \lambda_0, \boldsymbol{\lambda}) \mapsto \mathcal{L}(p; \lambda_0, \boldsymbol{\lambda})$ is stationary at p_Y (given by Eq. (8.87)) for $\lambda_0 = \lambda_0^{\text{sol}}$ and $\boldsymbol{\lambda} = \boldsymbol{\lambda}^{\text{sol}}$.

- The second step deals with the explicit construction of a family \mathcal{F}_p of pdf indexed by $(\lambda_0, \boldsymbol{\lambda})$, which renders $p \mapsto \mathcal{L}(p; \lambda_0, \boldsymbol{\lambda})$ extremum. It is further proved that this extremum is unique and turns out to be a maximum. For any $(\lambda_0, \boldsymbol{\lambda})$ fixed in $\mathbb{R}^+ \times \mathcal{C}_{\lambda}$, it can first be deduced from the calculus of variations (Theorem 3.11.16, p. 341, in [101]) that the aforementioned extremum, denoted by $p_{\lambda_0, \boldsymbol{\lambda}}$, is written as

$$p_{\lambda_0, \boldsymbol{\lambda}}(\mathbf{y}) = \exp(-\lambda_0 - \langle \boldsymbol{\lambda}, \mathbf{g}(\mathbf{y}) \rangle), \quad \forall \mathbf{y} \in \mathbb{R}^N. \quad (8.90)$$

For any fixed value of λ_0 in \mathbb{R}^+ and $\boldsymbol{\lambda}$ in \mathcal{C}_{λ} , the uniqueness of this extremum directly follows from the uniqueness of the solution for the Euler equation that is derived from the calculus of variations. Upon calculating the second-order derivative with respect to p , at point $p_{\lambda_0, \boldsymbol{\lambda}}$, of the Lagrangian, it can be shown that this extremum is, indeed, a maximum.

- In a third step, using Eq. (8.90), it is proved that if there exists $(\lambda_0^{\text{sol}}, \boldsymbol{\lambda}^{\text{sol}})$ in $\mathbb{R}^+ \times \mathcal{C}_{\lambda}$ such that the solution of the constraint equations $\int_{\mathbb{R}^N} p_{\lambda_0, \boldsymbol{\lambda}}(\mathbf{y}) d\mathbf{y} = 1$ and $\int_{\mathbb{R}^N} \mathbf{g}(\mathbf{y}) p_{\lambda_0, \boldsymbol{\lambda}}(\mathbf{y}) d\mathbf{y} = \mathbf{f}$, in $(\lambda_0, \boldsymbol{\lambda})$ and then $(\lambda_0^{\text{sol}}, \boldsymbol{\lambda}^{\text{sol}})$ is unique. These constraints are rewritten as

$$\int_{\mathbb{R}^N} \exp(-\lambda_0 - \langle \boldsymbol{\lambda}, \mathbf{g}(\mathbf{y}) \rangle) d\mathbf{y} = 1. \quad (8.91)$$

$$\int_{\mathbb{R}^N} \mathbf{g}(\mathbf{y}) \exp(-\lambda_0 - \langle \boldsymbol{\lambda}, \mathbf{g}(\mathbf{y}) \rangle) d\mathbf{y} = \mathbf{f}. \quad (8.92)$$

Introducing the notations,

$$\boldsymbol{\Lambda} = (\lambda_0, \boldsymbol{\lambda}) \text{ and } \boldsymbol{\Lambda}^{\text{sol}} = (\lambda_0^{\text{sol}}, \boldsymbol{\lambda}^{\text{sol}}) \text{ that belong to } \mathcal{C}_{\boldsymbol{\Lambda}} = \mathbb{R}^+ \times \mathcal{C}_{\boldsymbol{\lambda}} \subset \mathbb{R}^{1+\mu},$$

$$\mathbf{F} = (1, \mathbf{f}) \text{ and } \mathbf{G}(\mathbf{y}) = (1, \mathbf{g}(\mathbf{y})) \text{ that belong to } \mathbb{R}^{1+\mu},$$

these constraint equations are written as

$$\int_{\mathbb{R}^N} \mathbf{G}(\mathbf{y}) \exp(-\langle \boldsymbol{\Lambda}, \mathbf{G}(\mathbf{y}) \rangle) d\mathbf{y} = \mathbf{F}. \quad (8.93)$$

It is assumed that the optimization problem stated by Eq. (8.84) is well posed in the sense that the constraints are algebraically independent, that is to say, that there exists a bounded subset \mathcal{S} of \mathbb{R}^N , with $\int_{\mathcal{S}} d\mathbf{y} > 0$, such that for any nonzero vector \mathbf{v} in $\mathbb{R}^{1+\mu}$,

$$\int_{\mathcal{S}} \langle \mathbf{v}, \mathbf{G}(\mathbf{y}) \rangle^2 d\mathbf{y} > 0. \quad (8.94)$$

Let $\boldsymbol{\Lambda} \mapsto H(\boldsymbol{\Lambda})$ be the function defined by

$$H(\boldsymbol{\Lambda}) = \langle \boldsymbol{\Lambda}, \mathbf{F} \rangle + \int_{\mathbb{R}^N} \exp(-\langle \boldsymbol{\Lambda}, \mathbf{G}(\mathbf{y}) \rangle) d\mathbf{y}. \quad (8.95)$$

The gradient $\nabla H(\boldsymbol{\Lambda})$ of $H(\boldsymbol{\Lambda})$ with respect to $\boldsymbol{\Lambda}$ is written as

$$\nabla H(\boldsymbol{\Lambda}) = \mathbf{F} - \int_{\mathbb{R}^N} \mathbf{G}(\mathbf{y}) \exp(-\langle \boldsymbol{\Lambda}, \mathbf{G}(\mathbf{y}) \rangle) d\mathbf{y}, \quad (8.96)$$

so that any solution of $\nabla H(\boldsymbol{\Lambda}) = \mathbf{0}$ satisfies Eq. (8.93) (and conversely). It is assumed that H admits at least one critical point. The Hessian matrix $[H''(\boldsymbol{\Lambda})]$ is written as

$$[H''(\boldsymbol{\Lambda})] = \int_{\mathbb{R}^N} \mathbf{G}(\mathbf{y}) \otimes \mathbf{G}(\mathbf{y}) \exp(-\langle \boldsymbol{\Lambda}, \mathbf{G}(\mathbf{y}) \rangle) d\mathbf{y}. \quad (8.97)$$

Since $\mathcal{S} \subset \mathbb{R}^N$, it turns out that, for any nonzero vector \mathbf{v} in $\mathbb{R}^{1+\mu}$,

$$\langle [H''(\boldsymbol{\Lambda})]\mathbf{v}, \mathbf{v} \rangle \geq \int_{\mathcal{S}} \langle \mathbf{v}, \mathbf{G}(\mathbf{y}) \rangle^2 \exp(-\langle \boldsymbol{\Lambda}, \mathbf{G}(\mathbf{y}) \rangle) d\mathbf{y} > 0, \quad (8.98)$$

Therefore, function $\boldsymbol{\Lambda} \mapsto H(\boldsymbol{\Lambda})$ is strictly convex that ensures the uniqueness of the critical point of H (should it exist). Under the aforementioned assumption of algebraic independence for the constraints, it follows that if $\boldsymbol{\Lambda}^{\text{sol}}$ (such that

the constraint defined by Eq. (8.93) is fulfilled) exists, then Λ^{sol} is unique and corresponds to the solution of the following optimization problem:

$$\Lambda^{\text{sol}} = \arg \min_{\Lambda \in \mathcal{C}_\Lambda} H(\Lambda), \quad (8.99)$$

where H is the strictly convex function defined by Eq. (8.95). The unique solution p_Y of the optimization problem defined by Eq. (8.84) is given by Eq. (8.87) with $(\lambda_0^{\text{sol}}, \lambda^{\text{sol}}) = \Lambda^{\text{sol}}$.

11.2 Numerical Calculation of the Lagrange Multipliers

When there is no explicit solution $(\lambda_0^{\text{sol}}, \lambda^{\text{sol}}) = \Lambda^{\text{sol}}$ of Eq. (8.93) in Λ , Λ^{sol} must be numerically calculated and the numerical method used must be robust for the high dimension. The numerical method could be based on the optimization problem defined by Eq. (8.99). Unfortunately, with such a formulation, the constant of normalization, $c_0 = \exp(-\lambda_0)$, is directly involved in the numerical calculations, what is not robust in high dimension. The numerical method proposed hereinafter [11] is based on the minimization of the convex objective function introduced in [1]. Using Eqs. (8.80) and (8.87), pdf p_Y can be rewritten as

$$p_Y(\mathbf{y}) = c_0(\lambda^{\text{sol}}) \exp(- < \lambda^{\text{sol}}, \mathbf{g}(\mathbf{y}) >), \quad \forall \mathbf{y} \in \mathbb{R}^N, \quad (8.100)$$

in which $c_0(\lambda)$ is defined by

$$c_0(\lambda) = \left\{ \int_{\mathbb{R}^N} \exp(- < \lambda, \mathbf{g}(\mathbf{y}) >) d\mathbf{y} \right\}^{-1}. \quad (8.101)$$

Since $\exp(-\lambda_0) = c_0(\lambda_0)$, and taking into account Eq. (8.101), the constraint equation defined by Eq. (8.92) can be rewritten as

$$\int_{\mathbb{R}^N} \mathbf{g}(\mathbf{y}) c_0(\lambda) \exp(- < \lambda, \mathbf{g}(\mathbf{y}) >) d\mathbf{y} = \mathbf{f}. \quad (8.102)$$

The optimization problem defined by Eq. (8.99), which allows for calculating $(\lambda_0^{\text{sol}}, \lambda^{\text{sol}}) = \Lambda^{\text{sol}}$, is replaced by the more convenient optimization problem that allows λ^{sol} to be computed,

$$\lambda^{\text{sol}} = \arg \min_{\lambda \in \mathcal{C}_\lambda \subset \mathbb{R}^\mu} \Gamma(\lambda), \quad (8.103)$$

in which the objective function Γ is defined by

$$\Gamma(\lambda) = < \lambda, \mathbf{f} > - \log(c_0(\lambda)). \quad (8.104)$$

Once λ^{sol} is calculated, c_0^{sol} is given by $c_0^{\text{sol}} = c_0(\lambda^{\text{sol}})$. Let $\{\mathbf{Y}_\lambda, \lambda \in \mathcal{C}_\lambda\}$ be the family of random variables with values in \mathbb{R}^N , for which pdf $p_{\mathbf{Y}_\lambda}$ is defined, for all λ in \mathcal{C}_λ , by

$$p_{\mathbf{Y}_\lambda}(\mathbf{y}) = c_0(\lambda) \exp(- < \lambda, \mathbf{g}(\mathbf{y}) >), \quad \forall \mathbf{y} \in \mathbb{R}^N. \quad (8.105)$$

The gradient vector $\nabla \Gamma(\lambda)$ and the Hessian matrix $[\Gamma''(\lambda)]$ of function $\lambda \mapsto \Gamma(\lambda)$ can be written as

$$\nabla \Gamma(\lambda) = \mathbf{f} - E\{\mathbf{g}(\mathbf{Y}_\lambda)\}, \quad (8.106)$$

$$[\Gamma''(\lambda)] = E\{\mathbf{g}(\mathbf{Y}_\lambda) \mathbf{g}(\mathbf{Y}_\lambda)^T\} - E\{\mathbf{g}(\mathbf{Y}_\lambda)\} E\{\mathbf{g}(\mathbf{Y}_\lambda)\}^T. \quad (8.107)$$

Matrix $[\Gamma''(\lambda)]$ is thus the covariance matrix of the random vector $\mathbf{g}(\mathbf{Y}_\lambda)$ and is positive definite (the constraints have been assumed to be algebraically independent). Consequently, function $\lambda \mapsto \Gamma(\lambda)$ is strictly convex and reaches its minimum for λ^{sol} which is such that $\nabla \Gamma(\lambda^{\text{sol}}) = \mathbf{0}$. The optimization problem defined by Eq. (8.103) can be solved using any minimization algorithm. Since function Γ is strictly convex, the Newton iterative method can be applied to the increasing function $\lambda \mapsto \nabla \Gamma(\lambda)$ for searching λ^{sol} such that $\nabla \Gamma(\lambda^{\text{sol}}) = \mathbf{0}$. This iterative method is not unconditionally convergent. Consequently, an under-relaxation is introduced and the iterative algorithm is written as

$$\lambda^{\ell+1} = \lambda^\ell - \alpha [\Gamma''(\lambda^\ell)]^{-1} \nabla \Gamma(\lambda^\ell), \quad (8.108)$$

in which α belongs to $[0, 1]$ in order to ensure the convergence. At each iteration ℓ , the error is calculated by

$$\text{err}(\ell) = \frac{\|\mathbf{f} - E\{\mathbf{g}(\mathbf{Y}_{\lambda^\ell})\}\|}{\|\mathbf{f}\|} = \frac{\|\nabla \Gamma(\lambda^\ell)\|}{\|\mathbf{f}\|}, \quad (8.109)$$

in order to control the convergence. The performance of the algorithm depends on the choice of the initial condition that can be found in [11]. For high dimension problem, the mathematical expectations appearing in Eqs. (8.106), (8.107), and (8.109) are calculated using a Markov chain Monte Carlo (MCMC) method that does not require the calculation of the normalization constant $c_0(\lambda)$ in the pdf defined by Eq. (8.105).

11.3 Generator for Random Vector \mathbf{Y}_λ and Estimation of the Mathematical Expectations in High Dimension

For λ fixed in $\mathcal{C}_\lambda \subset \mathbb{R}^\mu$, the pdf $p_{\mathbf{Y}_\lambda}$ on \mathbb{R}^N of the \mathbb{R}^N -valued random variable \mathbf{Y}_λ is defined by Eq. (8.105). Let w be a given mapping from \mathbb{R}^N into an Euclidean space such that $E\{w(\mathbf{Y}_\lambda)\} = \int_{\mathbb{R}^N} w(\mathbf{y}) p_{\mathbf{Y}_\lambda} d\mathbf{y}$ is finite. For instance, w can be

such that $w(\mathbf{Y}_\lambda) = \mathbf{g}(\mathbf{Y}_\lambda)$ or $w(\mathbf{Y}_\lambda) = \mathbf{g}(\mathbf{Y}_\lambda)\mathbf{g}(\mathbf{Y}_\lambda)^T$. These two choices allow for calculating the mathematical expectation in high dimension, $E\{\mathbf{g}(\mathbf{Y}_\lambda)\}$ and $E\{\mathbf{g}(\mathbf{Y}_\lambda)\mathbf{g}(\mathbf{Y}_\lambda)^T\}$, which are required for computing the gradient and the Hessian defined by Eqs. (8.106) and (8.107).

The estimation of $E\{w(\mathbf{Y}_\lambda)\}$ requires a generator of realizations of random vector \mathbf{Y}_λ , which is constructed using the Markov chain Monte Carlo method (MCMC) [59, 95, 117]. With the MCMC method, the transition kernel of the homogeneous Markov chain can be constructed using the Metropolis-Hastings algorithm [57, 75] (that requires the definition of a good proposal distribution), the Gibbs sampling [42] (that requires the knowledge of the conditional distribution), or the slice sampling [83] (that can exhibit difficulties related to the general shape of the probability distribution, in particular for multimodal distributions). In general, these algorithms are efficient, but can also be not efficient if there exist attraction regions which do not correspond to the invariant measure under consideration and tricky even in high dimension. These cases cannot easily be detected and are time consuming.

We refer the reader to the references given hereinbefore for the usual MCMC methods, and we present after a more advanced method that is very robust in high dimension, which have been introduced in [112] and used, for instance, in [11, 51]. The method presented looks like to the Gibbs approach but corresponds to a more direct construction of a random generator of realizations for random variable \mathbf{Y}_λ whose probability distribution is $p_{\mathbf{Y}_\lambda} d\mathbf{y}$. The difference between the Gibbs algorithm and the proposed algorithm is that the convergence in the proposed method can be studied with all the mathematical results concerning the existence and uniqueness of Itô stochastic differential equation (ISDE). In addition, a parameter is introduced which allows the transient part of the response to be killed in order to get more rapidly the stationary solution corresponding to the invariant measure. Thus, the construction of the transition kernel by using the detailed balance equation is replaced by the construction of an ISDE, which admits $p_{\mathbf{Y}_\lambda} d\mathbf{y}$ (defined by Eq. (8.105)) as a unique invariant measure. The ergodic method or the Monte Carlo method is used for estimating $E\{w(\mathbf{Y}_\lambda)\}$.

11.3.1 Random Generator and Estimation of Mathematical Expectations

It is assumed that λ is fixed in $\mathcal{C}_\lambda \subset \mathbb{R}^\mu$, and for simplifying the notation, λ is omitted. Let $\mathbf{u} \mapsto \Phi(\mathbf{u})$ be the function from \mathbb{R}^N into \mathbb{R} defined by

$$\Phi(\mathbf{u}) = \langle \lambda, \mathbf{g}(\mathbf{u}) \rangle, \quad (8.110)$$

Let $\{(\mathbf{U}(r), \mathbf{V}(r)), r \in \mathbb{R}^+\}$ be the Markov stochastic process defined on the probability space $(\Theta, \mathcal{T}, \mathcal{P})$, indexed by $\mathbb{R}^+ = [0, +\infty[$, with values in $\mathbb{R}^N \times \mathbb{R}^N$, satisfying, for all $r > 0$, the following ISDE with initial conditions:

$$d\mathbf{U}(r) = \mathbf{V}(r) dr, \quad (8.111)$$

$$d\mathbf{V}(r) = -\nabla_{\mathbf{u}}\Phi(\mathbf{U}(r)) dr - \frac{1}{2}f_0\mathbf{V}(r) dr + \sqrt{f_0} d\mathbf{W}(r), \quad (8.112)$$

$$\mathbf{U}(0) = \mathbf{u}_0, \quad \mathbf{V}(0) = \mathbf{v}_0 \quad a.s., \quad (8.113)$$

in which \mathbf{u}_0 and \mathbf{v}_0 are given vectors in \mathbb{R}^N (that will be taken as zero in the application presented later) and where $\mathbf{W} = (W_1, \dots, W_N)$ is the normalized Wiener process defined on $(\Theta, \mathcal{T}, \mathcal{P})$ indexed by \mathbb{R}^+ with values in \mathbb{R}^N . The matrix-valued autocorrelation function $[R_{\mathbf{W}}(r, r')] = E\{\mathbf{W}(r)\mathbf{W}(r')^T\}$ of \mathbf{W} is then written as $[R_{\mathbf{W}}(r, r')] = \min(r, r') [I_n]$. In Eq. (8.112), the free parameter $f_0 > 0$ allows a dissipation term to be introduced in the nonlinear second-order dynamical system (formulated in the Hamiltonian form with an additional dissipative term) in order to kill the transient part of the response and consequently to get more rapidly the stationary solution corresponding to the invariant measure. It is assumed that function \mathbf{g} is such that function $\mathbf{u} \mapsto \Phi(\mathbf{u})$ (i) is continuous on \mathbb{R}^N , (ii) is such that $\mathbf{u} \mapsto \|\nabla_{\mathbf{u}}\Phi(\mathbf{u})\|$ is a locally bounded function on \mathbb{R}^N (i.e., is bounded on all compact set in \mathbb{R}^N), and (iii) is such that

$$\inf_{\|\mathbf{u}\| > R} \Phi(\mathbf{u}) \rightarrow +\infty \quad \text{if} \quad R \rightarrow +\infty, \quad (8.114)$$

$$\inf_{\mathbf{u} \in \mathbb{R}^n} \Phi(\mathbf{u}) = \Phi_{\min} \quad \text{with} \quad \Phi_{\min} \in \mathbb{R}, \quad (8.115)$$

$$\int_{\mathbb{R}^n} \|\nabla_{\mathbf{u}}\Phi(\mathbf{u})\| e^{-\Phi(\mathbf{u})} d\mathbf{u} < +\infty. \quad (8.116)$$

Under hypotheses (i) to (iii), and using Theorems 4 to 7 in pages 211 to 216 of Ref. [105], in which the Hamiltonian is taken as $\mathbb{H}(\mathbf{u}, \mathbf{v}) = \|\mathbf{v}\|^2/2 + \Phi(\mathbf{u})$, and using [33, 62] for the ergodic property, it can be deduced that the problem defined by Eqs. (8.111), (8.112), and (8.113) admits a unique solution. This solution is a second-order diffusion stochastic process $\{(\mathbf{U}(r), \mathbf{V}(r)), r \in \mathbb{R}^+\}$, which converges to a stationary and ergodic diffusion stochastic process $\{(\mathbf{U}_{st}(r_{st}), \mathbf{V}_{st}(r_{st})), r_{st} \geq 0\}$, when r goes to infinity, associated with the invariant probability measure $P_{st}(d\mathbf{u}, d\mathbf{v}) = \rho_{st}(\mathbf{u}, \mathbf{v}) d\mathbf{u} d\mathbf{v}$. The probability density function $(\mathbf{u}, \mathbf{v}) \mapsto \rho_{st}(\mathbf{u}, \mathbf{v})$ on $\mathbb{R}^N \times \mathbb{R}^N$ is the unique solution of the steady-state Fokker-Planck equation associated with Eqs. (8.111)–(8.112) and is written (see pp. 120 to 123 in [105]), as

$$\rho_{st}(\mathbf{u}, \mathbf{v}) = c_N \exp \left\{ -\frac{1}{2} \|\mathbf{v}\|^2 - \Phi(\mathbf{u}) \right\}, \quad (8.117)$$

in which c_N is the constant of normalization. Equations (8.105), (8.110), and (8.117) yield

$$p_{\mathbf{Y}_{\lambda}}(\mathbf{y}) = \int_{\mathbb{R}^N} \rho_{st}(\mathbf{y}, \mathbf{v}) d\mathbf{v}, \quad \forall \mathbf{y} \in \mathbb{R}^N. \quad (8.118)$$

Random variable \mathbf{Y}_λ (for which the pdf $p_{\mathbf{Y}_\lambda}$ is defined by Eq. (8.105)) can then be written, for all fixed positive value of r_{st} , as

$$\mathbf{Y}_\lambda = \mathbf{U}_{\text{st}}(r_{\text{st}}) = \lim_{r \rightarrow +\infty} \mathbf{U}(r) \quad \text{in probability distribution.} \quad (8.119)$$

The free parameter $f_0 > 0$ introduced in Eq. (8.112) allows a dissipation term to be introduced in the nonlinear dynamical system for obtaining more rapidly the asymptotic behavior corresponding to the stationary and ergodic solution associated with the invariant measure. Using Eq. (8.119) and the ergodic property of stationary stochastic process \mathbf{U}_{st} yield

$$E\{w(\mathbf{Y}_\lambda)\} = \lim_{R \rightarrow +\infty} \frac{1}{R} \int_0^R w(\mathbf{U}(r, \theta)) dr, \quad (8.120)$$

in which, for $\theta \in \Theta$, $\mathbf{U}(\cdot, \theta)$ is any realization of \mathbf{U} .

11.3.2 Discretization Scheme and Estimating the Mathematical Expectations

A discretization scheme must be used for numerically solving Eqs. (8.111), (8.112), and (8.113). For general surveys on discretization schemes for ISDE, we refer the reader to [63, 118, 119] (among others). The present case, related to a Hamiltonian dynamical system, has also been analyzed using an implicit Euler scheme in [120]. Hereinafter, we present the Störmer-Verlet scheme, which is an efficient scheme that preserves energy for nondissipative Hamiltonian dynamical systems (see [56] for reviews about this scheme in the deterministic case, and see [17] and the references therein for the stochastic case).

Let $M \geq 1$ be an integer. The ISDE defined by Eqs. (8.111), (8.112), and (8.113) is solved on the finite interval $\mathcal{R} = [0, (M - 1) \Delta r]$, in which Δr is the sampling step of the continuous index parameter r . The integration scheme is based on the use of the M sampling points r_k such that $r_k = (k - 1) \Delta r$ for $k = 1, \dots, M$. The following notations are introduced: $\mathbf{U}^k = \mathbf{U}(r_k)$, $\mathbf{V}^k = \mathbf{V}(r_k)$, and $\mathbf{W}^k = \mathbf{W}(r_k)$, for $k = 1, \dots, M$, with $\mathbf{U}^1 = \mathbf{u}_0$, $\mathbf{V}^1 = \mathbf{v}_0$, and $\mathbf{W}^1 = \mathbf{0}$. Let $\{\Delta \mathbf{W}^{k+1} = \mathbf{W}^{k+1} - \mathbf{W}^k, k = 1, \dots, M-1\}$ be the family of the independent Gaussian second-order centered \mathbb{R}^N -valued random variables such that $E\{\Delta \mathbf{W}^{k+1} (\Delta \mathbf{W}^{k+1})^T\} = \Delta r [I_n]$. For $k = 1, \dots, M - 1$, the Störmer-Verlet scheme yields

$$\mathbf{U}^{k+\frac{1}{2}} = \mathbf{U}^k + \frac{\Delta r}{2} \mathbf{V}^k, \quad (8.121)$$

$$\mathbf{V}^{k+1} = \frac{1-b}{1+b} \mathbf{V}^k + \frac{\Delta r}{1+b} \mathbf{L}^{k+\frac{1}{2}} + \frac{\sqrt{f_0}}{1+b} \Delta \mathbf{W}^{k+1}, \quad (8.122)$$

$$\mathbf{U}^{k+1} = \mathbf{U}^{k+\frac{1}{2}} + \frac{\Delta r}{2} \mathbf{V}^{k+1}, \quad (8.123)$$

with the initial condition defined by (8.113), where $b = f_0 \Delta r / 4$ and where $\mathbf{L}^{k+\frac{1}{2}}$ is the \mathbb{R}^N -valued random variable such that $\mathbf{L}^{k+\frac{1}{2}} = -\{\nabla_{\mathbf{u}} \Phi(\mathbf{u})\}_{\mathbf{u}=\mathbf{U}^{k+\frac{1}{2}}}.$

For a given realization θ in Θ , the sequence $\{\mathbf{U}^k(\theta), k = 1, \dots, M\}$ is constructed using Eqs. (8.121), (8.122), and (8.123). The discretization of Eq. (8.120) yields the following estimation of the mathematical expectation:

$$E\{w(\mathbf{Y}_\lambda)\} = \lim_{M \rightarrow +\infty} \hat{w}_M, \quad \hat{w}_M = \frac{1}{M - M_0 + 1} \sum_{k=M_0}^M w(\mathbf{U}^k(\theta)), \quad (8.124)$$

in which, for f_0 fixed, the integer $M_0 > 1$ is chosen to remove the transient part of the response induced by the initial condition.

For details concerning the optimal choice of the numerical parameters, such as M_0 , M , f_0 , Δ_r , \mathbf{u}_0 , and \mathbf{v}_0 , we refer the reader to [11, 51, 54, 112].

12 Nonparametric Stochastic Model For Constitutive Equation in Linear Elasticity

This section deals with a nonparametric stochastic model for random elasticity matrices in the framework of the three-dimensional linear elasticity in continuum mechanics, using the methodologies and some of the results that have been given in the two previous sections: “Fundamental Ensembles for Positive-Definite Symmetric Real Random Matrices” and “MaxEnt as a Numerical Tool for Constructing Ensemble of Random Matrices.” The developments given hereinafter correspond to a synthesis of works detailed in [51, 53, 54].

From a continuum mechanics point of view, the framework is the 3D linear elasticity of a homogeneous random medium (material) at a given scale. Let $[\tilde{\mathbf{C}}]$ be the random elasticity matrix for which the nonparametric stochastic model has to be derived. Random matrix $[\tilde{\mathbf{C}}]$ is defined on the probability space $(\Theta, \mathcal{T}, \mathcal{P})$ and is with values in $\mathbb{M}_n^+(\mathbb{R})$ with $n = 6$. This matrix corresponds to the so-called Kelvin’s matrix representation of the fourth-order symmetric elasticity tensor in 3D linear elasticity [71]. The symmetry classes for a linear elastic material, that is to say, the linear elastic symmetries, are [23] isotropic, cubic, transversely isotropic, trigonal, tetragonal, orthotropic, monoclinic, and anisotropic. From a stochastic modeling point of view, the random elasticity matrix $[\tilde{\mathbf{C}}]$ satisfies the following properties:

- (i) Random matrix $[\tilde{\mathbf{C}}]$ is assumed to have a mean value that belongs to $\mathbb{M}_n^+(\mathbb{R})$, but is, in mean, close to a given symmetry class induced by a material symmetry, denoted as $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ and which is a subset of $\mathbb{M}_n^+(\mathbb{R})$,

$$[\tilde{\mathbf{C}}] = E\{[\tilde{\mathbf{C}}]\} \in \mathbb{M}_n^+(\mathbb{R}). \quad (8.125)$$

- (ii) Random matrix $[\tilde{\mathbf{C}}]$ admits a positive-definite lower bound $[C_\ell]$ belonging to $\mathbb{M}_n^+(\mathbb{R})$

$$[\tilde{\mathbf{C}}] - [C_\ell] > 0 \quad a.s. \quad (8.126)$$

- (iii) The statistical fluctuations of random elasticity matrix $[\tilde{\mathbf{C}}]$ belong mainly to the symmetry class, but can be more or less anisotropic with respect to the above symmetry. The level of statistical fluctuations in the symmetry class must be controlled independently of the level of statistical anisotropic fluctuations.

12.1 Positive-Definite Matrices Having a Symmetry Class

For the positive-definite symmetric ($n \times n$) real matrices, a given symmetry class is defined by a subset $\mathbb{M}_n^{\text{sym}}(\mathbb{R}) \subset \mathbb{M}_n^+(\mathbb{R})$ such that any matrix $[M]$ exhibiting the above symmetry then belongs to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ and can be written as

$$[M] = \sum_{j=1}^N m_j [E_j^{\text{sym}}], \quad \mathbf{m} = (m_1, \dots, m_N) \in \mathcal{C}_{\mathbf{m}} \subset \mathbb{R}^N, \quad [E_j^{\text{sym}}] \in \mathbb{M}_n^S(\mathbb{R}), \quad (8.127)$$

in which $\{[E_j^{\text{sym}}], j = 1, \dots, N\}$ is the matrix algebraic basis of $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ (Walpole's tensor basis [122]) and where the admissible subset $\mathcal{C}_{\mathbf{m}}$ of \mathbb{R}^N is such that

$$\mathcal{C}_{\mathbf{m}} = \{\mathbf{m} \in \mathbb{R}^N \mid \sum_{j=1}^N m_j [E_j^{\text{sym}}] \in \mathbb{M}_n^+(\mathbb{R})\}. \quad (8.128)$$

It should be noted that the basis matrices $[E_j^{\text{sym}}]$ are symmetric matrices belonging to $\mathbb{M}_n^S(\mathbb{R})$, but are not positive definite, that is to say, do not belong to $\mathbb{M}_n^+(\mathbb{R})$. The dimension N for all material symmetry classes is 2 for isotropic, 3 for cubic, 5 for transversely isotropic, 6 or 7 for trigonal, 6 or 7 for tetragonal, 9 for orthotropic, 13 for monoclinic, and 21 for anisotropic. The following properties are proved (see [54, 122]):

- (i) If $[M]$ and $[M']$ belong to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$, then

$$[M][M'] \in \mathbb{M}_n^{\text{sym}}(\mathbb{R}), \quad [M]^{-1} \in \mathbb{M}_n^{\text{sym}}(\mathbb{R}), \quad [M]^{1/2} \in \mathbb{M}_n^{\text{sym}}(\mathbb{R}). \quad (8.129)$$

- (ii) Any matrix $[N]$ belonging to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ can be written as

$$[N] = \exp_{\mathbb{M}}([\mathcal{N}]), \quad [\mathcal{N}] = \sum_{j=1}^N y_j [E_j^{\text{sym}}], \quad \mathbf{y} = (y_1, \dots, y_N) \in \mathbb{R}^N, \quad (8.130)$$

in which $\exp_{\mathbb{M}}$ is the exponential of symmetric real matrices. It should be noted that matrix $[\mathcal{N}]$ is a symmetric real matrix but does not belong to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ (because \mathbf{y} is in \mathbb{R}^N and therefore $[\mathcal{N}]$ is not a positive-definite matrix).

12.2 Representation Introducing a Positive-Definite Lower Bound

Using Eq. (8.126), the representation of random elasticity matrix $[\tilde{\mathbf{C}}]$ is written as

$$[\tilde{\mathbf{C}}] = [C_\ell] + [\mathbf{C}], \quad (8.131)$$

in which the lower bound is the deterministic matrix $[C_\ell]$ belonging to $\mathbb{M}_n^+(\mathbb{R})$ and where $[\mathbf{C}] = [\tilde{\mathbf{C}}] - [C_\ell]$ is a random matrix with values in $\mathbb{M}_n^+(\mathbb{R})$. The mean value $[\underline{\mathbf{C}}] = E\{[\mathbf{C}]\}$ of $[\mathbf{C}]$ is written as

$$[\underline{\mathbf{C}}] = [\tilde{\mathbf{C}}] - [C_\ell] \in \mathbb{M}_n^+(\mathbb{R}), \quad (8.132)$$

in which $[\tilde{\mathbf{C}}]$ is defined by Eq. (8.125). Such a lower bound can be defined in two ways:

- (1) If some microstructural information is available, $[C_\ell]$ may be computed, either by using some well-known micromechanics-based bounds (such as the Reuss bound, for heterogeneous materials made up with ordered phases with deterministic properties) or by using a numerical approximation based on the realizations of the stochastic lower bound obtained from computational homogenization and invoking the Huet partition theorem (see the discussion in [49]).
- (2) In the absence of such information, a simple a priori expression for $[C_\ell]$ can be obtained as $[C_\ell] = \epsilon[\tilde{\mathbf{C}}]$ with $0 \leq \epsilon < 1$, from which it can be deduced that $[\underline{\mathbf{C}}] = (1 - \epsilon)[\tilde{\mathbf{C}}] > 0$.

12.3 Introducing Deterministic Matrices $[\underline{\mathbf{A}}]$ and $[\underline{\mathbf{S}}]$

Let $[\underline{\mathbf{A}}]$ be the deterministic matrix in $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ defined by

$$[\underline{\mathbf{A}}] = P^{\text{sym}}([\underline{\mathbf{C}}]), \quad (8.133)$$

in which $[\underline{\mathbf{C}}] \in \mathbb{M}_n^+(\mathbb{R})$ is defined by Eq. (8.132) and where P^{sym} is the projection operator from $\mathbb{M}_n^+(\mathbb{R})$ on $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$.

- (i) For a given symmetry class with $N < 21$, if there is no anisotropic statistical fluctuations, then the mean matrix $[\underline{\mathbf{C}}]$ belongs to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ and consequently $[\underline{\mathbf{A}}]$ is equal to $[\underline{\mathbf{C}}]$.

- (ii) If the class of symmetry is anisotropic (thus $N = 21$), then $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ coincides with $\mathbb{M}_n^+(\mathbb{R})$ and again $[\underline{A}]$ is equal to the mean matrix $[\underline{C}]$ that belongs to $\mathbb{M}_n^+(\mathbb{R})$.
- (iii) In general, for a given symmetry class with $N < 21$, and due to the presence of anisotropic statistical fluctuations, the mean matrix $[\underline{C}]$ of random matrix $[\mathbf{C}]$ belongs to $\mathbb{M}_n^+(\mathbb{R})$ but does not belong to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$. For this case, an invertible deterministic $(n \times n)$ real matrix $[\underline{S}]$ is introduced such that

$$[\underline{C}] = [\underline{S}]^T [\underline{A}] [\underline{S}]. \quad (8.134)$$

The construction of $[\underline{S}]$ is performed as follows. Let $[L_{\underline{C}}]$ and $[L_{\underline{A}}]$ be the upper triangular real matrices with positive diagonal entries resulting from the Cholesky factorization of matrices $[\underline{C}]$ and $[\underline{A}]$,

$$[\underline{C}] = [L_{\underline{C}}]^T [L_{\underline{C}}], \quad [\underline{A}] = [L_{\underline{A}}]^T [L_{\underline{A}}]. \quad (8.135)$$

Therefore, the matrix $[\underline{S}]$ is written as

$$[\underline{S}] = [L_{\underline{A}}]^{-1} [L_{\underline{C}}]. \quad (8.136)$$

It should be noted that for cases (i) and (ii), Eq. (8.136) shows that $[\underline{S}] = [I_n]$.

12.4 Nonparametric Stochastic Model for $[\mathbf{C}]$

In order that the statistical fluctuations of random matrix $[\mathbf{C}]$ belong mainly to the symmetry class $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ and exhibit more or less some anisotropic fluctuations around this symmetry class, and in order that the level of statistical fluctuations in the symmetry class is controlled independently of the level of statistical anisotropic fluctuation, the use of the nonparametric method leads us to introduce the following representation:

$$[\mathbf{C}] = [\underline{S}]^T [\mathbf{A}]^{1/2} [\mathbf{G}_0] [\mathbf{A}]^{1/2} [\underline{S}], \quad (8.137)$$

in which:

- (1) The deterministic $(n \times n)$ real matrix $[\underline{S}]$ is defined by Eq. (8.136).
- (2) $[\mathbf{G}_0]$ belongs to ensemble SG_0^+ of random matrices and models the anisotropic statistical fluctuations. The mean value of random matrix $[\mathbf{G}_0]$ is matrix $[I_n]$ (see Eq. (8.13)). The level of the statistical fluctuations of $[\mathbf{G}_0]$ is controlled by the hyperparameter δ defined by Eq. (8.15).
- (3) The random matrix $[\mathbf{A}]^{1/2}$ is the square root of a random matrix $[\mathbf{A}]$ with values in $\mathbb{M}_n^{\text{sym}}(\mathbb{R}) \subset \mathbb{M}_n^+(\mathbb{R})$, which models the statistical fluctuations in the given

symmetry class and which is statistically independent of random matrix $[G_0]$. The mean value of random matrix $[A]$ is the matrix $[\underline{A}]$ defined by Eq. (8.133),

$$E\{[A]\} = [\underline{A}] \in \mathbb{M}_n^{\text{sym}}(\mathbb{R}) \subset \mathbb{M}_n^+(\mathbb{R}). \quad (8.138)$$

The level of the statistical fluctuations of $[A]$ is controlled by the coefficient of variation δ_A defined by

$$\delta_A = \left\{ \frac{E\{\|A - \underline{A}\|_F^2\}}{\|\underline{A}\|_F^2} \right\}^{1/2}. \quad (8.139)$$

Taking into account the statistical independence of A and G_0 and taking the mathematical expectation of the two members of Eq. (8.137) yield Eq. (8.134).

12.4.1 Remarks Concerning the Control of the Statistical Fluctuations and the Limit Cases

- (1) For a given symmetry class with $N < 21$, if the level of anisotropic statistical fluctuations goes to zero, that is to say, if $\delta \rightarrow 0$ what implies that $[G_0]$ goes to $[I_n]$ (in probability distribution) and implies that $[\underline{A}]$ goes to $[\underline{C}]$ and thus $[\underline{S}]$ goes to $[I_n]$, then Eq. (8.137) shows that $[C]$ goes to $[A]$ (in probability distribution), which is a random matrix with values in $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$.
- (2) If the given symmetry class is anisotropic ($N = 21$) and $\delta_A \rightarrow 0$, then $[\underline{A}]$ goes to the mean matrix $[\underline{C}]$, $[\underline{S}]$ goes to $[I_n]$, and $[A]$ goes to $[\underline{A}]$ that goes to $[\underline{C}]$ (in probability distribution). Then $[C]$ goes to $[\underline{C}]^{1/2} [G_0] [\underline{C}]^{1/2}$, which is the full anisotropic nonparametric stochastic modeling of $[C]$.

12.5 Construction of $[A]$ Using the MaxEnt Principle

In this section, random matrix $[A]$ that allows for describing the statistical fluctuations in the class of symmetry $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ with $N < 21$ is constructed using the MaxEnt principle and, in particular, using all the results and notations introduced in Sect. 10.

12.5.1 Defining the Available Information

Let $p_{[A]}$ be the unknown pdf of random matrix $[A]$, with respect to volume element $d^S A$ on $\mathbb{M}_n^S(\mathbb{R})$ (see Eq. (8.1)), with values in the given symmetry class $\mathbb{M}_n^{\text{sym}}(\mathbb{R}) \subset \mathbb{M}_n^+(\mathbb{R}) \subset \mathbb{M}_n^S(\mathbb{R})$ with $N < 21$. The support, $\text{supp } p_{[A]}$, is the subset $\mathbb{S}_n = \mathbb{M}_n^{\text{sym}}(\mathbb{R})$, and the normalization condition is given by Eq. (8.74). The available information is defined by

$$E[A] = [\underline{A}], \quad E\{\log(\det[A])\} = c_A, \quad |c_A| < +\infty, \quad (8.140)$$

in which $[\underline{A}]$ is the matrix in \mathbb{S}_n , defined by Eq. (8.133), and where the second available information is introduced in order that pdf $[A] \mapsto p_{[\underline{A}]}([A])$ decreases toward zero when $\|A\|_F$ goes to zero. The constant c_A that has no physical meaning is re-expressed as a function of the hyperparameter δ_A defined by Eq. (8.139). This available information defines the vector $\mathbf{f} = (f_1, \dots, f_\mu)$ in \mathbb{R}^μ with $\mu = n(n+1)/2 + 1$ and defines the mapping $[A] \mapsto \mathcal{G}([A]) = (\mathcal{G}_1([A]), \dots, \mathcal{G}_\mu([A]))$ from \mathbb{S}_n into \mathbb{R}^μ , such that (see Eq. (8.75))

$$E\{\mathcal{G}([\mathbf{A}])\} = \mathbf{f}. \quad (8.141)$$

12.5.2 Defining the Parameterization

The objective is to construct the parameterization of ensemble $\mathbb{S}_n = \mathbb{M}_n^{\text{sym}}(\mathbb{R})$, such that any matrix $[A]$ in $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ is written (see Eq. (8.76)) as

$$[A] = [\mathcal{A}(\mathbf{y})], \quad (8.142)$$

in which $\mathbf{y} = (y_1, \dots, y_N)$ is a vector in \mathbb{R}^N and where $\mathbf{y} \mapsto [\mathcal{A}(\mathbf{y})]$ is a given mapping from \mathbb{R}^N into $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$. Let $[\underline{A}]^{1/2}$ be the square root of matrix $[\underline{A}] \in \mathbb{M}_n^{\text{sym}}(\mathbb{R}) \subset \mathbb{M}_n^+(\mathbb{R})$ that is defined by Eq. (8.133). Due to Eq. (8.129), $[\underline{A}]^{1/2}$ belongs to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$. Any matrix $[A]$ in $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ can then be written as

$$[A] = [\underline{A}]^{1/2} [N] [\underline{A}]^{1/2}, \quad (8.143)$$

in which, due to Eq. (8.129) and due to the invertibility of $[\underline{A}]^{1/2}$, $[N]$ is a unique matrix belonging to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$. Using Eq. (8.130), matrix $[N]$ has the following representation:

$$[N] = \exp_{\mathbb{M}}([\mathcal{N}(\mathbf{y})]), \quad [\mathcal{N}(\mathbf{y})] = \sum_{j=1}^N y_j [E_j^{\text{sym}}], \quad \mathbf{y} = (y_1, \dots, y_N) \in \mathbb{R}^N, \quad (8.144)$$

Consequently, Eqs. (8.143) and (8.144) define the parameterization $[A] = [\mathcal{A}(\mathbf{y})]$.

12.5.3 Construction of $[\mathbf{A}]$ Using the Parameterization and Generator of Realizations

The random matrix $[\mathbf{A}]$ with values in $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ is then written

$$[\mathbf{A}] = [\underline{A}]^{1/2} [\mathbf{N}] [\underline{A}]^{1/2}, \quad (8.145)$$

in which $[\mathbf{N}]$ is the random matrix with values in $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$, which is written as

$$[\mathbf{N}] = \exp_{\mathbb{M}}([\mathcal{N}(\mathbf{Y})]), \quad [\mathcal{N}(\mathbf{Y})] = \sum_{j=1}^N Y_j [E_j^{\text{sym}}], \quad (8.146)$$

in which $\mathbf{Y} = (Y_1, \dots, Y_N)$ is the random vector with values in \mathbb{R}^N whose pdf $p_{\mathbf{Y}}$ on \mathbb{R}^N and the generator of realizations have been detailed in Sect. 10. Since $[\mathbf{N}]$ can be written as $[\mathbf{N}] = [\underline{\mathbf{A}}]^{-1/2} [\mathbf{A}] [\underline{\mathbf{A}}]^{-1/2}$, and since $E[\mathbf{A}] = [\underline{\mathbf{A}}]$ (see Eq. (8.140)), it can be deduced that

$$E\{[\mathbf{N}]\} = [I_n]. \quad (8.147)$$

13 Nonparametric Stochastic Model of Uncertainties in Computational Linear Structural Dynamics

The nonparametric method for stochastic modeling of uncertainties has been introduced in [106, 107] to take into account both the model-parameter uncertainties and the model uncertainties induced by modeling errors in computational linear structural dynamics, without separating the contribution of each one of these two types of uncertainties.

The nonparametric method is presented hereinafter for linear vibrations of fixed linear structures (no rigid body displacement, but only deformation), formulated in the frequency domain, and for which two cases are considered:

- The case of damped linear elastic structures for which the damping and the stiffness matrices of the computational model are independent of the frequency.
- The case of linear viscoelastic structures for which the damping and the stiffness matrices of the computational model depend on the frequency.

13.1 Methodology

The methodology of the nonparametric method consists in introducing:

- (i) A mean computational model for the linear dynamics of the structure,
- (ii) A reduced-order model (ROM) of the mean computational model,
- (iii) The nonparametric stochastic modeling of both the model-parameter uncertainties and the model uncertainties induced by modeling errors, consisting in modeling the mass, damping, and stiffness matrices of the ROM by random matrices,
- (iv) A prior probability model of the random matrices based on the use of the fundamental ensembles of random matrices introduced previously,
- (v) An estimation of the hyperparameters of the prior probability model of uncertainties if some experimental data are available.

The extension to the case of vibrations of free linear structures (presence of rigid body displacements and of elastic deformations) is straightforward, because it is sufficient to construct the ROM (which is then devoted only to the prediction of the

structural deformations) in projecting the response on the elastic structural modes (without including the rigid body modes) [89].

13.2 Mean Computational Model in Linear Structural Dynamics

The dynamical system is a damped fixed elastic structure for which the vibrations are studied around a static equilibrium configuration considered as a natural state without prestresses and which is subjected to an external load. For given nominal values of the parameters of the dynamical system, the finite element model [128] is called the mean computational model, which is written, in the time domain, as

$$[\mathbb{M}] \ddot{\mathbf{x}}(t) + [\mathbb{D}] \dot{\mathbf{x}}(t) + [\mathbb{K}] \mathbf{x}(t) = \mathbb{f}(t), \quad (8.148)$$

in which $\mathbf{x}(t)$ is the vector of the m degrees of freedom (DOF) (displacements and/or rotations); $\dot{\mathbf{x}}(t)$ and $\ddot{\mathbf{x}}(t)$ are the velocity and acceleration vectors; $\mathbb{f}(t)$ is the external load vector of the m inputs (forces and/or moments); and $[\mathbb{M}]$, $[\mathbb{D}]$, and $[\mathbb{K}]$ are the mass, damping, and stiffness matrices of the mean computational model, respectively, which belong to $\mathbb{M}_m^+(\mathbb{R})$.

- The solution $\{\mathbf{x}(t), t > 0\}$ of the time evolution problem is constructed in solving Eq. (8.148) for $t > 0$ with the initial conditions $\mathbf{x}(0) = \mathbf{x}_0$ and $\dot{\mathbf{x}}(0) = \mathbf{v}_0$.
- The forced response $\{\mathbf{x}(t), t \in \mathbb{R}\}$ is such that, for all t fixed in \mathbb{R} , $\mathbf{x}(t)$ verifies Eq. (8.148), and its Fourier transform $\hat{\mathbf{x}}(\omega) = \int_{\mathbb{R}} e^{-i\omega t} \mathbf{x}(t) dt$ is such that, for all ω in \mathbb{R} ,

$$(-\omega^2 [\mathbb{M}] + i\omega [\mathbb{D}] + [\mathbb{K}]) \hat{\mathbf{x}}(\omega) = \hat{\mathbf{f}}(\omega), \quad (8.149)$$

in which $\hat{\mathbf{f}}$ is the Fourier transform of \mathbb{f} . As $[\mathbb{M}]$, $[\mathbb{D}]$, and $[\mathbb{K}]$ are positive-definite matrices, the $\mathbb{M}_m(\mathbb{C})$ -valued frequency response function $\omega \mapsto [\hat{\mathbf{h}}(\omega)] = (-\omega^2 [\mathbb{M}] + i\omega [\mathbb{D}] + [\mathbb{K}])^{-1}$ is a bounded function on \mathbb{R} . From a point of view of the nonparametric stochastic modeling of uncertainties, it is equivalent of presenting the time evolution problem or the forced response problem expressed in the frequency domain. Nevertheless, for such a linear system, the analysis is mainly carried out in the frequency domain. In order to limit the developments, the forced response problem expressed in the frequency domain is presented.

13.3 Reduced-Order Model (ROM) of the Mean Computational Model

The ROM of the mean computational model is constructed for analyzing the response of the structure over a frequency band \mathcal{B} (bounded symmetric interval of pulsations in rad/s) such that

$$\mathcal{B} = [-\omega_{\max}, -\omega_{\min}] \cup [\omega_{\min}, \omega_{\max}], \quad 0 \leq \omega_{\min} < \omega_{\max} < +\infty, \quad (8.150)$$

and is obtained in using the method of modal superposition (or modal analysis) [8, 87]. The generalized eigenvalue problem associated with the mass and stiffness matrices of the mean computational model is written as

$$[\mathbb{K}] \boldsymbol{\phi} = \lambda [\mathbb{M}] \boldsymbol{\phi}, \quad (8.151)$$

for which the eigenvalues $0 < \lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_m$ and the associated elastic structural modes $\{\boldsymbol{\phi}_1, \boldsymbol{\phi}_2, \dots, \boldsymbol{\phi}_m\}$ are such that

$$<[\mathbb{M}] \boldsymbol{\phi}_\alpha, \boldsymbol{\phi}_\beta> = \mu_\alpha \delta_{\alpha\beta}, \quad (8.152)$$

$$<[\mathbb{K}] \boldsymbol{\phi}_\alpha, \boldsymbol{\phi}_\beta> = \mu_\alpha \omega_\alpha^2 \delta_{\alpha\beta}, \quad (8.153)$$

in which $\omega_\alpha = \sqrt{\lambda_\alpha}$ is the eigenfrequency of elastic structural mode $\boldsymbol{\phi}_\alpha$ whose normalization is defined by the generalized mass μ_α . Let \mathbb{H}_n be the subspace of \mathbb{R}^m spanned by $\{\boldsymbol{\phi}_1, \dots, \boldsymbol{\phi}_n\}$ with $n \ll m$ and let \mathbb{H}_n^c be its complexified (i.e., $\mathbb{H}_n^c = \mathbb{H}_n + i \mathbb{H}_n$). Let $[\Phi]$ be the $(m \times n)$ real matrix whose columns are vectors $\{\boldsymbol{\phi}_1, \dots, \boldsymbol{\phi}_n\}$. The ROM of the mean computational model is obtained as the projection $\mathbf{x}^n(\omega)$ of $\hat{\mathbf{x}}(\omega)$ on \mathbb{H}_n^c , which is written as $\mathbf{x}^n(\omega) = [\Phi] \mathbf{q}(\omega)$ in which $\mathbf{q}(\omega)$ is the vector in \mathbb{C}^n of the generalized coordinates and is written, for all ω in \mathcal{B} , as

$$\mathbf{x}^n(\omega) = [\Phi] \mathbf{q}(\omega), \quad (8.154)$$

$$(-\omega^2[M] + i\omega[D] + [K]) \mathbf{q}(\omega) = \mathbf{f}(\omega), \quad (8.155)$$

in which $[M]$, $[D]$, and $[K]$ (generalized mass, damping, and stiffness matrices) belong to $\mathbb{M}_n^+(\mathbb{R})$ and are such that

$$[M]_{\alpha\beta} = \mu_\alpha \delta_{\alpha\beta}, \quad [D]_{\alpha\beta} = <[\mathbb{D}] \boldsymbol{\phi}_\beta, \boldsymbol{\phi}_\alpha>, \quad [K]_{\alpha\beta} = \mu_\alpha \omega_\alpha^2 \delta_{\alpha\beta}. \quad (8.156)$$

In general, $[D]$ is a full matrix. The generalized force $\mathbf{f}(\omega)$ is a \mathbb{C}^n -vector such that $\mathbf{f}(\omega) = [\Phi]^T \hat{\mathbf{f}}(\omega)$ in which $\hat{\mathbf{f}}$ is the Fourier transform of \mathbf{f} , which is assumed to be a bounded function on \mathbb{R} .

13.3.1 Convergence of the ROM with Respect to n Over Frequency Band of Analysis \mathcal{B}

For the given frequency band of analysis \mathcal{B} , and for a fixed value of the relative error ε_0 with $0 < \varepsilon_0 \ll 1$, let n_0 (depending on ε_0) be the smallest value of n such that $1 \leq n_0 < m$, for which, for all ω in \mathcal{B} , the convergence of the ROM (with respect to dimension n) is reached with relative error ε_0 (if n_0 was equal to m , then ε would be equal to 0). The value of n_0 is such that

$$\forall n \geq n_0, \quad \int_{\mathcal{B}} \|[\hat{\mathbb{H}}(\omega)] - [\hat{\mathbb{H}}^n(\omega)]\|_F^2 d\omega \leq \varepsilon_0 \int_{\mathcal{B}} \|[\hat{\mathbb{H}}(\omega)]\|_F^2 d\omega, \quad (8.157)$$

in which $[\hat{\mathbb{H}}^n(\omega)] = [\Phi](-\omega^2[M] + i\omega[D] + [K])^{-1}[\Phi]^T$. In practice, for large computational model, Eq. (8.157) is replaced by a convergence analysis of \mathbf{x}^n to \mathbf{x} on \mathcal{B} for a given subset of generalized forces \mathbf{f} .

13.4 Nonparametric Stochastic Model of Both the Model-Parameter Uncertainties and the Model Uncertainties (Modeling Errors)

For the given frequency band of analysis \mathcal{B} , and for n fixed to the value n_0 such that Eq. (8.157) is verified, the nonparametric stochastic model of uncertainties consists in replacing in Eq. (8.155) the deterministic matrices $[M]$, $[D]$, and $[K]$ by random matrices $[\mathbf{M}]$, $[\mathbf{D}]$, and $[\mathbf{K}]$ defined on the probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in $\mathbb{M}_n^+(\mathbb{R})$. The deterministic ROM defined by Eqs. (8.154) and (8.155) is then replaced by the following stochastic ROM:

$$\mathbf{X}^n(\omega) = [\Phi] \mathbf{Q}(\omega), \quad (8.158)$$

$$(-\omega^2[\mathbf{M}] + i\omega[\mathbf{D}] + [\mathbf{K}]) \mathbf{Q}(\omega) = \mathbf{f}(\omega), \quad (8.159)$$

in which, for all ω in \mathcal{B} , $\mathbf{X}^n(\omega)$ and $\mathbf{Q}(\omega)$ are \mathbb{C}^m - and \mathbb{C}^n -valued random vectors defined on probability space $(\Theta, \mathcal{T}, \mathcal{P})$.

13.4.1 Available Information for Constructing a Prior Probability Model of $[\mathbf{M}]$, $[\mathbf{D}]$, and $[\mathbf{K}]$

The available information for constructing the prior probability model of random matrices $[\mathbf{M}]$, $[\mathbf{D}]$, and $[\mathbf{K}]$ using the MaxEnt principle are the following:

- (i) Random matrices $[\mathbf{M}]$, $[\mathbf{D}]$, and $[\mathbf{K}]$ are with values in $\mathbb{M}_n^+(\mathbb{R})$.
- (ii) The mean values of these random matrices are chosen as the corresponding matrices in the ROM of the mean computational model,

$$E\{[\mathbf{M}]\} = [M], \quad E\{[\mathbf{D}]\} = [D], \quad E\{[\mathbf{K}]\} = [K]. \quad (8.160)$$

- (iii) The prior probability model of these random matrices must be chosen such that, for all ω in \mathcal{B} , the solution $\mathbf{Q}(\omega)$ of Eq. (8.159) is a second-order \mathbb{C}^n -valued random variable, that is to say, such that

$$E\{\|(-\omega^2[\mathbf{M}] + i\omega[\mathbf{D}] + [\mathbf{K}])^{-1}\|_F^2\} < +\infty, \quad \forall \omega \in \mathcal{B}. \quad (8.161)$$

13.4.2 Prior Probability Model of [M], [D], and [K], Hyperparameters and Generator of Realizations

The joint pdf of random matrices $[M]$, $[D]$, and $[K]$ is constructed using the MaxEnt principle under the constraints defined by the available information described before. Taking into account such an available information, it is proved [107] that these three random matrices are statistically independent. Taking into account Eqs. (8.52), (8.55), (8.160), and (8.161), each random matrix $[M]$, $[D]$, and $[K]$ is then chosen in ensemble SE_e^+ of the positive-definite random matrices with a given mean value and an arbitrary positive-definite lower bound. The level of uncertainties, for each type of forces (mass, damping, and stiffness), is controlled by the three hyperparameters δ_M , δ_D , and δ_K of the pdf of random matrices $[M]$, $[D]$, and $[K]$, which are defined by Eq. (8.56). The generator of realizations for ensemble SE_e^+ has explicitly been described.

13.5 Case of Linear Viscoelastic Structures

The dynamical system is a fixed viscoelastic structure for which the vibrations are studied around a static equilibrium configuration considered as a natural state without prestresses and which is subjected to an external load. Consequently, in the frequency domain, the damping and stiffness matrices depend on frequency ω , instead of to be independent of the frequency as in the previous analyzed case. Consequently, two aspects must be addressed. The first one is relative to the choice of the basis for constructing the ROM, and the second one is the nonparametric stochastic modeling of the frequency dependent damping and stiffness matrices which are related by a Hilbert transform; we then use for such a nonparametric stochastic modeling ensemble SE^{HT} of a pair of positive-definite matrix-valued random functions related to a Hilbert transform.

13.5.1 Mean Computational Model, ROM, and Convergence

In such a case, the mean computational model defined by Eq. (8.149) is replaced by the following:

$$(-\omega^2 [M] + i\omega[D(\omega)] + [K(\omega)]) \hat{x}(\omega) = \hat{f}(\omega), \quad (8.162)$$

For constructing the ROM, the projection basis is chosen as previously in taking the stiffness matrix at zero frequency. The generalized eigenvalue problem, defined by Eq. (8.151), is then rewritten as $[K(0)]\phi = \lambda[M]\phi$. With such a choice of a basis, Eqs. (8.154) to (8.156) that defined the ROM for all ω belonging to the frequency band of analysis \mathcal{B} are replaced by

$$\mathbf{x}^n(\omega) = [\Phi] \mathbf{q}(\omega), \quad (8.163)$$

$$(-\omega^2[M] + i\omega[D(\omega)] + [K(\omega)]) \mathbf{q}(\omega) = \mathbf{f}(\omega), \quad (8.164)$$

in which $[M]$, $[D(\omega)]$, and $[K(\omega)]$ belong to $\mathbb{M}_n^+(\mathbb{R})$ and are such that

$$[M]_{\alpha\beta} = \mu_\alpha \delta_{\alpha\beta}, [D(\omega)]_{\alpha\beta} = <[\mathbb{D}(\omega)] \phi_\beta, \phi_\alpha>, [K(\omega)]_{\alpha\beta} = <[\mathbb{K}(\omega)] \phi_\beta, \phi_\alpha>. \quad (8.165)$$

The matrices $[D(\omega)]$ and $[K(\omega)]$ are full matrices belonging to $\mathbb{M}_n^+(\mathbb{R})$, which verify (see [89]) all the mathematical properties introduced in the construction of ensemble SE^{HT} and, in particular, verify Eqs. (8.65) to (8.68). For ε_0 fixed, the value n_0 of the dimension n of the ROM is such that Eq. (8.157) holds (equation in which the frequency dependence of the damping and stiffness matrices is introduced). In practice, for large computational model, this criterion is replaced by a convergence analysis of \mathbf{x}^n to \mathbf{x} on \mathcal{B} for a given subset of generalized forces \mathbf{f} .

13.5.2 Nonparametric Stochastic Model of Both the Model-Parameter Uncertainties and the Model Uncertainties (Modeling Errors)

For the given frequency band of analysis \mathcal{B} , and for n fixed to the value n_0 , the nonparametric stochastic model of uncertainties consists in replacing in Eq. (8.164) the deterministic matrices $[M]$, $[D(\omega)]$, and $[K(\omega)]$ by random matrices $[\mathbf{M}]$, $[\mathbf{D}(\omega)]$, and $[\mathbf{K}(\omega)]$ defined on the probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in $\mathbb{M}_n^+(\mathbb{R})$. The deterministic ROM defined by Eqs. (8.163) and (8.164) is then replaced by the following stochastic ROM:

$$\mathbf{X}^n(\omega) = [\Phi] \mathbf{Q}(\omega), \quad (8.166)$$

$$(-\omega^2[\mathbf{M}] + i\omega[\mathbf{D}(\omega)] + [\mathbf{K}(\omega)]) \mathbf{Q}(\omega) = \mathbf{f}(\omega), \quad (8.167)$$

in which, for all ω in \mathcal{B} , $\mathbf{X}^n(\omega)$ and $\mathbf{Q}(\omega)$ are \mathbb{C}^m - and \mathbb{C}^n -valued random vectors defined on probability space $(\Theta, \mathcal{T}, \mathcal{P})$.

13.5.3 Available Information for Constructing a Prior Probability Model of $[\mathbf{M}]$, $[\mathbf{D}(\omega)]$, and $[\mathbf{K}(\omega)]$

The available information for constructing the prior probability model of random matrices $[\mathbf{M}]$, $[\mathbf{D}(\omega)]$, and $[\mathbf{K}(\omega)]$ using the MaxEnt principle are, for all ω in \mathcal{B} :

- (i) Random matrices $[\mathbf{M}]$, $[\mathbf{D}(\omega)]$, and $[\mathbf{K}(\omega)]$ are with values in $\mathbb{M}_n^+(\mathbb{R})$.
- (ii) The mean values of these random matrices are chosen as the corresponding matrices in the ROM of the mean computational model,

$$E\{[\mathbf{M}]\} = [M], E\{[\mathbf{D}(\omega)]\} = [D(\omega)], E\{[\mathbf{K}(\omega)]\} = [K(\omega)]. \quad (8.168)$$

- (iii) The random matrices $[\mathbf{D}(\omega)]$ and $[\mathbf{K}(\omega)]$ are such that

$$[\mathbf{D}(-\omega)] = [\mathbf{D}(\omega)], [\mathbf{K}(-\omega)] = [\mathbf{K}(\omega)]. \quad (8.169)$$

- (iv) The prior probability model of these random matrices must be chosen for that, for all ω in \mathcal{B} , the solution $\mathbf{Q}(\omega)$ of Eq. (8.167) is a second-order \mathbb{C}^n -valued random variable, that is to say, for that

$$E\{\|(-\omega^2[\mathbf{M}] + i\omega[\mathbf{D}(\omega)] + [\mathbf{K}(\omega)])^{-1}\|_F^2\} < +\infty, \quad \forall \omega \in \mathcal{B}. \quad (8.170)$$

- (v) The algebraic dependence between $[\mathbf{D}(\omega)]$ and $[\mathbf{K}(\omega)]$ induced by the causality must be preserved, which means that random matrix $[\mathbf{K}(\omega)]$ is given by Eq. (8.72) as a function of random matrix $[\mathbf{K}(0)]$ and the family of random matrices $\{\mathbf{D}(\omega), \omega \geq 0\}$,

$$[\mathbf{K}(\omega)] = [\mathbf{K}(0)] + \frac{2\omega^2}{\pi} \text{p.v.} \int_0^{+\infty} \frac{1}{\omega^2 - \omega'^2} [\mathbf{D}(\omega')] d\omega', \quad \forall \omega \geq 0. \quad (8.171)$$

13.5.4 Prior Probability Model of $[\mathbf{M}]$, $[\mathbf{D}(\omega)]$, and $[\mathbf{K}(0)]$, Hyperparameters, and Generator of Realizations

Taking into account the available information, the use of the MaxEnt principle yields that random matrices $[\mathbf{M}]$, $\{[\mathbf{D}(\omega)], \omega \geq 0\}$, and $[\mathbf{K}(0)]$ are statistically independent.

- As previously, random matrix $[\mathbf{M}]$ is chosen in ensemble SE_ϵ^+ of the positive-definite random matrices with a given mean value and an arbitrary positive-definite lower bound. The pdf is explicitly defined and depends on the hyperparameter δ_M defined by Eq. (8.56). The generator of realizations is the generator of the ensemble SE_ϵ^+ , which was explicitly defined.
- For all fixed ω , random matrices $[\mathbf{D}(\omega)]$ and $[\mathbf{K}(0)]$ that are statistically independent are constructed as explained in the section devoted to ensemble SE^{HT} . The levels of uncertainties of random matrices $[\mathbf{D}(\omega)]$ and $[\mathbf{K}(0)]$ are controlled by the two frequency-independent hyperparameters δ_D and δ_K introduced in paragraphs (i) and (ii) located after Eq. (8.70). The generator of realizations is directly deduced from the generator of realizations of fundamental ensemble SG_ϵ^+ , which was explicitly defined.
- With such a nonparametric stochastic modeling, the level of uncertainties is controlled by hyperparameters δ_M , δ_D , and δ_K , and the generators of realizations of random matrices $[\mathbf{M}]$, $[\mathbf{D}(\omega)]$, and $[\mathbf{K}(0)]$ are explicitly described.

13.6 Estimation of the Hyperparameters of the Nonparametric Stochastic Model of Uncertainties

For the nonparametric stochastic model of uncertainties in computational linear structural dynamics, dimension n of the ROM is fixed to the value n_0 for which the response of the ROM of the mean computational model is converged with respect to n . The prior probability model of uncertainties then depends on the vector-valued hyperparameter $\boldsymbol{\delta}_{\text{npar}} = (\delta_M, \delta_D, \delta_K)$ belonging to an admissible set $\mathcal{C}_{\text{npar}}$.

- If no experimental data are available, then $\boldsymbol{\delta}_{\text{npar}}$ must be considered as a vector-valued parameter for performing a sensitivity analysis of the stochastic solution with respect to the level of uncertainties. Such a nonparametric stochastic model of both the model-parameter uncertainties and the model uncertainties then

allows the robustness of the solution to be analyzed as a function of the level of uncertainties which is controlled by δ_{npar} .

- If experimental data are available, an estimation of δ_{npar} can be carried out, for instance, using a least square method or the maximum likelihood method [102, 117, 123]. Let \mathbf{W} be the random real vector which is observed, which is independent of ω , but which depends on $\{\mathbf{X}^n(\omega), \omega \in \mathcal{B}\}$ where $\mathbf{X}^n(\omega)$ is the second-order random complex vector given by Eq. (8.158) or (8.166). For all $\delta_{\text{npar}} \in \mathcal{C}_{\text{npar}}$, the probability density function of \mathbf{W} is denoted as $\mathbf{w} \mapsto p_{\mathbf{W}}(\mathbf{w}; \delta_{\text{npar}})$. Using the maximum likelihood method, the optimal value $\delta_{\text{npar}}^{\text{opt}}$ of δ_{npar} is estimated by maximizing the logarithm of the likelihood function,

$$\delta_{\text{npar}}^{\text{opt}} = \arg \max_{\delta_{\text{npar}} \in \mathcal{C}_{\text{npar}}} \sum_{\ell=1}^{v_{\text{exp}}} \log p_{\mathbf{W}}(\mathbf{w}_{\ell}^{\text{exp}}; \delta_{\text{npar}}). \quad (8.172)$$

in which $\mathbf{w}_1^{\text{exp}}, \dots, \mathbf{w}_{v_{\text{exp}}}^{\text{exp}}$ are v_{exp} independent experimental data corresponding to \mathbf{W} .

14 Parametric-Nonparametric Uncertainties in Computational Nonlinear Structural Dynamics

The last two presented sections have been devoted to the nonparametric stochastic model of both the model-parameter uncertainties and the model uncertainties induced by the modeling errors, without separating the contribution of each one of these two types of uncertainties. Sometimes, there is an interest of separating the uncertainties for a small number of model parameters that exhibit an important sensitivity on the responses, from uncertainties induced by the model uncertainties and the uncertainties on other model parameters.

Such an objective requires to use a parametric-nonparametric stochastic model of uncertainties, also called the generalized probabilistic approach of uncertainties in computational structural dynamics, which has been introduced in [113].

As the nonparametric stochastic model of uncertainties has been presented in the previous sections for linear dynamical systems formulated in the frequency domain, in the present section, the parametric-nonparametric stochastic model of uncertainties is presented in computational nonlinear structural dynamics formulated in the time domain.

14.1 Mean Nonlinear Computational Model in Structural Dynamics

The dynamical system is a damped fixed structure for which the nonlinear vibrations are studied in the time domain around a static equilibrium configuration considered as a natural state without prestresses and subjected to an external load. For given

nominal values of the model parameters of the dynamical system, the basic finite element model is called the mean nonlinear computational model. In addition, it is assumed that a set of model parameters has been identified as sensitive parameters that are uncertain. These uncertain model parameters are the components of a vector $\tilde{\mathbf{y}}$ belonging to an admissible set \mathcal{C}_{par} which is a subset of \mathbb{R}^N . It is assumed that a parameterization is constructed such that $\tilde{\mathbf{y}} = \mathcal{Y}(\mathbf{y})$ in which $\mathbf{y} \mapsto \mathcal{Y}(\mathbf{y})$ is a given and known function from \mathcal{C}_{par} into \mathbb{R}^N . For instance, if the component \tilde{y}_j of $\tilde{\mathbf{y}}$ must belong to $[0, +\infty[$, then \tilde{y}_j could be defined as $\exp(y_j)$ with $y_j \in \mathbb{R}$, which yields $\mathcal{Y}_j(\mathbf{y}) = \exp(y_j)$. Hereinafter, it is then assumed that the uncertain model parameters are represented by vector $\mathbf{y} = (y_1, \dots, y_N)$ belonging to \mathbb{R}^N . The nonlinear mean computational model, depending on uncertain model parameter \mathbf{y} , is written as

$$[\mathbb{M}(\mathbf{y})]\ddot{\mathbf{x}}(t) + [\mathbb{D}(\mathbf{y})]\dot{\mathbf{x}}(t) + [\mathbb{K}(\mathbf{y})]\mathbf{x}(t) + \mathbb{f}_{\text{NL}}(\mathbf{x}(t), \dot{\mathbf{x}}(t); \mathbf{y}) = \mathbb{f}(t; \mathbf{y}), \quad (8.173)$$

in which $\mathbf{x}(t)$ is the unknown time response vector of the m degrees of freedom (DOF) (displacements and/or rotations); $\dot{\mathbf{x}}(t)$ and $\ddot{\mathbf{x}}(t)$ are the velocity and acceleration vectors respectively; $\mathbb{f}(t; \mathbf{y})$ is the known external load vector of the m inputs (forces and/or moments); $[\mathbb{M}(\mathbf{y})]$, $[\mathbb{D}(\mathbf{y})]$, and $[\mathbb{K}(\mathbf{y})]$ are the mass, damping, and stiffness matrices of the linear part of the mean nonlinear computational model, respectively, which belong to $M_m^+(\mathbb{R})$; and $(\mathbf{x}(t), \dot{\mathbf{x}}(t)) \mapsto \mathbb{f}_{\text{NL}}(\mathbf{x}(t), \dot{\mathbf{x}}(t); \mathbf{y})$ is the nonlinear mapping that models the local nonlinear forces (such as nonlinear elastic barriers).

We are interested in the time evolution problem defined by Eq. (8.173) for $t > 0$ with the initial conditions $\mathbf{x}(0) = \mathbf{x}_0$ and $\dot{\mathbf{x}}(0) = \mathbf{v}_0$.

14.2 Reduced-Order Model (ROM) of the Mean Nonlinear Computational Model

For all \mathbf{y} fixed in \mathbb{R}^N , let $\{\phi_1(\mathbf{y}), \dots, \phi_m(\mathbf{y})\}$ be an algebraic basis of \mathbb{R}^m constructed, for instance, either using the elastic structural modes of the linearized system, using the elastic structural modes of the underlying linear system, or using the POD (proper orthogonal decomposition) modes of the nonlinear system). Hereinafter, it is assumed that the elastic structural modes of the underlying linear system are used for constructing the ROM of the mean nonlinear computational model (such a choice is not intrusive with respect to a black-box software, but in counterpart requires a large parallel computation induced by all the sampling values of \mathbf{y} , which are considered by the stochastic solver).

For each value of \mathbf{y} given in \mathbb{R}^N , the generalized eigenvalue problem associated with the mean mass and stiffness matrices is written as

$$[\mathbb{K}(\mathbf{y})]\boldsymbol{\phi}(\mathbf{y}) = \lambda(\mathbf{y})[\mathbb{M}(\mathbf{y})]\boldsymbol{\phi}(\mathbf{y}), \quad (8.174)$$

for which the eigenvalues $0 < \lambda_1(\mathbf{y}) \leq \lambda_2(\mathbf{y}) \leq \dots \leq \lambda_m(\mathbf{y})$ and the associated elastic structural modes $\{\phi_1(\mathbf{y}), \phi_2(\mathbf{y}), \dots, \phi_m(\mathbf{y})\}$ are such that

$$\langle [\mathbb{M}(\mathbf{y})] \phi_\alpha(\mathbf{y}), \phi_\beta(\mathbf{y}) \rangle = \mu_\alpha(\mathbf{y}) \delta_{\alpha\beta}, \quad (8.175)$$

$$\langle [\mathbb{K}(\mathbf{y})] \phi_\alpha(\mathbf{y}), \phi_\beta(\mathbf{y}) \rangle = \mu_\alpha(\mathbf{y}) \omega_\alpha(\mathbf{y})^2 \delta_{\alpha\beta}, \quad (8.176)$$

in which $\omega_\alpha(\mathbf{y}) = \sqrt{\lambda_\alpha(\mathbf{y})}$ is the eigenfrequency of elastic structural mode $\phi_\alpha(\mathbf{y})$ whose normalization is defined by the generalized mass $\mu_\alpha(\mathbf{y})$. Let $[\phi(\mathbf{y})]$ be the $(m \times n)$ real matrix whose columns are vectors $\{\phi_1(\mathbf{y}), \dots, \phi_n(\mathbf{y})\}$. For \mathbf{y} fixed in \mathbb{R}^N and for all fixed $t > 0$, the ROM is obtained as the projection $\mathbf{x}^n(t)$ of $\mathbf{x}(t)$ on the subspace of \mathbb{R}^m spanned by $\{\phi_1(\mathbf{y}), \dots, \phi_n(\mathbf{y})\}$ with $n \ll m$, which is written as $\mathbf{x}^n(t) = [\phi(\mathbf{y})] \mathbf{q}(t)$ in which $\mathbf{q}(t)$ is the vector in \mathbb{R}^n of the generalized coordinates and is written, for all $t > 0$, as

$$\mathbf{x}^n(t) = [\phi(\mathbf{y})] \mathbf{q}(t), \quad (8.177)$$

$$[M(\mathbf{y})] \ddot{\mathbf{q}}(t) + [D(\mathbf{y})] \dot{\mathbf{q}}(t) + [K(\mathbf{y})] \mathbf{q}(t) + \mathbf{F}_{\text{NL}}(\mathbf{q}(t), \dot{\mathbf{q}}(t); \mathbf{y}) = \mathbf{f}(t; \mathbf{y}), \quad (8.178)$$

in which $[M(\mathbf{y})]$, $[D(\mathbf{y})]$, and $[K(\mathbf{y})]$ (generalized mass, damping, and stiffness matrices) belong to $\mathbb{M}_n^+(\mathbb{R})$ and are such that

$$[M(\mathbf{y})]_{\alpha\beta} = \mu_\alpha(\mathbf{y}) \delta_{\alpha\beta}, \quad [D(\mathbf{y})]_{\alpha\beta} = \langle [\mathbb{D}(\mathbf{y})] \phi_\beta(\mathbf{y}), \phi_\alpha(\mathbf{y}) \rangle, \quad (8.179)$$

$$[K(\mathbf{y})]_{\alpha\beta} = \mu_\alpha(\mathbf{y}) \omega_\alpha(\mathbf{y})^2 \delta_{\alpha\beta}. \quad (8.180)$$

In general, $[D(\mathbf{y})]$ is a full matrix. The generalized force $\mathbf{f}(t; \mathbf{y})$ is a \mathbb{R}^n -vector such that $\mathbf{f}(t; \mathbf{y}) = [\phi(\mathbf{y})]^T \mathbb{f}(t; \mathbf{y})$. The generalized nonlinear force is such that $\mathbf{F}_{\text{NL}}(\mathbf{q}(t), \dot{\mathbf{q}}(t); \mathbf{y}) = [\phi(\mathbf{y})]^T \mathbb{f}_{\text{NL}}([\phi(\mathbf{y})] \mathbf{q}(t), [\phi(\mathbf{y})] \dot{\mathbf{q}}(t); \mathbf{y})$.

Convergence of the ROM with respect to n . Let n_0 be the value of n , for which, for a given accuracy and for all \mathbf{y} in \mathbb{R}^N , the response \mathbf{x}^n is converged to \mathbf{x} for all $n > n_0$.

14.3 Parametric-Nonparametric Stochastic Modeling of Uncertainties

In all this section, the value of n is fixed to the value n_0 defined hereinbefore.

14.3.1 Methodology

- The parametric stochastic modeling of uncertainties consists in modeling uncertain model parameter \mathbf{y} by a second-order random variable $\mathbf{Y} = (Y_1, \dots, Y_N)$, defined on the probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in \mathbb{R}^N . Consequently,

deterministic matrices $[M(\mathbf{y})]$, $[D(\mathbf{y})]$, and $[K(\mathbf{y})]$ defined by Eqs. (8.179)–(8.180) become the second-order random matrices, $[M(\mathbf{Y})]$, $[D(\mathbf{Y})]$, and $[K(\mathbf{Y})]$, defined on probability space $(\Theta, \mathcal{T}, \mathcal{P})$, with values in $\mathbb{M}_n^+(\mathbb{R})$. The mean values of these random matrices are the matrices in $\mathbb{M}_n^+(\mathbb{R})$ such that

$$[\underline{M}] = E\{[M(\mathbf{Y})]\}, \quad [\underline{D}] = E\{[D(\mathbf{Y})]\}, \quad [\underline{K}] = E\{[K(\mathbf{Y})]\}, \quad (8.181)$$

- The nonparametric stochastic modeling of uncertainties consists, for all \mathbf{y} fixed in \mathbb{R}^N , in modeling matrices $[M(\mathbf{y})]$, $[D(\mathbf{y})]$, and $[K(\mathbf{y})]$ defined by Eqs. (8.179)–(8.180), by the second-order random matrices $[\mathbf{M}(\mathbf{y})] = \{\theta' \mapsto [\mathbf{M}(\theta'; \mathbf{y})]\}$, $[\mathbf{D}(\mathbf{y})] = \{\theta' \mapsto [\mathbf{D}(\theta'; \mathbf{y})]\}$, and $[\mathbf{K}(\mathbf{y})] = \{\theta' \mapsto [\mathbf{K}(\theta'; \mathbf{x})]\}$, defined on another probability space $(\Theta', \mathcal{T}', \mathcal{P}')$ (and thus independent of \mathbf{Y}), with values in $\mathbb{M}_n^+(\mathbb{R})$.
 - The parametric-nonparametric stochastic modeling of uncertainties consists, in Eq. (8.178)):
- (i) In modeling $[M(\mathbf{y})]$, $[D(\mathbf{y})]$, and $[K(\mathbf{y})]$ by random matrices $[\mathbf{M}(\mathbf{y})]$, $[\mathbf{D}(\mathbf{y})]$, and $[\mathbf{K}(\mathbf{y})]$,
 - (ii) In modeling uncertain model parameter \mathbf{y} by the \mathbb{R}^N -valued random variable \mathbf{Y} .

Consequently, the statistically dependent random matrices $[\mathbf{M}(\mathbf{Y})] = \{(\theta, \theta') \mapsto [\mathbf{M}(\theta'; \mathbf{Y}(\theta))]\}$, $[\mathbf{D}(\mathbf{Y})] = \{(\theta, \theta') \mapsto [\mathbf{D}(\theta'; \mathbf{Y}(\theta))]\}$ and $[\mathbf{K}(\mathbf{Y})] = \{(\theta, \theta') \mapsto [\mathbf{K}(\theta'; \mathbf{Y}(\theta))]\}$ are measurable mappings from $\Theta \times \Theta'$ into $\mathbb{M}_n^+(\mathbb{R})$. The deterministic ROM defined by Eqs. (8.177)–(8.178) is then replaced by the following stochastic ROM:

$$\mathbf{X}^n(t) = [\phi(\mathbf{Y})] \mathbf{Q}(t), \quad (8.182)$$

$$[\mathbf{M}(\mathbf{Y})] \ddot{\mathbf{Q}}(t) + [\mathbf{D}(\mathbf{Y})] \dot{\mathbf{Q}}(t) + [\mathbf{K}(\mathbf{Y})] \mathbf{Q}(t) + \mathbf{F}_{NL}(\mathbf{Q}(t), \dot{\mathbf{Q}}(t); \mathbf{Y}) = \mathbf{f}(t; \mathbf{Y}), \quad (8.183)$$

in which for all fixed t , $\mathbf{X}^n(t) = \{(\theta, \theta') \mapsto \mathbf{X}^n(\theta, \theta'; t)\}$ and $\mathbf{Q}(t) = \{(\theta, \theta') \mapsto \mathbf{Q}(\theta, \theta'; t)\}$ are \mathbb{R}^m - and \mathbb{R}^n -valued random vectors defined for (θ, θ') in $\Theta \times \Theta'$.

14.3.2 Prior Probability Model of \mathbf{Y} , Hyperparameters, and Generator of Realizations

The prior pdf $p_{\mathbf{Y}}$ on \mathbb{R}^N of random vector \mathbf{Y} is constructed using the MaxEnt principle under the constraints defined by the available information given by Eq. (8.81), as explained in Sect. 11, in which a generator of realizations $\{\mathbf{Y}(\theta), \theta \in \Theta\}$ has been detailed. Such a generator depends on the hyperparameters related to the available information. In general, the hyperparameters are the mean vector $\underline{\mathbf{y}} = E\{\mathbf{Y}\}$ belonging to \mathbb{R}^N and a vector-valued hyperparameter δ_{par} that belongs to an admissible set \mathcal{C}_{par} , which allows the level of parametric uncertainties to be controlled.

14.3.3 Prior Probability Model of $[M(y)]$, $[D(y)]$, and $[K(y)]$, Hyperparameters, and Generator of Realizations

Similarly to the construction given in section entitled “Nonparametric Stochastic Model of Uncertainties in Computational Linear Structural Dynamics”, for all \mathbf{y} fixed in \mathbb{R}^N , random matrices $[M(\mathbf{y})]$, $[D(\mathbf{y})]$, and $[K(\mathbf{y})]$, are statistically independent and written as

$$[M(\mathbf{y})] = [L_M(\mathbf{y})]^T [G_M] [L_M(\mathbf{y})], \quad (8.184)$$

$$[D(\mathbf{y})] = [L_D(\mathbf{y})]^T [G_D] [L_D(\mathbf{y})], \quad (8.185)$$

$$[K(\mathbf{y})] = [L_K(\mathbf{y})]^T [G_K] [L_K(\mathbf{y})], \quad (8.186)$$

in which, for all \mathbf{y} in \mathbb{R}^N , $[L_M(\mathbf{y})]$, $[L_D(\mathbf{y})]$, and $[L_K(\mathbf{y})]$ are the upper triangular matrices such that (Cholesky factorization) $[M(\mathbf{y})] = [L_M(\mathbf{y})]^T [L_M(\mathbf{y})]$, $[D(\mathbf{y})] = [L_D(\mathbf{y})]^T [L_D(\mathbf{y})]$, and $[K(\mathbf{y})] = [L_K(\mathbf{y})]^T [L_K(\mathbf{y})]$. In Eqs. (8.184) to (8.186), $[G_M]$, $[G_D]$, and $[G_K]$ are independent random matrices defined on probability space $(\Theta', \mathcal{T}', \mathcal{P}')$, with values in $\mathbb{M}_n^+(\mathbb{R})$, independent of \mathbf{y} , and belonging to fundamental ensemble SG_ε^+ of random matrices. The level of nonparametric uncertainties is controlled by the coefficients of variation δ_{G_M} , δ_{G_D} , and δ_{G_K} defined by Eq. (8.24) and the vector-valued parameter δ_{npar} is defined as $\delta_{\text{npar}} = (\delta_M, \delta_D, \delta_K)$ that belongs to an admissible set $\mathcal{C}_{\text{npar}}$. The generator of realizations $\{[G_M(\theta')], [G_D(\theta')], [G_K(\theta')]\}$ for θ' in Θ' is explicitly described in the section devoted to the construction of ensembles SG_ε^+ and SG_0^+ .

14.3.4 Mean Values of Random Matrices $[M(Y)]$, $[D(Y)]$, $[K(Z)]$ and Hyperparameters of the Parametric-Nonparametric Stochastic Model of Uncertainties

Taking into account the construction presented hereinbefore, we have

$$E\{[M(Y)]\} = [\underline{M}], \quad E\{[D(Y)]\} = [\underline{D}], \quad E\{[K(Y)]\} = [\underline{K}], \quad (8.187)$$

in which the matrices $[\underline{M}]$, $[\underline{D}]$, and $[\underline{K}]$ are the deterministic matrices defined by Eq. (8.181). The hyperparameters of the parametric-nonparametric stochastic model of uncertainties are

$$\underline{\mathbf{y}} \in \mathbb{R}^N, \quad \delta_{\text{par}} \in \mathcal{C}_{\text{par}}, \quad \delta_{\text{npar}} = (\delta_M, \delta_D, \delta_K) \in \mathcal{C}_{\text{npar}}. \quad (8.188)$$

14.4 Estimation of the Hyperparameters of the Parametric-Nonparametric Stochastic Model of Uncertainties

The value of n is fixed to the value n_0 that has been defined. The parametric-nonparametric stochastic model of uncertainties is controlled by the hyperparameters defined by Eq. (8.188).

- If no experimental data are available, then $\underline{\mathbf{y}}$ can be fixed to a nominal value \mathbf{y}_0 , and δ_{par} and δ_{npar} must be considered as parameters to perform a sensitivity analysis of the stochastic solution. Such a parametric-nonparametric stochastic model of uncertainties allows the robustness of the solution to be analyzed as a function of the level of uncertainties controlled by δ_{par} and δ_{npar} .
- If experimental data are available, an estimation of $\underline{\mathbf{y}}$, δ_{par} , and δ_{npar} can be carried out, for instance, using a least square method or the maximum likelihood method [102, 117, 123]. Let \mathbf{W} be the random real vector which is observed, which is independent of t , but which depends on $\{\mathbf{X}^n(t), t \geq 0\}$ where $\mathbf{X}^n(t)$ is the second-order stochastic solution of Eq. (8.182)–(8.183) for $t > 0$ with initial conditions for $t = 0$. Let $\mathbf{r} = (\underline{\mathbf{y}}, \delta_{\text{par}}, \delta_{\text{npar}})$ be the vector-valued hyperparameter belonging to the admissible set $\mathcal{C}_{\mathbf{r}} = \mathbb{R}^N \times \mathcal{C}_{\text{par}} \times \mathcal{C}_{\text{npar}}$. For all \mathbf{r} in $\mathcal{C}_{\mathbf{r}}$, the probability density function of \mathbf{W} is denoted as $\mathbf{w} \mapsto p_{\mathbf{W}}(\mathbf{w}; \mathbf{r})$. Using the maximum likelihood method, the optimal values \mathbf{r}^{opt} of \mathbf{r} are estimated by maximizing the logarithm of the likelihood function,

$$\mathbf{r}^{\text{opt}} = \arg \max_{\mathbf{r} \in \mathcal{C}_{\mathbf{r}}} \sum_{\ell=1}^{v_{\text{exp}}} \log p_{\mathbf{W}}(\mathbf{w}_{\ell}^{\text{exp}}; \mathbf{r}). \quad (8.189)$$

in which $\mathbf{w}_1^{\text{exp}}, \dots, \mathbf{w}_{v_{\text{exp}}}^{\text{exp}}$ are v_{exp} independent experimental data corresponding to \mathbf{W} .

15 Key Research Findings and Applications

15.1 Propagation of Uncertainties Using Nonparametric or Parametric-Nonparametric Stochastic Models of Uncertainties

The stochastic modeling introduces some random vectors and some random matrices in the stochastic computational models. Consequently, a stochastic solver is required. Two distinct classes of techniques can be used:

- The first one is constituted of the stochastic spectral methods, pioneered by Roger Ghanem in 1990–1991 [43, 44], consisting in performing a projection of the Galerkin type (see [45, 46, 67, 69, 84, 121]), and of separated representations methods [34, 85]. This class of techniques allows for obtaining a great precision for the approximated solution that is constructed.
- The second class is composed of methods based on a direct simulation of which the most popular is the Monte Carlo numerical simulation method (see, for instance, [41, 96]). With such a method, the convergence can be controlled during the computation, and its speed of convergence is independent of the stochastic dimension and can be improved using either advanced Monte Carlo simulation procedures [100], or a technique of subset simulation [6], or finally a method of

local simulation domain [93]. The Monte Carlo simulation method is a stochastic solver that is particularly well adapted to the high stochastic dimension induced by the random matrices introduced by the nonparametric method of uncertainties.

15.2 Experimental Validations of the Nonparametric Method of Uncertainties

The nonparametric stochastic modeling of uncertainties has been experimentally validated through applications in different domains of computational sciences and engineering, in particular:

- In linear dynamics, for the dynamics of complex structures in the low-frequency domain [7, 12, 13]; for the dynamics of structures with nonhomogeneous uncertainties, in the low-frequency domain [24] and in transient dynamics [35]; and finally for the dynamics of composite sandwich panels in low- and medium-frequency domains [25];
- In nonlinear dynamics, for nonlinear structural dynamics of fuel assemblies [9], for nonlinear post-buckling static and dynamical analyses of uncertain cylindrical shells [21], and for some nonlinear reduced-order models [81];
- In linear structural acoustics, for the vibroacoustic of complex structures in low- and medium-frequency domains [38], with sound-insulation layers [39], and for the wave propagation in multilayer live tissues in the ultrasonic domain [30];
- In continuum mechanics of solids, for the nonlinear thermomechanical analysis [97] and the heat transfer in complex composite panels [98] and for linear elasticity of composites reinforced with fibers at mesoscale [48].

15.3 Additional Ingredients for the Nonparametric Stochastic Modeling of Uncertainties

Some important ingredients have been developed for having the tools required for performing the nonparametric stochastic modeling of uncertainties in linear and nonlinear dynamics of mechanical systems, in particular:

- The dynamic substructuring with uncertain substructures which allows for the nonparametric modeling of nonhomogeneous uncertainties in different parts of a structure [116];
- The nonparametric stochastic modeling of uncertain structures with uncertain boundary conditions/coupling between substructures [78];
- The nonparametric stochastic modeling of matrices that depend on the frequency and that are related by a Hilbert transform due to the existence of causality properties, such as those encountered in the linear viscoelasticity theory [89, 115];
- The multi-body dynamics for which there are uncertain bodies (mass, center of mass, inertia tensor), for which the uncertainties in the bodies come from a lack

of knowledge of the distribution of the mass inside the bodies (for instance, the spatial distribution of the passengers inside a high-speed train) [10];

- The nonparametric stochastic modeling in vibroacoustics of complex systems for low- and medium-frequency domains, including the stochastic modeling of the coupling matrices between the structure and the acoustic cavities [38, 89, 110];
- The formulation of the nonparametric stochastic modeling of the nonlinear operators occurring in the static and the dynamics of uncertain geometrically nonlinear structures [21, 77, 81].

15.4 Applications of the Nonparametric Stochastic Modeling of Uncertainties in Different Fields of Computational Sciences and Engineering

- In dynamics:

Aeronautics and aerospace engineering systems [7, 20, 78, 88, 91]

Biomechanics [30, 31]

Environment for well integrity for geologic CO₂ sequestration [32]

Nuclear engineering [9, 12, 13, 29]

Pipe conveying fluid [94]

Rotordynamics [79, 80, 82]

Soil-structure interaction and wave propagation in soils [4, 5, 26, 27]

Vibration of turbomachines [18, 19, 22, 70]

Vibroacoustics of automotive vehicles [3, 38–40, 61]

- In continuum mechanics of heterogeneous materials:

Composites reinforced with fibers [48]

Heat transfer of complex composite panels [98]

Nonlinear thermomechanics in heterogeneous materials [97]

Polycrystalline microstructures [49]

Porous materials [52]

Random elasticity tensors of materials exhibiting symmetry properties [51, 53]

16 Conclusions

In this chapter, fundamental mathematical tools have been presented concerning the random matrix theory, which are useful for many problems encountered in uncertainty quantification, in particular for the nonparametric method of the multiscale stochastic modeling of heterogeneous elastic materials, and for the nonparametric stochastic models of uncertainties in computational structural dynamics. The explicit construction of ensembles of random matrices but also the presentation of numerical tools for constructing general ensembles of random matrices are presented and can be used in high dimension. Many applications and validations have

already been performed in many fields of computational sciences and engineering, but the methodologies and tools presented can be used and developed for many other problems for which uncertainties must be quantified.

Maximin Sliced Latin Hypercube Designs with Application to Cross Validating Prediction Error

9

Yan Chen, David M. Steinberg, and Peter Qian

Abstract

This paper introduces an approach to construct a new type of design, called a maximin sliced Latin hypercube design. This design is a special type of Latin hypercube design that can be partitioned into smaller slices of Latin hypercube designs, where both the whole design and each slice are optimal under the maximin criterion. To construct these designs, a two-step construction method for generating sliced Latin hypercubes is proposed. Several examples are presented to evaluate the performance of the algorithm. An application of this type of optimal design in estimating prediction error by cross validation is also illustrated here.

1 Introduction

Computer experiments are widely used in science and engineering to model complex physical phenomena. The Latin hypercube design (LHD), introduced in [8], is a popular choice for computer experiments. When an LHD with n points on the input space $(0, 1)^q$ is projected onto any single dimension, precisely one point falls into each of the n intervals: $(0, \frac{1}{n}], (\frac{1}{n}, \frac{2}{n}], \dots, (\frac{n-1}{n}, 1]$ for that direction. For simplicity, this paper only considers a special type of LHD, where the projection of any point is the midpoint of one of the evenly spaced intervals.

It is common to apply a secondary criterion in choosing a Latin hypercube design from among the many that exist. One popular criterion is called *maximin* [5], which evaluates a design in terms of the minimum distance between any pair of design points:

$$\min_{1 \leq i < j \leq n} d_{ij}, \quad (9.1)$$

where d_{ij} is the Euclidean distance between the i th point and the j th point of the design. The asymptotic optimality of maximin designs is also discussed in [5]. A related criterion, called ϕ_p , is proposed in [10], which is scalar valued and computationally cheaper than criterion (9.1).

The *sliced Latin hypercube design* (SLHD) was introduced in [13] for collective evaluation of computer models. An SLHD is a special Latin hypercube design that can be partitioned into slices of smaller Latin hypercube designs, which can be constructed by random permutation of each column in the design matrix [13]. As a result, the generated design is not optimal under any given criterion. This chapter focuses on constructing a “best” SLHD which preserves the maximin optimality not only as one LHD but also in each slice. Note that the existing criteria for optimal LHDs, such as the maximin criterion (9.1), are not directly applicable here, as it cannot control the distance in each slice and in the whole design simultaneously. Also, in algorithmic searches for optimal designs, new designs are often obtained by exchanging two elements in one column, which could destroy the sliced structure in SLHDs. These issues motivate us to define a new maximin criterion for SLHD and to modify the enhanced stochastic evolutionary algorithm [4] to construct this new maximin SLHD.

The chapter is organized as follows. Relevant definitions and notations are given in Sect. 2. An example that motivates the proposed maximin criterion for SLHDs is shown in Sect. 3. The algorithm for constructing maximin SLHDs is introduced in Sect. 4 and evaluated with a simulation study in Sect. 5. An application of maximin SLHDs in cross validation of prediction error for Gaussian process regression is discussed in Sect. 6. The conclusions can be found in Sect. 7.

2 Notation and Definition

2.1 Sliced Latin Hypercube

A Latin hypercube of n points in q dimensions, as defined in [8], is an $n \times q$ matrix with a permutation of the integers $\{1, 2, \dots, n\}$ in each column. Given an n by q Latin hypercube X , an LHD can be constructed as

$$(X - U)/n, \quad (9.2)$$

where the entries of U follow independent uniform distributions on $[0, 1)$. Similarly, SLHDs are generated using sliced Latin hypercubes in [13]. For any positive integers t and m with $n = mt$, an n by q matrix X is called a sliced Latin hypercube with t slices if two conditions are satisfied: (i) X is a Latin hypercube of size n ; (ii) when dividing X by rows into small blocks of $m \times q$ matrixes $\{X^{(1)}, X^{(2)}, \dots, X^{(t)}\}$, each $\lceil X^{(i)}/t \rceil$ is a smaller Latin hypercube of m runs, where $\lceil X^{(i)}/t \rceil$ is obtained by taking the smallest integer no less than the corresponding element of $X^{(i)}/t$.

As a stepping stone to generating an n by q sliced Latin hypercube with t slices, [13] proposed an algorithm to construct q independent m by t sliced permutation matrices, which they denote as $SPM(m, t)$. $SPM(m, t)$ is constructed by the following steps. First, divide the elements of $Z_n = \{1, 2, \dots, n\}$ into m blocks, b_1, \dots, b_m , where $b_i = \{a \in Z_n | \lceil a/t \rceil = i\}$. Next, generate $SPM(m, t)$ in two steps: (1) for $i = 1, \dots, m$, fill the i th row of an $m \times t$ empty matrix H with a uniform permutation on the set b_i , with the permutations carried out independently in each row; (2) for $j = 1, \dots, t$, randomly shuffle the entries in the j th column of H , with the permutations carried out independently in each column.

Let H_1, \dots, H_q be q m by t sliced permutation matrices. For $i = 1, 2, \dots, t$, $X^{(i)}$ can be constructed by letting its j th column be the i th column of H_j , for $j = 1, 2, \dots, q$. Then the sliced Latin hypercube X can be generated by combining $X^{(1)}, \dots, X^{(t)}$ row by row. Finally, an SLHD is constructed by (9.2). For simplicity, this paper only considers a special class of SLHDs where each element of U is fixed to be 0.5. Since the algorithm carries out m independent permutations on t numbers in step 1 and t independent permutations on m numbers in step 2, there are $[(m!)^t(t!)^m]^q$ sliced Latin hypercubes in total among $(n!)^q$ different Latin hypercubes. An alternative construction algorithm is discussed in Sect. 2.4.

2.1.1 Sampling Properties of SLHD

Consider an experiment using t similar computer models, f_1, f_2, \dots, f_t . Assume each f_i has input \mathbf{x} , which is uniformly distributed on $(0, 1]^q$. For $i = 1, \dots, t$, define $\mu_i = E[f_i(\mathbf{x})]$. Given the value of each f_i at m selected input values, the goal is to estimate μ_1, \dots, μ_t and a linear combination of μ_1, \dots, μ_t . For $0 \leq \lambda_i \leq 1$, $i = 1, \dots, t$, the linear combination is defined as

$$\eta = \sum_{i=1}^t \lambda_i \mu_i. \quad (9.3)$$

Consider three different schemes for selecting the input values: (i) IID, take an independent and identically distributed sample of m runs for each f_i , with the t samples generated independently; (ii) LHD, obtain t independent ordinary Latin hypercube designs of m runs, each of which is associated with one f_i ; (iii) SLHD, generate an $n \times q$ SLHD with t slices, where each slice is assigned to one f_i .

For any of these schemes, let $\mathbf{D}^{(i)}$ denote the design set for f_i , $i = 1, \dots, t$. Denote the k th row of $\mathbf{D}^{(i)}$ as $\mathbf{d}_k^{(i)}$. For $i = 1, \dots, t$, μ_i is estimated by

$$\hat{\mu}_i = \frac{1}{m} \sum_{k=1}^m f_i(\mathbf{d}_k^{(i)}), \quad (9.4)$$

and η is estimated by

$$\hat{\eta} = \sum_{i=1}^t \lambda_i \hat{\mu}_i. \quad (9.5)$$

The following theorem, taken from [13], shows the effect of the design set on the variance of the $\hat{\mu}_i$ and $\hat{\eta}$.

Theorem 1. Suppose that for $i = 1, \dots, t$, $f_i(\mathbf{x})$ is monotonic in each argument x_j of $\mathbf{x} = (x_1, \dots, x_q)$, and any pair of functions f_{i_1} and f_{i_2} , $i_1 \neq i_2$, are either both increasing or both decreasing in each argument x_j of \mathbf{x} . Then, it is derived in [13] that

(i) for $i = 1, \dots, t$ and $\hat{\mu}_i$ defined in (9.4),

$$\text{var}_{\text{SLHD}}(\hat{\mu}_i) \leq \text{var}_{\text{IID}}(\hat{\mu}_i); \text{ and} \quad (9.6)$$

(ii) for $\hat{\eta}$ defined in (9.5),

$$\text{var}_{\text{SLHD}}(\hat{\eta}) \leq \text{var}_{\text{LHD}}(\hat{\eta}) \leq \text{var}_{\text{IID}}(\hat{\eta}) \quad (9.7)$$

2.2 Optimality Criteria

The optimal design defined by the original maximin criterion (9.1) is not unique. To break ties among all the maximin designs, the following criterion is proposed in [10]. For a given design X , define a distance list $\mathbf{d} = (d_1, d_2, \dots, d_k)$ in which the elements are the distinct, increasing values of the distances between two rows in X . Let $\mathbf{J} = (J_1, J_2, \dots, J_k)$ be the corresponding index list, where J_i is the number of pairs of sites in the design separated by distance d_i . Under the generalized maximin criterion, design X is optimal if it sequentially maximizes d_i 's and minimizes J_i 's in the following order: $d_1, J_1, d_2, J_2, \dots, d_k, J_k$. A scalar-valued design criterion was also proposed in [10] as a computationally cheaper substitute for the maximin criterion:

$$\phi_p = \left[\sum_{i=1}^k J_i d_i^{-p} \right]^{1/p}, \quad (9.8)$$

where p is a positive integer. For large enough p , the designs that minimize ϕ_p are optimal designs under the generalized maximin criterion.

2.3 The Enhanced Stochastic Evolutionary Algorithm

To construct maximin SLHDs, the enhanced stochastic evolutionary algorithm in [4] needs to be modified. The original algorithm is a general method that can be applied to find a design X_{best} that is optimal with respect to a criterion $f(\cdot)$. The algorithm searches through the design space by exchanging elements within one column and deciding whether to accept the new design with a threshold-based criterion. As shown below, it consists of double loops in which the inner loop decides whether to accept a new design, while the outer loop controls the entire optimization process by adjusting the threshold T_h in the acceptance criterion of the inner loop.

Some guidelines are provided in [4] for the choices of J and M . Typically, J is set to be $n_e/5$ but no larger than 50, where n_e is the number of all possible distinct element changes in one column of the design. For an LHD of size n , it is $\binom{n}{2}$. The recommended choice for the parameter M is $2n_e q/J$ but no larger than 100, where q is the number of factors in the design.

The outer loop controls threshold T_h in the acceptance criterion of the inner loop. Initially, T_h is set to be a small value, then it will be adjusted based on whether one cycle of the inner loop could actually improve the current design. In the improving process, T_h is maintained on a small value so that only better design or slightly worse design will be accepted. In particular, T_h will be decreased if $n_{acpt}/M > 10\%$ and $n_{impt} < n_{acpt}$; T_h will be increased if $n_{acpt}/M \leq 10\%$; and T_h will remain the same otherwise. In the exploration process, if $n_{acpt}/M \leq 10\%$, T_h will be quickly increased until $n_{acpt}/M > 10\%$, after which T_h will be slowly decreased until $n_{acpt}/M > 10\%$.

Algorithm 1 The enhanced stochastic evolutionary algorithm

Input: An initial design X_0 , the optimality criterion $f(\cdot)$ to be minimized.
Initialization: $X = X_0$, $X_{best} = X$, $T_h = T_{h0}$, $i = 0$.

```

while  $i < N$  do
     $X_{old.best} = X_{best}$ ,
     $n_{acpt} = 0$ ,  $n_{impt} = 0$ ,  $flag_{imp} = 0$ ,  $j = 0$ .
    while  $j < M$  do
        Randomly pick  $J$  distinct element exchanges within the current column ( $j \bmod q$ ),
        and choose the best design  $X_{try}$  based on  $f(\cdot)$ .
        if  $f(X_{try}) - f(X) \leq T_h \cdot \text{uniform}[0, 1]$  then
             $X \leftarrow X_{try}$ ,  $n_{acpt} \leftarrow n_{acpt} + 1$ .
            if  $f(X) < f(X_{best})$  then
                 $|X_{best} \leftarrow X$ ,  $n_{impt} \leftarrow n_{impt} + 1$ .
            end
        end
         $j \leftarrow j + 1$ 
    end
    if  $f(X_{old.best}) - f(X_{best}) > tol$  then
         $|flag_{imp} = 1$ .
    end
    Update  $T_h$  based on  $n_{acpt}$ ,  $n_{impt}$  and  $flag_{imp}$ .
     $i \leftarrow i + 1$ .
end
```

Algorithm 2 Two-step Construction for Sliced Latin Hypercube

Initialize: n by q arrays \mathbf{B} , \mathbf{C} .
for $i \leftarrow 1$ **to** t **do**
 Generate $\mathbf{B}^{(i)}$ as an m by q Latin hypercube.
 Set the i th block of \mathbf{B} to be $\mathbf{B}^{(i)}$.
end
for $i \leftarrow 1$ **to** q **do**
for $j \leftarrow 1$ **to** m **do**
 Find the entries with value j in the i th column of \mathbf{B} ,
 set the corresponding entries in \mathbf{C} to be a permutation on $\{0, 1, \dots, t - 1\}$.
 end
end
Construct a sliced Latin hypercube $X = t\mathbf{B} - \mathbf{C}$.

2.4 An Alternate Construction Method for SLHDs

In order to break down the proposed algorithm for construction of maximin SLHDs into two stages, Algorithm 2 is introduced here as a new construction for an n by q sliced Latin hypercube with t slices and m points in each slice.

Lemma 1. *The array generated by Algorithm 2 is a sliced Latin hypercube of size n , with t slices and m points in each slice.*

Proof. Since \mathbf{B} consists of t Latin hypercubes of size m , there are t entries in each column of \mathbf{B} with value i , for $i \in \{1, 2, \dots, m\}$. By construction, the corresponding entries in \mathbf{C} are set to be a permutation on $\{0, 1, \dots, t-1\}$. As a result, each column of \mathbf{X} takes value from $\{ti - j \mid i = 1, 2, \dots, m; j = 0, 1, \dots, t-1\} = \{1, 2, \dots, n\}$. By definition, the resulting design \mathbf{X} is a Latin hypercube of size n .

Furthermore, the i th block of $\lceil \mathbf{X}/t \rceil$ is $\mathbf{B}^{(i)}$, an m by q Latin hypercube. Hence, design \mathbf{X} is a sliced Latin hypercube with t slices and m points in each slice. \square

This alternate method generates the design slice by slice, which provides flexibility for optimizing smaller designs as part of the construction of maximin SLHDs. The proposed algorithm in Sect. 4 is therefore based on this construction for SLHDs.

Example 1. To illustrate this construction method, consider the generation of an SLHD with $m = 3$, $t = 4$, and $q = 2$.

Step 1: Combine four randomly generated 3 by 2 Latin hypercubes to get \mathbf{B} (in transpose):

$$\mathbf{B}^T = \left(\begin{array}{ccc|cc|cc|cc} 1 & 2 & 3 & 2 & 1 & 3 & 1 & 2 & 3 & 1 & 2 \\ 2 & 3 & 1 & 1 & 3 & 2 & 1 & 3 & 2 & 3 & 2 \\ \end{array} \right).$$

Step 2: Each column of \mathbf{C} contains three permutations on $\{0, 1, 2, 3\}$, where each of the 12 combinations between $\{1, 2, 3\}$ and $\{0, 1, 2, 3\}$ appears exactly once for the pairing between one column of \mathbf{B} and \mathbf{C} . Here,

$$\mathbf{C}^T = \left(\begin{array}{ccc|cc|cc|cc} 0 & 1 & 3 & 3 & 1 & 1 & 2 & 2 & 0 & 2 & 3 & 0 \\ 0 & 2 & 2 & 0 & 0 & 1 & 3 & 3 & 3 & 1 & 0 & 2 & 1 \\ \end{array} \right).$$

$$\text{So } \mathbf{X}^T = 4 * \mathbf{B}^T - \mathbf{C}^T = \left(\begin{array}{ccc|cc|cc|cc} 4 & 7 & 9 & 5 & 3 & 11 & 2 & 6 & 12 & 10 & 1 & 8 \\ 8 & 10 & 2 & 4 & 11 & 5 & 1 & 9 & 7 & 12 & 6 & 3 \\ \end{array} \right).$$

Since \mathbf{B} contains t permutations on m integers in each column and \mathbf{C} contains m permutations on t integers in each column, this construction method can generate all $[(m!)^t (t!)^m]^q$ different sliced Latin hypercube designs defined in [13]. For any randomly generated \mathbf{X} , the corresponding pair (\mathbf{B}, \mathbf{C}) can be recovered by $\mathbf{B} = \lceil \mathbf{X}/t \rceil$, $\mathbf{C} = t\mathbf{B} - \mathbf{X}$.

3 A Motivating Example

In this section, the general ideas of maximin SLHDs are derived based on the comparison of four SLHDs with two slices, given in Fig. 9.1. Black circles and red squares are used to represent different slices. Design (a) is based on a sliced Latin hypercube generated by random permutation as in [13], while design (d) is constructed by the proposed algorithm in Sect. 4. Design (b) is obtained by

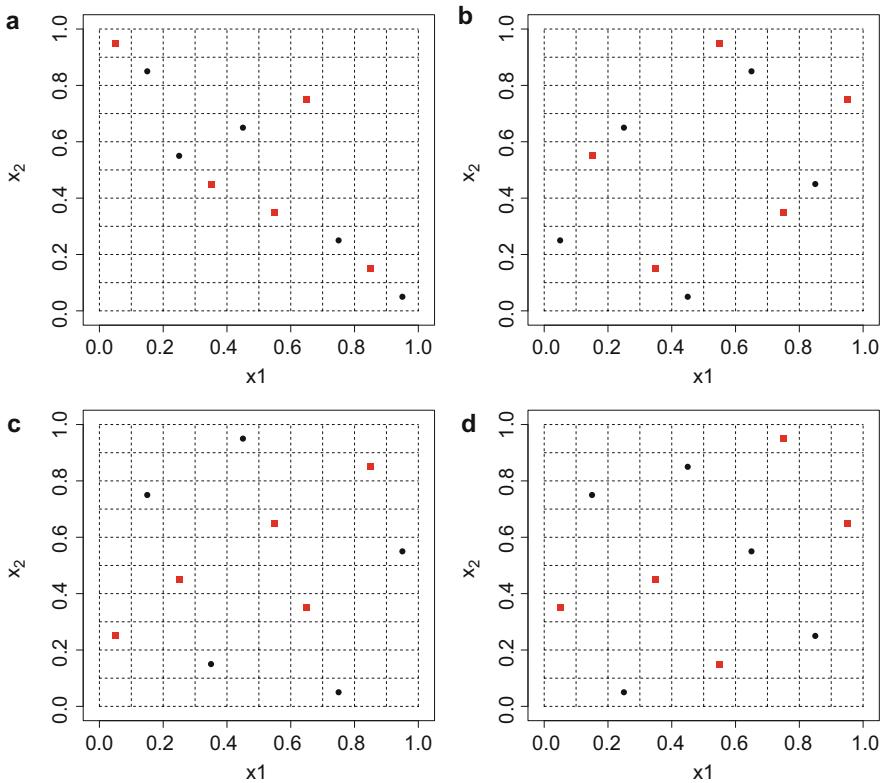

Fig. 9.1 Example SLHDs with ten runs, two factors, and two slices

generating two maximin LHDs by the enhanced stochastic evolutionary algorithm and then combining the two to get an LHD. Design (c) is constructed by splitting a 10-run maximin LHD into two slices arbitrarily.

The four designs are evaluated based on the maximin distance criterion evaluated on the whole design and also on each slice alone. Design (a) is undesirable, considering the whole design or one particular slice alone. Design (b) is better than (a) in the sense that both slices are good designs based on the maximin criterion. However, when putting the two slices together, some points lie very close to one another. This means maximin SLHDs cannot be constructed by working on different slices separately. Design (c) is the opposite case of (b): the whole design is not far from a maximin LHD, but for the slice in red squares, the inter-site distance is small for some points. This shows that the enhanced stochastic evolutionary algorithm cannot be directly used for the construction of maximin SLHDs because of the sliced structure. Design (d) is the best: not only the whole design but also each slice alone has good space-filling properties under the maximin criterion. Since SLHDs have a sliced structure, it is natural to define a maximin SLHD to be a design that has control of the minimum distance in each slice as well as in the whole design. To

construct such designs, it is necessary to define a new maximin criterion for SLHDs and to modify the enhanced stochastic evolutionary algorithm to optimize for such a design.

4 Construction of Maximin SLHD

A maximin SLHD should maximize the minimum distance in the whole design and in each slice simultaneously. The original ϕ_p criterion in (9.8) is generalized for SLHDs as follows:

$$\phi_p^s(\mathbf{X}) = w \left[\sum_{i=1}^t \phi_p(\mathbf{X}^{(i)})/t \right] + (1-w)\phi_p(\mathbf{X}), \quad (9.9)$$

where \mathbf{X} is an SLHD with t slices $\{\mathbf{X}^{(1)}, \mathbf{X}^{(2)}, \dots, \mathbf{X}^{(t)}\}$, and w is the weight to be specified. An SLHD is defined to be a maximin SLHD if it minimizes criterion $\phi_p^s(\cdot)$ among all possible SLHDs of the same size.

Based on the alternative construction of sliced Latin hypercubes proposed in Sect. 2.4, the algorithm for constructing maximin SLHDs contains two steps: (1) generate different slices in $\mathbf{B} = \lceil \mathbf{X}/t \rceil$ as t independent maximin LHDs; (2) construct optimal \mathbf{C} while keeping the between-slice distance structure of $\lceil \mathbf{X}/t \rceil$. The optimal \mathbf{C} is defined by the following criterion:

$$\psi_p = \left[\sum_{1 \leq i, j \leq n, j-i > m} (d_{ij})^{-p} \right]^{1/p}, \quad (9.10)$$

where the constraint $\{j - i > m\}$ ensures that d_{ij} measures the distances between points from different slices in \mathbf{X} . This ψ_p works in the same way as ϕ_p in (9.8) but only controls the between-slice distance. The details of the proposed method for constructing maximin SLHDs are given in Algorithm 3.

A simple modification can be made for the enhanced stochastic evolutionary algorithm to construct optimal sliced Latin hypercubes. The element exchanges within one column could be restricted to those that could keep the sliced structure. There are two types of such “sliced exchanges” within one column: (i) exchange two elements within the same slice; (ii) exchange two elements in different slices if they correspond to the same level in $\lceil \mathbf{X}/t \rceil$. For example, for a sliced Latin hypercube with three slices, levels $\{1, 2, 3\}$ in the same column of the design can be switched, because $\lceil 1/3 \rceil = \lceil 2/3 \rceil = \lceil 3/3 \rceil = 1$. Algorithm 3 is therefore compared to this modified enhanced stochastic evolutionary algorithm called “SlicedEx,” where new designs are obtained by the two types of element exchanges that keep the structure in sliced Latin hypercubes.

The proposed maximin SLHD construction is closely related to a similar proposal in a recent article [1]. Both papers independently proposed the same maximin

Algorithm 3 Constructing Maximin Sliced Latin Hypercube.

Step 1:

Generate different slices of \mathbf{B} as t independent optimal Latin hypercubes under the ϕ_p criterion in (9.8) using the enhanced stochastic evolutionary algorithm.

Step 2:

- For $j = 1, \dots, q$, generate \mathbf{p}_j to be a random permutation on $\{0, 1, \dots, t - 1\}$. Set all elements of in the i th slice of the j th column of \mathbf{C} to be the i th element of \mathbf{p}_j , for $i = 1, 2, \dots, t$.
- Construct new \mathbf{C} by exchanging elements in two different slices that correspond to the same levels in \mathbf{B} , where the new design $\mathbf{X} = t\mathbf{B} - \mathbf{C}$ is evaluated by ψ_p in (9.10) in the enhanced stochastic evolutionary algorithm.

Obtain $\mathbf{X} = t\mathbf{B} - \mathbf{C}$ as the maximin sliced Latin hypercube.

criterion for SLHDs, as shown in (9.9), but used different construction algorithms. The main differences of the two algorithms are summarized as follows, where the actual numerical comparison is shown in Sect. 5. (i) The algorithm in [1] is based on a standard simulated annealing (SA) algorithm established in [7], which accepts a new design \mathbf{X}_{try} with probability $\exp\{-[f(\mathbf{X}_{try}) - f(\mathbf{X})]/T_h\}$, where T_h will be monotonically reduced by a cooling schedule. (ii) The first stage of Algorithm 3 constructs each slice of \mathbf{B} separately, whereas the method in [1] directly works on \mathbf{B} , avoiding duplicated rows by swapping elements. (iii) The second stage in Algorithm 3 uses (9.10) to control between-slice distances, whereas the optimality criterion used in [1] is still (9.9). (iv) The algorithm in [1] uses a more efficient way to update $\phi_p(\mathbf{X}_{try})$, which allows it to be faster for large designs. The application of the proposed maximin SLHDs in this chapter is mainly used for cross validating prediction errors, whereas the design constructed in [1] is used for fitting computer experiments with both continuous and categorical variables.

5 Numerical Illustration

The following examples are used for construction of an n by q maximin SLHD \mathbf{D} with t slices and m points in each slice in the following examples. To evaluate the performance of the proposed algorithm and “SlicedEx,” two other methods, called “Combine” and “Split,” are also performed. The procedure “Combine” simply puts t maximin Latin hypercubes together to get a Latin hypercube. This design would provide a reference for evaluating each slice of a maximin SLHD. Method “Split” randomly splits a maximin Latin hypercube into slices and is used to provide a reference value for the whole design. The four methods are coded by Matlab, with details listed below. In addition, the algorithm in [1] is also performed using R package “SLHD” (contributed by the authors of [1]), with results summarized in tables under the column named “BA-SA.”

- Proposed: Algorithm 3 in Sect. 4.
- SlicedEx: in the enhanced stochastic evolutionary algorithm, construct a new design by “sliced exchanges” that keep the sliced structure; evaluate new designs by ϕ_p defined in (9.8).
- Combine: combine t small maximin Latin hypercubes to get one Latin hypercube.
- Split: split a maximin Latin hypercube into t slices, where each slice is not necessarily a Latin hypercube.

This chapter considers a specific type of SLHD constructed by

$$\mathbf{D} = (X - 0.5)/n, \quad (9.11)$$

where X is a sliced Latin hypercube. Hence, the projection of the design onto any factor is the midpoints of n evenly spaced intervals on $[0, 1]$. Each of the five algorithms specified below is used to generate X first, then the resulting design \mathbf{D} is obtained by formula (9.11). The optimality criteria in (9.8), (9.9), and (9.10) are evaluated on \mathbf{D} in the search process of the algorithms. By adjusting parameters of the enhanced stochastic evolutionary algorithm, the time for constructing the designs is set to be close for all the algorithms. Let \mathbf{D}_1 denote the worst slice in \mathbf{D} under criterion ϕ_p in (9.8). Each procedure is replicated 50 times. The means of $\phi_p(\mathbf{D})$, $\phi_p^s(\mathbf{D})$, $\phi_p(\mathbf{D}_1)$, and CPU time are summarized in tables, where p is set to be 30 in each criterion, and the weight w is chosen to be 1/2. Boxplots of $\phi_p(\mathbf{D})$ and $\phi_p(\mathbf{D}_1)$ are also given. The “box” goes from the first quartile to the third quartile, and the line within the box indicates the median of the data set. Boxplots may also have lines extending vertically from the boxes (whiskers) showing variability outside the upper and lower quartiles.

Example 1. Consider the construction of a maximin SLHD with 50 runs, 2 factors, and 5 slices. The results are shown in Table 9.1 and Fig. 9.2.

Example 2. Consider the construction of a maximin SLHD with 80 runs, 2 factors, and 8 slices. The results are shown in Table 9.2 and Fig. 9.3.

Example 3. Consider the construction of a maximin SLHD with 120 runs, 2 factors, and 12 slices. The results are shown in Table 9.3 and Fig. 9.4.

Example 4. Consider the construction of a maximin SLHD with 50 runs, 10 factors, and 5 slices. The results are shown in Table 9.4 and Fig. 9.5.

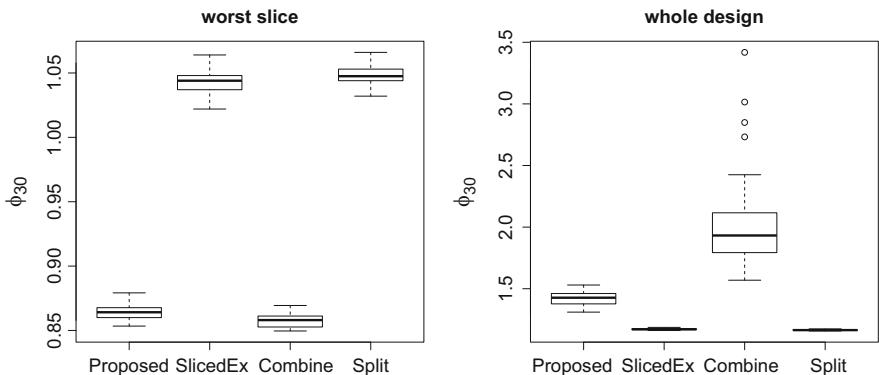

First, the comparison among methods “Proposed,” “SlicedEx,” “Combine,” and “Split” is summarized as follows. (i) Considering the worst slice in the design, the proposed method is significantly better than “SlicedEx” but slightly worse than

Table 9.3 Construction of maximin SLHDs with 120 runs, 2 factors, and 12 slices

$\phi_p(\mathbf{D})$	1.419	1.171	2.031	1.165	1.171
$\phi_p(\mathbf{D}_1)$	0.8648	1.042	0.8578	1.048	0.8895
$\phi_p^s(\mathbf{D})$	1.136	1.098	1.441	1.098	1.024
CPU Time(s)	38.70	38.94	38.13	37.45	41.40

**Fig. 9.5** Boxplot of $\phi_p(\mathbf{D}_1)$ and $\phi_p(\mathbf{D})$ for maximin SLHDs with 50 runs, 10 factors, and 5 slices

“Combine.” (ii) The proposed method is the best under criterion ϕ_p^s in (9.9) except for Example 4, in which the design has ten points in ten dimensions for each of the five slices. In that example, the advantage of “Proposed” over “SlicedEx” in terms of between-slice distance is not that obvious, since the pairwise distances between ten points in ten-dimensional space would not be very small. (iii) Based on the results in Examples 1, 2, and 3, “SlicedEx” is slightly better than the two-step method in terms of the whole design when there are only five slices, but the difference tends to be smaller as more slices are added; eventually the proposed method outperforms “SlicedEx” when the number of slices is 12. This makes sense intuitively, since compared with working on the whole design, it is more efficient to optimize and evaluate different slices separately, especially when the number of slices is not small. Then, compared with the proposed method, the algorithm in [1] is worse in terms of $\phi_p(\mathbf{D}_1)$ but is better in terms of $\phi_p^s(\mathbf{D})$ and $\phi_p(\mathbf{D})$. This could be a result of a more efficient updating scheme of ϕ_p used in [1] or some subtle difference between the SA algorithm in [1] and the ESE algorithm, such as the parameter setting and the acceptance criterion.

6 Application to the Estimation of Prediction Error

6.1 Evaluation of Multiple Computer Models

Consider the collective evaluation of t similar computer models, f_1, f_2, \dots, f_t , where each f_i has inputs drawn from the uniform distribution on $(0, 1]^q$. Define f to be a linear combination of f_i 's, i.e., $\sum_{i=1}^t \lambda_i f_i$. To approximate f_i and f , the following ordinary Kriging model in [15] is used:

$$y = \beta + Z(\mathbf{x}), \quad (9.12)$$

where the Gaussian process $Z(\mathbf{x})$ is assumed to have mean 0 and covariance function:

$$R(\mathbf{x}, \mathbf{w}) = \sigma^2 \prod_{j=1}^q \exp\{-\theta_j(x_j - w_j)^2\}. \quad (9.13)$$

Given the set of responses $\{f_i(\mathbf{x}) : \mathbf{x} \in \mathbf{D}_i\}$, the computation of \hat{f}_i as the predictor is obtained by maximizing the likelihood of (9.12) or, equivalently, the BLUP estimator. Similarly, let \hat{f} denote the predictor of f using the response set from the whole design $\mathbf{D} = (\mathbf{D}_1, \mathbf{D}_2, \dots, \mathbf{D}_t)$.

In the simulation, the following five designs are used for $\mathbf{D} = (\mathbf{D}_1, \mathbf{D}_2, \dots, \mathbf{D}_t)$:

- LHD: \mathbf{D} is an LHD, and \mathbf{D}_i 's are obtained by randomly splitting \mathbf{D} into t slices.
- MLHD: \mathbf{D} is a maximin LHD, and \mathbf{D}_i 's are obtained by randomly splitting \mathbf{D} into t slices.
- IMLH: \mathbf{D} is an LHD, and \mathbf{D}_i 's are independent maximin LHDs.
- SLHD: \mathbf{D} is an LHD, and \mathbf{D}_i 's are independent LHDs.
- MSLH: \mathbf{D} is a maximin SLHD, and \mathbf{D}_i 's are its slices.

Table 9.5 Average of the mean squared prediction error using 100 Replications in Example 1

		LHD	MLHD	IMLH	SLHD	MSLH
f_1	$m = 5$	0.1483	0.1567	0.1224	0.1250	0.1214
	$m = 10$	0.0941	0.0894	0.0698	0.0781	0.0707
	$m = 20$	0.0678	0.0596	0.0465	0.0545	0.0464
	$m = 40$	0.0503	0.0438	0.0327	0.0411	0.0334
\hat{f}	$m = 5$	0.0483	0.0424	0.0588	0.0516	0.0567
	$m = 10$	0.0360	0.0302	0.0421	0.0406	0.0389
	$m = 20$	0.0289	0.0230	0.0329	0.0311	0.0288
	$m = 40$	0.0288	0.0212	0.0280	0.0290	0.0252

Example 1. Consider the following example from [13]:

$$\begin{aligned} f_1(\mathbf{x}) &= \log\left(\frac{1}{\sqrt{x_1}} + \frac{1}{\sqrt{x_2}}\right), \\ f_2(\mathbf{x}) &= \log\left(\frac{0.98}{\sqrt{x_1}} + \frac{0.95}{\sqrt{x_2}}\right), \\ f_3(\mathbf{x}) &= \log\left(\frac{1.02}{\sqrt{x_1}} + \frac{1.02}{\sqrt{x_2}}\right), \\ f_4(\mathbf{x}) &= \log\left(\frac{1}{\sqrt{x_1}} + \frac{1.03}{\sqrt{x_2}}\right), \end{aligned}$$

and $f(\mathbf{x}) = \frac{1}{4} \sum_{i=1}^4 f_i(\mathbf{x})$. For each choice of the size of D_i (denoted as m), the parameters for the algorithm are adjusted so that the construction time for the three types of optimal designs is close. Table 9.5 provides the comparison between the designs in terms of the mean squared prediction error on a separate 1000 run LHD test design. In this example, “MSLH” and “IMLH” achieve the lowest prediction error for f_1 ; “MLHD” is the best considering the prediction error for f . In this example, lower ϕ_p value of the design matrix is associated with smaller prediction error of the Kriging model.

6.2 Cross Validation of Prediction Error

In this section, the mean squared prediction error (MSPE) for Gaussian process regression is estimated by cross validation [16]. Given the value of an unknown function f on n_L data points, $y_{L,i} = f(x_{L,i})$, for $i = 1, 2, \dots, n_L$, let \hat{f} be the BLUP predictor obtained with MLE parameter estimates. Given a large testing data set $T = (\mathbf{x}_{T,i}, y_{T,i})$ of n_T observations, MSPE can be estimated by:

$$MSPE_{test} = \frac{1}{n_T} \sum_{i=1}^{n_T} (y_{T,i} - \hat{f}(\mathbf{x}_{T,i}))^2.$$

However, a testing data set is usually not available in practice, while K-fold cross validation can be easily implemented to find an estimate based on the learning data L only. The procedure starts by dividing L into t slices, L_1, L_2, \dots, L_t , with m points in each slice. For $k = 1, 2, \dots, K$, build a predictor \hat{f}_{-k} based on data $L \setminus L_k$ by Gaussian process regression, and then calculate $MSPE_{CV,k}$ as the mean squared prediction error of \hat{f}_{-k} on the remaining slice L_k . The cross-validation estimator is the average of the mean squared prediction errors on all t slices:

$$MSPE_{CV} = \frac{1}{t} \sum_{k=1}^t MSPE_{CV,k}.$$

In the simulation, the five designs discussed previously are still used to generate the learning data L for K-fold cross validation. The leave-one-out estimator is a special case of K-fold cross validation, where the number of slices t is equal to the size of the training data n_L . To simplify the computation, [15] proposes a pseudo version of the leave-one-out estimator, in which \hat{f}_{-k} uses the maximum likelihood estimates of the covariance parameters in (9.13) based on the complete data L . For reference, these two leave-one-out estimates of MSPE are also computed based on the optimal design MLHD.

The quantity $MSPE_{test}$ is close to the true squared prediction error given a large testing data set. Hence, $MSPE_{CV} - MSPE_{test}$ is considered as the bias of the cross-validation estimates to evaluate different designs. In addition, the standard deviation of the prediction error on t slices $\{MSPE_{CV,1}, MSPE_{CV,2}, \dots, MSPE_{CV,t}\}$ is also computed, which is denoted as s_{cv} . The computation time to construct optimal designs MLHD, IMLH, and MSLH is set to be close by adjusting the parameters of these algorithms.

Example 2. This example considers the Branin function [6] on the domain $[-5, 10] \times [0, 15]$. The response takes the form:

$$f(x_1, x_2) = (x_2 - \frac{5.1}{4\pi^2}x_1^2 + \frac{5}{\pi}x_1 - 6)^2 + 10(1 - \frac{1}{8\pi})\cos(x_1) + 10.$$

The testing set is generated by LHD with 5000 runs. The predictor \hat{f} is obtained by Gaussian process regression on a learning data set of size 36. The K-fold cross-validation estimate with six slices is obtained for each of the five sampling schemes. The leave-one-out estimate and its pseudo version are also calculated using a maximin LHD. The result of 50 replications is shown in Fig. 9.6 and Table 9.6.

Example 3. This example uses a multimodal six-hump camel back function from [14]:

$$f(x_1, x_2) = (4 - 2.1x_1^2 + x_1^4/3)x_1^2 + x_1x_2 + (-4 + 4x_2^2)x_2^2,$$

Fig. 9.8 Boxplot of $MSPE_{CV} - MSPE_{test}$ in Example 4

Example 4. This example uses the 3 dimensional Ishigami function from [3]. The original function is defined on $[-\pi, \pi]^3$:

$$f(x_1, x_2, x_3) = \sin(x_1) + 7 \sin^2(x_2) + 0.1x_3^4 \sin(x_1).$$

The testing set is generated by an LHD with 10000 runs. The predictor \hat{f} is obtained by Gaussian process regression on a learning data set of size 80. The K-fold cross-validation estimate with eight slices is obtained for each of the five sampling schemes. The leave-one-out estimate and its pseudo version are also calculated using a maximin LHD. The result of 50 replications is shown in Fig. 9.8 and Table 9.8.

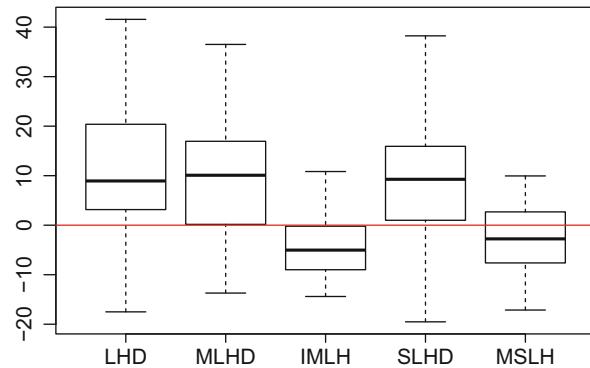

Example 5. This example uses the eight-dimensional borehole function investigated in [9], which models water flow rate through a borehole drilled from the ground surface through two aquifers. The flow rate is given by

$$f(r, r_w, T_u, T_l, H_u, H_l, L, K_w) = \frac{2\pi(H_u - H_l)}{\log(r/r_w) \left(1 + \frac{2LT_u}{\log(r/r_w)r_w^2K_w} + \frac{T_u}{T_l} \right)}.$$

The testing set is generated by an LHD with 10000 runs. The predictor \hat{f} is obtained by Gaussian process regression on a learning data set of size 90. The

K-fold cross-validation estimate with five slices is obtained for each of the five sampling schemes. The leave-one-out estimate and its pseudo version are also calculated based on a maximin LHD. The result of 50 replications is shown in Fig. 9.9 and Table 9.9.

Based on the examples in this section, the conclusions are listed as follows.

- The true version of the leave-one-out estimate is the best based on the bias criterion: $MSPE_{CV} - MSPE_{test}$. However, this estimate is known to have large variation because of the similarity between the training data sets. Furthermore,

given a larger learning data set, the leave-one-out estimate is not practical because of the repeated calculation of the maximum likelihood estimate.

- The pseudo version of the leave-one-out estimate can be applied for large data sets, but it is not accurate.
- Randomly splitting an LHD or a maximin LHD to perform K-fold cross validation leads to large variation in the estimate.
- Designs “IMLH” and “MSLH” are the best among all five choices in terms of the bias of the K-fold cross validation. For the standard deviation of the estimate, “MSLH” is slightly better. In Example 5, K-fold cross validation using “IMLH” underestimates the prediction error, which could be a result of the small between-slice distances.

7 Conclusion

One important application of SLHD (and therefore maximin SLHD) is for fitting multiple computer models with similar response, which, as discussed in [13], has the advantage of reducing predictive variance. Other potential applications include computer models with qualitative and quantitative factors [2, 11, 12], cross validation, and stochastic optimization. It has been shown in [5] that the maximin design is asymptotically D-optimal under the Gaussian process regression model with correlation function $\text{corr}(\mathbf{x}_i, \mathbf{x}_j) = [\rho(\|\mathbf{x}_i - \mathbf{x}_j\|)]^k$, as $k \rightarrow \infty$, where $\rho(\cdot)$ is a decreasing function. With this asymptotic D-optimality, the maximin SLHD is expected to improve the performance of SLHD for these various applications.

The Bayesian Approach to Inverse Problems 10

Masoumeh Dashti and Andrew M. Stuart

Abstract

These lecture notes highlight the mathematical and computational structure relating to the formulation of, and development of algorithms for, the Bayesian approach to inverse problems in differential equations. This approach is fundamental in the quantification of uncertainty within applications involving the blending of mathematical models with data. The finite-dimensional situation is described first, along with some motivational examples. Then the development of probability measures on separable Banach space is undertaken, using a random series over an infinite set of functions to construct draws; these probability measures are used as priors in the Bayesian approach to inverse problems. Regularity of draws from the priors is studied in the natural Sobolev or Besov spaces implied by the choice of functions in the random series construction, and the Kolmogorov continuity theorem is used to extend regularity considerations to the space of Hölder continuous functions. Bayes' theorem is derived in this prior setting, and here interpreted as finding conditions under which the posterior is absolutely continuous with respect to the prior, and determining a formula for the Radon-Nikodym derivative in terms of the likelihood of the data. Having established the form of the posterior, we then describe various properties common to it in the infinite-dimensional setting. These properties include well-posedness, approximation theory, and the existence of maximum a posteriori estimators. We then describe measure-preserving dynamics, again on the infinite-dimensional space, including Markov chain Monte Carlo and sequential Monte Carlo methods, and measure-preserving reversible stochastic

differential equations. By formulating the theory and algorithms on the underlying infinite-dimensional space, we obtain a framework suitable for rigorous analysis of the accuracy of reconstructions, of computational complexity, as well as naturally constructing algorithms which perform well under mesh refinement, since they are inherently well defined in infinite dimensions.

1 Introduction

Many uncertainty quantification problems arising in the sciences and engineering require the incorporation of data into a model; indeed doing so can significantly reduce the uncertainty in model predictions and is hence a very important step in many applications. Bayes' formula provides the natural way to do this. The purpose of these lecture notes is to develop the Bayesian approach to inverse problems in order to provide a rigorous framework for the development of uncertainty quantification in the presence of data. Of course it is possible to simply discretize the inverse problem and apply Bayes' formula on a finite-dimensional space. However, we adopt a different approach: we formulate Bayes' formula on a separable Banach space and study its properties in this infinite dimensional setting. This approach, of course, requires considerably more mathematical sophistication and it is important to ask whether this is justified. The answer, of course, is "yes." The formulation of the Bayesian approach on a separable Banach space has numerous benefits: (i) it reveals an attractive well-posedness framework for the inverse problem, allowing for the study of robustness to changes in the observed data, or to numerical approximation of the forward model; (ii) it allows for direct links to be established with the classical theory of regularization, which has been developed in a separable Banach space setting; (iii) and it leads to new algorithmic approaches which build on the full power of analysis and numerical analysis to leverage the structure of the infinite-dimensional inference problem.

The remainder of this section contains a discussion of Bayesian inversion in finite dimensions, for motivational purposes, and two examples of partial differential equation (PDE) inverse problems. In Sect. 2 we describe the construction of priors on separable Banach spaces, using random series and employing the random series to discuss various Sobolev, Besov and Hölder regularity results. Section 3 is concerned with the statement and derivation of Bayes' theorem in this separable Banach space setting. In Sect. 4, we describe various properties common to the posterior, including well posedness in the Hellinger metric, a related approximation theory which leverages well posedness to deliver the required stability estimate, and the existence of maximum a posteriori (MAP) estimators; these address points (i) and (ii) above, respectively. Then, in Sect. 5, we discuss various discrete and continuous time Markov processes which preserve the posterior probability measure, including Markov chain Monte Carlo methods (MCMC), sequential Monte Carlo methods (SMC) and reversible stochastic partial differential equations, addressing point (iii) above. The infinite-dimensional perspective on algorithms is beneficial as it provides a direct way to construct algorithms which behave well under refinement

of finite-dimensional approximations of the underlying separable Banach space. We conclude in Sect. 6 and then an appendix collects together a variety of basic definitions and results from the theory of differential equations and probability. Each section is accompanied by bibliographical notes connecting the developments herein to the wider literature. The notes complement and build on other overviews of Bayesian inversion, and its relations to uncertainty quantification, which may be found in [92, 93]. All results (lemmas, theorems, etc.) which are quoted without proof are given pointers to the literature, where proofs may be found, within the bibliography of the section containing the result.

1.1 Bayesian Inversion on \mathbb{R}^n

Consider the problem of finding $u \in \mathbb{R}^n$ from $y \in \mathbb{R}^J$ where u and y are related by the equation

$$y = G(u).$$

We refer to y as *observed data* and to u as the *unknown*. This problem may be difficult for a number of reasons. We highlight two of these, both particularly relevant to our future developments.

1. The first difficulty, which may be illustrated in the case where $n = J$, concerns the fact that often the equation is perturbed by noise and so we should really consider the equation

$$y = G(u) + \eta, \quad (10.1)$$

where $\eta \in \mathbb{R}^J$ represents the *observational noise* which enters the observed data. Assume further that G maps \mathbb{R}^J into a proper subset of itself, Im_G , and that G has a unique inverse as a map from Im_G into \mathbb{R}^J . It may then be the case that, because of the noise, $y \notin \text{Im}_G$ so that simply inverting G on the data y will not be possible. Furthermore, the specific instance of η which enters the data may not be known to us; typically, at best, only the statistical properties of a typical noise η are known. Thus we cannot subtract η from the observed data y to obtain something in Im_G . Even if $y \in \text{Im}_G$, the uncertainty caused by the presence of noise η causes problems for the inversion.

2. The second difficulty is manifest in the case where $n > J$ so that the system is *underdetermined*: the number of equations is smaller than the number of unknowns. How do we attach a sensible meaning to the concept of solution in this case where, generically, there will be many solutions?

Thinking probabilistically enables us to overcome both of these difficulties. We will treat u , y and η as random variables and determine the joint probability

distribution of (u, y) . We then define the “solution” of the inverse problem to be the probability distribution of u given y , denoted $u|y$. This allows us to model the noise via its statistical properties, even if we do not know the exact instance of the noise entering the given data. And it also allows us to specify a priori the form of solutions that we believe to be more likely, thereby enabling us to attach weights to multiple solutions which explain the data. This is the *Bayesian approach* to inverse problems.

To this end, we define a random variable $(u, y) \in \mathbb{R}^n \times \mathbb{R}^J$ as follows. We let $u \in \mathbb{R}^n$ be a random variable with (Lebesgue) density $\rho_0(u)$. Assume that $y|u$ (y given u) is defined via the formula (10.1) where $G : \mathbb{R}^n \rightarrow \mathbb{R}^J$ is measurable and η is independent of u (we sometimes write this as $\eta \perp u$) and distributed according to measure \mathbb{Q}_0 with Lebesgue density $\rho(\eta)$. Then $y|u$ is simply found by shifting \mathbb{Q}_0 by $G(u)$ to measure \mathbb{Q}_u with Lebesgue density $\rho(y - G(u))$. It follows that $(u, y) \in \mathbb{R}^n \times \mathbb{R}^J$ is a random variable with Lebesgue density $\rho(y - G(u))\rho_0(u)$.

The following theorem allows us to calculate the distribution of the random variable $u|y$:

Theorem 1 (Bayes’ Theorem). *Assume that*

$$Z := \int_{\mathbb{R}^n} \rho(y - G(u))\rho_0(u)du > 0.$$

Then $u|y$ is a random variable with Lebesgue density $\rho^y(u)$ given by

$$\rho^y(u) = \frac{1}{Z} \rho(y - G(u))\rho_0(u).$$

Remarks 1. The following remarks establish the nomenclature of Bayesian statistics and also frame the previous theorem in a manner which generalizes to the infinite-dimensional setting.

- $\rho_0(u)$ is the **prior density**.
- $\rho(y - G(u))$ is the **likelihood**.
- $\rho^y(u)$ is the **posterior density**.
- It will be useful in what follows to define

$$\Phi(u; y) = -\log \rho(y - G(u)).$$

We call Φ the **potential**. This is the **negative log likelihood**.

- Note that Z is the probability of y . Bayes’ formula expresses

$$\mathbb{P}(u|y) = \frac{1}{\mathbb{P}(y)} \mathbb{P}(y|u)\mathbb{P}(u).$$

- Let μ^y be a measure on \mathbb{R}^n with density ρ^y and μ_0 a measure on \mathbb{R}^n with density ρ_0 . Then the conclusion of Theorem 1 may be written as:

$$\begin{aligned}\frac{d\mu^y}{d\mu_0}(u) &= \frac{1}{Z} \exp(-\Phi(u; y)), \\ Z &= \int_{\mathbb{R}^n} \exp(-\Phi(u; y)) \mu_0(du).\end{aligned}\tag{10.2}$$

Thus the posterior is absolutely continuous with respect to the prior, and the Radon-Nikodym derivative is proportional to the likelihood. This is rewriting Bayes' formula in the form

$$\frac{1}{\mathbb{P}(u)} \mathbb{P}(u|y) = \frac{1}{\mathbb{P}(y)} \mathbb{P}(y|u).$$

- The expression for the Radon-Nikodym derivative is to be interpreted as the statement that, for all measurable $f : \mathbb{R}^n \rightarrow \mathbb{R}$,

$$\mathbb{E}^{\mu^y} f(u) = \mathbb{E}^{\mu_0} \left(\frac{d\mu^y}{d\mu_0}(u) f(u) \right).$$

Alternatively we may write this in integral form as

$$\begin{aligned}\int_{\mathbb{R}^n} f(u) \mu^y(du) &= \int_{\mathbb{R}^n} \left(\frac{1}{Z} \exp(-\Phi(u; y)) f(u) \right) \mu_0(du) \\ &= \frac{\int_{\mathbb{R}^n} \exp(-\Phi(u; y)) f(u) \mu_0(du)}{\int_{\mathbb{R}^n} \exp(-\Phi(u; y)) \mu_0(du)}.\end{aligned}$$

□

1.2 Inverse Heat Equation

This inverse problem illustrates the first difficulty, labeled 1. in the previous subsection, which motivates the Bayesian approach to inverse problems. Let $D \subset \mathbb{R}^d$ be a bounded open set, with Lipschitz boundary ∂D . Then define the Hilbert space H and operator A as follows:

$$\begin{aligned}H &= \left(L^2(D), \langle \cdot, \cdot \rangle, \|\cdot\| \right); \\ A &= -\Delta, \quad \mathcal{D}(A) = H^2(D) \cap H_0^1(D).\end{aligned}$$

We make the following assumption about the spectrum of A which is easily verified for simple geometries, but in fact holds quite generally.

Assumption 1. *The eigenvalue problem*

$$A\varphi_j = \alpha_j \varphi_j,$$

has a countably infinite set of solutions, indexed by $j \in \mathbb{Z}^+$. They may be normalized to satisfy the L^2 -orthonormality condition

$$\langle \varphi_j, \varphi_k \rangle = \begin{cases} 1, & j = k \\ 0, & j \neq k, \end{cases}$$

and form a basis for H . Furthermore, the eigenvalues are positive and, if ordered to be increasing, satisfy $\alpha_j \asymp j^{\frac{2}{d}}$. \square

Here and in the remainder of the notes, the notation \asymp denotes the existence of constants $C^\pm > 0$ such that

$$C^- j^{2/d} \leq \alpha_j \leq C^+ j^{2/d} \quad (10.3)$$

for all $j \in \mathbb{N}$.

Any $w \in H$ can be written as

$$w = \sum_{j=1}^{\infty} \langle w, \varphi_j \rangle \varphi_j$$

and we can define the Hilbert scale of spaces $\mathcal{H}^t = \mathcal{D}(A^{t/2})$ as explained in Sect. A.1.3 for any $t > 0$ and with the norm

$$\|w\|_{\mathcal{H}^t}^2 = \sum_{j=1}^{\infty} j^{\frac{2t}{d}} |w_j|^2$$

where $w_j = \langle w, \varphi_j \rangle$.

Consider the heat conduction equation on D , with Dirichlet boundary conditions, writing it as an ordinary differential equation in H :

$$\frac{dv}{dt} + Av = 0, \quad v(0) = u. \quad (10.4)$$

We have the following:

Lemma 1. *Let Assumption 1 hold. Then for every $u \in H$ and every $s > 0$, there is a unique solution v of equation (10.4) in the space $C([0, \infty); H) \cap C((0, \infty); \mathcal{H}^s)$. We write $v(t) = \exp(-At)u$.*

To motivate this statement, and in particular the high degree of regularity seen at each fixed t , we argue as follows. Note that, if the initial condition is expanded in the eigenbasis as

$$u = \sum_{j=1}^{\infty} u_j \varphi_j, \quad u_j = \langle u, \varphi_j \rangle,$$

then the solution of (10.4) has the form

$$v(t) = \sum_{j=1}^{\infty} u_j e^{-\alpha_j t} \varphi_j.$$

Thus

$$\begin{aligned} \|v(t)\|_{\mathcal{H}^s}^2 &= \sum_{j=1}^{\infty} j^{2s/d} e^{-2\alpha_j t} |u_j|^2 \asymp \sum_{j=1}^{\infty} \alpha_j^s e^{-2\alpha_j t} |u_j|^2 \\ &= t^{-s} \sum_{j=1}^{\infty} (\alpha_j t)^s e^{-2\alpha_j t} |u_j|^2 \leq C t^{-s} \sum_{j=1}^{\infty} |u_j|^2 \\ &= C t^{-s} \|u\|_H^2. \end{aligned}$$

It follows that $v(t) \in \mathcal{H}^s$ for any $s > 0$, provided $u \in H$.

We are interested in the inverse problem of finding u from y where

$$y = v(1) + \eta = G(u) + \eta = e^{-A}u + \eta.$$

Here $\eta \in H$ is noise and $G(u) := v(1) = e^{-A}u$. Formally this looks like an infinite-dimensional linear version of the inverse problem (10.1), extended from finite dimensions to a Hilbert space setting. However, the infinite-dimensional setting throws up significant new issues. To see this, assume that there is $\beta_c > 0$ such that η has regularity \mathcal{H}^β if and only if $\beta < \beta_c$. Then y is not in the image space of G which is, of course, contained in $\cap_{s>0} \mathcal{H}^s$. Applying the formal inverse of G to y results in an object which is not in H .

To overcome this problem, we will apply a Bayesian approach and hence will need to put probability measures on the Hilbert space H ; in particular we will want to study $\mathbb{P}(u)$, $\mathbb{P}(y|u)$ and $\mathbb{P}(u|y)$, all probability measures on H .

1.3 Elliptic Inverse Problem

One motivation for adopting the Bayesian approach to inverse problems is that prior modeling is a transparent approach to dealing with under-determined inverse

problems; it forms a rational approach to dealing with the second difficulty, labeled 2 in Sect. 1.1. The elliptic inverse problem we now describe is a concrete example of an under-determined inverse problem.

As in Sect. 1.2, $D \subset \mathbb{R}^d$ denotes a bounded open set, with Lipschitz boundary ∂D . We define the Gelfand triple of Hilbert spaces $V \subset H \subset V^*$ by

$$H = (L^2(D), \langle \cdot, \cdot \rangle, \|\cdot\|), \quad V = (H_0^1(D), \langle \nabla \cdot, \nabla \cdot \rangle, \|\cdot\|_V = \|\nabla \cdot\|). \quad (10.5)$$

and V^* the dual of V with respect to the pairing induced by H . Note that $\|\cdot\| \leq C_p \|\cdot\|_V$ for some constant C_p : the Poincaré inequality.

Let $\kappa \in X := L^\infty(D)$ satisfy

$$\operatorname{ess\ inf}_{x \in D} \kappa(x) = \kappa_{\min} > 0. \quad (10.6)$$

Now consider the equation

$$-\nabla \cdot (\kappa \nabla p) = f, \quad x \in D, \quad (10.7a)$$

$$p = 0, \quad x \in \partial D. \quad (10.7b)$$

Lax-Milgram theory yields the following:

Lemma 2. *Assume that $f \in V^*$ and that κ satisfies (10.6). Then (10.7) has a unique weak solution $p \in V$. This solution satisfies*

$$\|p\|_V \leq \|f\|_{V^*}/\kappa_{\min}$$

and, if $f \in H$,

$$\|p\|_V \leq C_p \|f\|/\kappa_{\min}.$$

We will be interested in the inverse problem of finding κ from y where

$$y_j = l_j(p) + \eta_j, \quad j = 1, \dots, J. \quad (10.8)$$

Here $l_j \in V^*$ is a continuous linear functional on V and η_j is a noise.

Notice that the unknown, $\kappa \in X$, is a function (infinite dimensional), whereas the data from which we wish to determine κ is finite dimensional: $y \in \mathbb{R}^J$. The problem is severely under-determined, illustrating point 2 from Sect. 1.1. One way to treat such problems is by adopting the Bayesian framework, using prior modeling to fill in missing information. We will take the unknown function to be u where either $u = \kappa$ or $u = \log \kappa$. In either case, we will define $G_j(u) = l_j(p)$ and, noting that p is then a nonlinear function of u , (10.8) may be written as

$$y = G(u) + \eta \quad (10.9)$$

where $y, \eta \in \mathbb{R}^J$ and $G : X^+ \subseteq X \rightarrow \mathbb{R}^J$. The set X^+ is introduced because G may not be defined on the whole of X . In particular, the positivity constraint (10.6) is only satisfied on

$$X^+ := \left\{ u \in X : \text{ess inf}_{x \in D} u(x) > 0 \right\} \subset X \quad (10.10)$$

in the case where $\kappa = u$. On the other hand, if $\kappa = \exp(u)$, then the positivity constraint (10.6) is satisfied for any $u \in X$ and we may take $X^+ = X$.

Notice that we again need probability measures on function space, here the Banach space $X = L^\infty(D)$. Furthermore, in the case where $u = \kappa$, these probability measures should charge only positive functions, in view of the desired inequality (10.6). Probability on Banach spaces of functions is most naturally developed in the setting of separable spaces, which $L^\infty(D)$ is not. This difficulty can be circumvented in various different ways as we describe in what follows.

1.4 Bibliographic Notes

- Section 1.1. See [11] for a general overview of the Bayesian approach to statistics in the finite-dimensional setting. The Bayesian approach to linear inverse problems with Gaussian noise and prior in finite dimensions is discussed in [92, Chapters 2 and 6] and, with a more algorithmic flavor, in the book [53].
- Section 1.2. For details on the heat equation as an ODE in Hilbert space, and the regularity estimates of Lemma 1, see [70, 80]. The classical approach to linear inverse problems is described in numerous books; see, for example, [32, 51]. The case where the spectrum of the forward map G decays exponentially, as arises for the heat equation, is sometimes termed *severely ill posed*. The Bayesian approach to linear inverse problems was developed systematically in [68, 71], following from the seminal paper [36] in which the approach was first described; for further reading on ill-posed linear problems, see [92, Chapters 3 and 6]. Recovering the truth underlying the data from the Bayesian approach, known as *Bayesian posterior consistency*, is the topic of [3, 55]; generalizations to severely ill-posed problems, such as the heat equation, may be found in [4, 56].
- Section 1.3. See [33] for the Lax-Milgram theory which gives rise to Lemma 2. For classical inversion theory for the elliptic inverse problem – determining the permeability from the pressure in a Darcy model of flow in a porous medium – see [8, 86]; for Bayesian formulations see [24, 25]. For posterior consistency results see [99].

2 Prior Modeling

In this section we show how to construct probability measures on a function space, adopting a constructive approach based on random series. As explained in Sect. A.2.2, the natural setting for probability in a function space is that of a separable Banach space. A countable infinite sequence in the Banach space X will

be used for our random series; in the case where X is not separable, the resulting probability measure will be constructed on a separable subspace X' of X (see the discussion in Sect. 2.1).

Section 2.1 describes this general setting, and Sects. 2.2, 2.3 and 2.4 consider, in turn, three classes of priors termed uniform, Besov and Gaussian. In Sect. 2.5 we link the random series construction to the widely used random field perspective on spatial stochastic processes and we summarize in Sect. 2.6. We denote the prior measures constructed in this section by μ_0 .

2.1 General Setting

We let $\{\phi_j\}_{j=1}^\infty$ denote an infinite sequence in the Banach space X , with norm $\|\cdot\|$, of \mathbb{R} -valued functions defined on a domain D . We will either take $D \subset \mathbb{R}^d$, a bounded, open set with Lipschitz boundary or $D = \mathbb{T}^d$ the d -dimensional torus. We normalize these functions so that $\|\phi_j\| = 1$ for $j = 1, \dots, \infty$. We also introduce another element $m_0 \in X$, not necessarily normalized to 1. Define the function u by

$$u = m_0 + \sum_{j=1}^{\infty} u_j \phi_j. \quad (10.11)$$

By randomizing $\mathbf{u} := \{u_j\}_{j=1}^\infty$, we create real-valued random functions on D . (The extension to \mathbb{R}^n -valued random functions is straightforward, but omitted for brevity.)

We now define the deterministic sequence $\gamma = \{\gamma_j\}_{j=1}^\infty$ and the i.i.d. random sequence $\xi = \{\xi_j\}_{j=1}^\infty$, and set $u_j = \gamma_j \xi_j$. We assume that ξ is centred, i.e., that it has mean zero. Formally we see that the average value of u is then m_0 so that this element of X should be thought of as the *mean function*. We assume that $\gamma \in \ell_w^p$ for some $p \in [1, \infty)$ and some positive weight sequence $\{w_j\}$ (see Sect. A.1.1). We define $\Omega = \mathbb{R}^\infty$ and view ξ as a random element in the probability space $(\Omega, \mathcal{B}(\Omega), \mathbb{P})$ of i.i.d. sequences equipped with the product σ -algebra; we let \mathbb{E} denote expectation. This sigma algebra can be generated by cylinder sets if an appropriate distance d is defined on sequences. However, the distance d captures nothing of the properties of the random function u itself. For this reason we will be interested in the pushforward of the measure \mathbb{P} on the measure space $(\Omega, \mathcal{B}(\Omega))$ into a measure μ on $(X', \mathcal{B}(X'))$, where X' is a separable Banach space and $\mathcal{B}(X')$ denotes its Borel σ -algebra. Sometimes X' will be the same as X but not always: the space X may not be separable; and, although we have stated the normalization of the ϕ_j in X , they may of course live in smaller spaces X' , and u may do so too. For either of these reasons, X' may be a proper subspace of X .

In the next three subsections, we demonstrate how this general setting may be adapted to create a variety of useful prior measures on function space; the fourth subsection, which follows these three, relates the random series construction, in the Gaussian case, to the standard construction of Gaussian random fields. We will express many of our results in terms of the probability measure \mathbb{P} on i.i.d sequences, but all such results will, of course, have direct implications for the induced pushforward measures on the function spaces where the random functions

u live. We discuss this perspective in the summary Sect. 2.6. In dealing with the random series construction, we will also find it useful to consider the truncated random functions

$$u^N = m_0 + \sum_{j=1}^N u_j \phi_j, \quad u_j = \gamma_j \xi_j. \quad (10.12)$$

2.2 Uniform Priors

To construct the random functions (10.11), we take $X = L^\infty(D)$, choose the deterministic sequence $\gamma = \{\gamma_j\}_{j=1}^\infty \in \ell^1$ and specify the i.i.d. sequence $\xi = \{\xi_j\}_{j=1}^\infty$ by $\xi_1 \sim U[-1, 1]$, uniform random variables on $[-1, 1]$. Assume further that there are finite, strictly positive constants m_{\min}, m_{\max} , and δ such that

$$\begin{aligned} \text{ess inf}_{x \in D} m_0(x) &\geq m_{\min}; \\ \text{ess sup}_{x \in D} m_0(x) &\leq m_{\max}; \\ \|\gamma\|_{\ell^1} &= \frac{\delta}{1 + \delta} m_{\min}. \end{aligned}$$

The space X is not separable and so, instead, we work with the space X' found as the closure of the linear span of the functions $(m_0, \{\phi_j\}_{j=1}^\infty)$ with respect to the norm $\|\cdot\|_\infty$ on X . The Banach space $(X', \|\cdot\|_\infty)$ is separable.

Theorem 2. *The following holds \mathbb{P} -almost surely: the sequence of functions $\{u^N\}_{N=1}^\infty$ given by (10.12) is Cauchy in X' , and the limiting function u given by (10.11) satisfies*

$$\frac{1}{1 + \delta} m_{\min} \leq u(x) \leq m_{\max} + \frac{\delta}{1 + \delta} m_{\min} \quad a.e. \quad x \in D.$$

Proof. Let $N > M$. Then, \mathbb{P} -a.s.,

$$\begin{aligned} \|u^N - u^M\|_\infty &= \left\| \sum_{j=M+1}^N u_j \phi_j \right\|_\infty \\ &\leq \left\| \sum_{j=M+1}^N \gamma_j \xi_j \phi_j \right\|_\infty \\ &\leq \sum_{j=M+1}^\infty |\gamma_j| |\xi_j| \|\phi_j\|_\infty \\ &\leq \sum_{j=M+1}^\infty |\gamma_j|. \end{aligned}$$

The right-hand side tends to zero as $M \rightarrow \infty$ by the dominated convergence theorem and hence the sequence is Cauchy in X' .

We have \mathbb{P} -a.s. and for a.e. $x \in D$,

$$\begin{aligned} u(x) &\geq m_0(x) - \sum_{j=1}^{\infty} |u_j| \|\phi_j\|_{\infty} \\ &\geq \text{ess inf}_{x \in D} m_0(x) - \sum_{j=1}^{\infty} |\gamma_j| \\ &\geq m_{\min} - \|\gamma\|_{\ell^1} \\ &= \frac{1}{1+\delta} m_{\min}. \end{aligned}$$

Proof of the upper bound is similar. \square

Example 1. Consider the random function (10.11) as specified in this section. By Theorem 2 we have that, \mathbb{P} -a.s.,

$$u(x) \geq \frac{1}{1+\delta} m_{\min} > 0, \quad \text{a.e. } x \in D. \quad (10.13)$$

Set $\kappa = u$ in the elliptic equation (10.6), so that the coefficient κ in the equation and the solution p are random variables on $(\mathbb{R}^{\infty}, \mathcal{B}(\mathbb{R}^{\infty}), \mathbb{P})$. Since (10.13) holds \mathbb{P} -a.s., Lemma 2 shows that, again \mathbb{P} -a.s.,

$$\|p\|_V \leq (1+\delta) \|f\|_{V^*} / m_{\min}.$$

Since the r.h.s. is nonrandom, we have that for all $r \in \mathbb{Z}^+$ the random variable $p \in L_{\mathbb{P}}^r(\Omega; V)$:

$$\mathbb{E}\|p\|_V^r < \infty.$$

In fact $\mathbb{E} \exp(\alpha \|p\|_V^r) < \infty$ for all $r \in \mathbb{Z}^+$ and $\alpha \in (0, \infty)$. \square

We now consider the situation where the family $\{\phi_j\}_{j=1}^{\infty}$ has a uniform Hölder exponent α and study the implications for Hölder continuity of the random function u . Specifically we assume that there are $C, a > 0$ and $\alpha \in (0, 1]$ such that, for all $j \geq 1$,

$$|\phi_j(x) - \phi_j(y)| \leq C j^a |x - y|^{\alpha}, \quad x, y \in D. \quad (10.14)$$

and

$$|m_0(x) - m_0(y)| \leq C |x - y|^{\alpha}, \quad x, y \in D. \quad (10.15)$$

Theorem 3. Assume that u is given by (10.11) where the collection of functions $(m_0, \{\phi_j\}_{j=1}^\infty)$ satisfy (10.14) and (10.15). Assume further that $\sum_{j=1}^\infty |\gamma_j|^2 j^{a\theta} < \infty$ for some $\theta \in (0, 2)$. Then \mathbb{P} -a.s. we have $u \in C^{0,\beta}(D)$ for all $\beta < \frac{\alpha\theta}{2}$.

Proof. This is an application of Corollary 5 of the Kolmogorov continuity theorem and S_1 and S_2 are as defined there. We use θ in place of the parameter δ appearing in Corollary 5 in order to avoid confusion with δ appearing in Theorem 2 above and in (10.17) below. Note that, since m_0 has assumed Hölder regularity α , which exceeds $\frac{\alpha\theta}{2}$ since $\theta \in (0, 2)$, it suffices to consider the centred case where $m_0 \equiv 0$. We let $f_j = \gamma_j \phi_j$ and complete the proof by noting that

$$S_1 = \sum_{j=1}^\infty |\gamma_j|^2 \leq S_2 \leq \sum_{j=1}^\infty |\gamma_j|^2 j^{a\theta} < \infty.$$

Example 2. Let $\{\phi_j\}$ denote the Fourier basis for $L^2(D)$ with $D = [0, 1]^d$. Then we may take $a = \alpha = 1$. If $\gamma_j = j^{-s}$, then $s > 1$ ensures $\gamma \in \ell^1$. Furthermore

$$\sum_{j=1}^\infty |\gamma_j|^2 j^{a\theta} = \sum_{j=1}^\infty j^{\theta-2s} < \infty$$

for $\theta < 2s - 1$. We thus deduce that $u \in C^{0,\beta}([0, 1]^d)$ for all $\beta < \min\{s - \frac{1}{2}, 1\}$.

2.3 Besov Priors

For this construction of random functions, we take X to be the Hilbert space

$$X := \dot{L}^2(\mathbb{T}^d) = \left\{ u : \mathbb{T}^d \rightarrow \mathbb{R} \mid \int_{\mathbb{T}^d} |u(x)|^2 dx < \infty, \int_{\mathbb{T}^d} u(x) dx = 0 \right\}$$

of real valued periodic functions in dimension $d \leq 3$ with inner product and norm denoted by $\langle \cdot, \cdot \rangle$ and $\|\cdot\|$, respectively. We then set $m_0 = 0$ and let $\{\phi_j\}_{j=1}^\infty$ be an orthonormal basis for X . Consequently, for any $u \in X$, we have for a.e. $x \in \mathbb{T}^d$,

$$u(x) = \sum_{j=1}^\infty u_j \phi_j(x), \quad u_j = \langle u, \phi_j \rangle. \quad (10.16)$$

Given a function $u : \mathbb{T}^d \rightarrow \mathbb{R}$ and the $\{u_j\}$ as defined in (10.16), we define the Banach space $X^{t,q}$ by

$$X^{t,q} = \left\{ u : \mathbb{T}^d \rightarrow \mathbb{R} \mid \|u\|_{X^{t,q}} < \infty, \int_{\mathbb{T}^d} u(x) dx = 0 \right\}$$

where

$$\|u\|_{X^{t,q}} = \left(\sum_{j=1}^{\infty} j^{(\frac{tq}{d} + \frac{q}{2} - 1)} |u_j|^q \right)^{\frac{1}{q}}$$

with $q \in [1, \infty)$ and $t > 0$. If $\{\phi_j\}$ form the Fourier basis and $q = 2$, then $X^{t,2}$ is the Sobolev space $\dot{H}^t(\mathbb{T}^d)$ of mean-zero periodic functions with t (possibly non-integer) square-integrable derivatives; in particular $X^{0,2} = \dot{L}^2(\mathbb{T}^d)$. On the other hand, if the $\{\phi_j\}$ form certain wavelet bases, then $X^{t,q}$ is the Besov space B_{qq}^t .

As described above, we assume that $u_j = \gamma_j \xi_j$ where $\xi = \{\xi_j\}_{j=1}^{\infty}$ is an i.i.d. sequence and $\gamma = \{\gamma_j\}_{j=1}^{\infty}$ is deterministic. Here we assume that ξ_1 is drawn from the centred measure on \mathbb{R} with density proportional to $\exp(-\frac{1}{2}|x|^q)$ for some $1 \leq q < \infty$ – we refer to this as a *q -exponential distribution*, noting that $q = 2$ gives a Gaussian and $q = 1$ a Laplace-distributed random variable. Then for $s > 0$ and $\delta > 0$, we define

$$\gamma_j = j^{-(\frac{s}{d} + \frac{1}{2} - \frac{1}{q})} \left(\frac{1}{\delta} \right)^{\frac{1}{q}}. \quad (10.17)$$

The parameter δ is a key scaling parameter which will appear in the statement of exponential moment bounds below.

We now prove convergence of the series (found from (10.12) with $m_0 = 0$)

$$u^N = \sum_{j=1}^N u_j \phi_j, \quad u_j = \gamma_j \xi_j \quad (10.18)$$

to the limit function

$$u(x) = \sum_{j=1}^{\infty} u_j \phi_j(x), \quad u_j = \gamma_j \xi_j, \quad (10.19)$$

in an appropriate space. To understand the sequence of functions $\{u^N\}$, it is useful to introduce the following function space:

$$L_{\mathbb{P}}^q(\Omega; X^{t,q}) := \left\{ v : D \times \Omega \rightarrow \mathbb{R} \mid \mathbb{E}(\|v\|_{X^{t,q}}^q) < \infty \right\}.$$

This is a Banach space, when equipped with the norm $\left(\mathbb{E}(\|v\|_{X^{t,q}}^q) \right)^{\frac{1}{q}}$. Thus every Cauchy sequence is convergent in this space.

Theorem 4. *For $t < s - \frac{d}{q}$, the sequence of functions $\{u^N\}_{N=1}^{\infty}$, given by (10.18) and (10.17) with ξ_1 drawn from a centred q -exponential distribution, is Cauchy in*

the Banach space $L_{\mathbb{P}}^q(\Omega; X^{t,q})$. Thus the infinite series (10.19) exists as an $L_{\mathbb{P}}^q$ -limit and takes values in $X^{t,q}$ almost surely, for all $t < s - \frac{d}{q}$.

Proof. For $N > M$,

$$\begin{aligned}\mathbb{E}\|u^N - u^M\|_{X^{t,q}}^q &= \delta^{-1} \mathbb{E} \sum_{j=M+1}^N j^{\frac{(t-s)q}{d}} |\xi_j|^q \\ &\asymp \sum_{j=M+1}^N j^{\frac{(t-s)q}{d}} \leq \sum_{j=M+1}^{\infty} j^{\frac{(t-s)q}{d}}.\end{aligned}$$

The sum on the right-hand side tends to 0 as $M \rightarrow \infty$, provided $\frac{(t-s)q}{d} < -1$, by the dominated convergence theorem. This completes the proof. \square

The previous theorem gives a sufficient condition, on t , for existence of the limiting random function. The following theorem refines this to an if and only if statement, in the context of almost sure convergence.

Theorem 5. Assume that u is given by (10.19) and (10.17) with ξ_1 drawn from a centred q -exponential distribution. Then the following are equivalent:

- (i) $\|u\|_{X^{t,q}} < \infty$ \mathbb{P} -a.s.;
- (ii) $\mathbb{E}(\exp(\alpha \|u\|_{X^{t,q}}^q)) < \infty$ for any $\alpha \in [0, \frac{\delta}{2}]$;
- (iii) $t < s - \frac{d}{q}$.

Proof. We first note that, for the random function in question,

$$\|u\|_{X^{t,q}}^q = \sum_{j=1}^{\infty} j^{(\frac{tq}{d} + \frac{q}{2} - 1)} |u_j|^q = \sum_{j=1}^{\infty} \delta^{-1} j^{-\frac{(s-t)q}{d}} |\xi_j|^q.$$

Now, for $\alpha < \frac{1}{2}$,

$$\begin{aligned}\mathbb{E} \exp(\alpha |\xi_1|^q) &= \int_{\mathbb{R}} \exp\left(-\left(\frac{1}{2} - \alpha\right)|x|^q\right) dx / \int_{\mathbb{R}} \exp\left(-\frac{1}{2}|x|^q\right) dx \\ &= (1 - 2\alpha)^{-\frac{1}{q}}.\end{aligned}$$

(iii) \Rightarrow (ii).

$$\begin{aligned}\mathbb{E}(\exp(\alpha \|u\|_{X^{t,q}}^q)) &= \mathbb{E}\left(\exp\left(\alpha \sum_{j=1}^{\infty} \delta^{-1} j^{-\frac{(s-t)q}{d}} |\xi_j|^q\right)\right) \\ &= \prod_{j=1}^{\infty} \left(1 - \frac{2\alpha}{\delta} j^{-\frac{(s-t)q}{d}}\right)^{-\frac{1}{q}}.\end{aligned}$$

For $\alpha < \frac{\delta}{2}$ the product converges if $\frac{(s-t)q}{d} > 1$, i.e., $t < s - \frac{d}{q}$ as required.

(ii) \Rightarrow (i).

If (i) does not hold, $Z := \|u\|_{X^{t,q}}^q$ is positive infinite on a set of positive measure S . Then, since for $\alpha > 0$, $\exp(\alpha Z) = +\infty$ if $Z = +\infty$, and $\mathbb{E} \exp(\alpha Z) \geq \mathbb{E}(\mathbb{1}_S \exp(\alpha Z))$, we get a contradiction.

(i) \Rightarrow (iii).

To show that (i) implies (iii), note that (i) implies that, almost surely,

$$\sum_{j=1}^{\infty} j^{(t-s)q/d} |\xi_j|^q < \infty.$$

This implies that $t < s$. To see this assume for contradiction that $t \geq s$. Then, almost surely,

$$\sum_{j=1}^{\infty} |\xi_j|^q < \infty.$$

Since there is a constant $c > 0$ with $\mathbb{E}|\xi_j|^q = c$ for any $j \in \mathbb{N}$, this contradicts the law of large numbers.

Now define $\zeta_j = j^{(t-s)q/d} |\xi_j|^q$. Using the fact that the ζ_j are nonnegative and independent, we deduce from Lemma 3 (below) that

$$\sum_{j=1}^{\infty} \mathbb{E}(\zeta_j \wedge 1) = \sum_{j=1}^{\infty} \mathbb{E}\left(j^{(t-s)q/d} |\xi_j|^q \wedge 1\right) < \infty.$$

Since $t < s$ we note that then

$$\begin{aligned} \mathbb{E}\zeta_j &= \mathbb{E}\left(j^{-(s-t)q/d} |\xi_j|^q\right) \\ &= \mathbb{E}\left(j^{-(s-t)q/d} |\xi_j|^q \mathbb{1}_{\{|\xi_j| \leq j^{(s-t)/d}\}}\right) + \mathbb{E}\left(j^{-(s-t)q/d} |\xi_j|^q \mathbb{1}_{\{|\xi_j| > j^{(s-t)/d}\}}\right) \\ &\leq \mathbb{E}\left((\zeta_j \wedge 1) \mathbb{1}_{\{|\xi_j| \leq j^{(s-t)/d}\}}\right) + I \\ &\leq \mathbb{E}\left(\zeta_j \wedge 1\right) + I, \end{aligned}$$

where

$$I \propto j^{-(s-t)q/d} \int_{j^{(s-t)/d}}^{\infty} x^q e^{-x^q/2} dx.$$

Noting that, since $q \geq 1$, the function $x \mapsto x^q e^{-x^q/2}$ is bounded, up to a constant of proportionality, by the function $x \mapsto e^{-\alpha x}$ for any $\alpha < \frac{1}{2}$, we see that there is a positive constant K such that

$$\begin{aligned} I &\leq K j^{-(s-t)q/d} \int_{j^{(s-t)/d}}^{\infty} e^{-\alpha x} dx \\ &= \frac{1}{\alpha} K j^{-(s-t)q/d} \exp(-\alpha j^{(s-t)/d}) \\ &:= \iota_j. \end{aligned}$$

Thus we have shown that

$$\sum_{j=1}^{\infty} \mathbb{E}(j^{-(s-t)q/d} |\xi_j|^q) \leq \sum_{j=1}^{\infty} \mathbb{E}(\zeta_j \wedge 1) + \sum_{j=1}^{\infty} \iota_j < \infty.$$

Since the ξ_j are i.i.d. this implies that

$$\sum_{j=1}^{\infty} j^{(t-s)q/d} < \infty,$$

from which it follows that $(s-t)q/d > 1$ and (iii) follows. \square

Lemma 3. *Let $\{I_j\}_{j=1}^{\infty}$ be an independent sequence of \mathbb{R}^+ -valued random variables. Then*

$$\sum_{j=1}^{\infty} I_j < \infty \quad a.s. \Leftrightarrow \sum_{j=1}^{\infty} \mathbb{E}(I_j \wedge 1) < \infty.$$

As in the previous subsection, we now study the situation where the family $\{\phi_j\}$ has a uniform Hölder exponent α and study the implications for Hölder continuity of the random function u . In this case, however, the basis functions are normalized in L^2 and not L^∞ ; thus we must make additional assumptions on the possible growth of the L^∞ norms of $\{\phi_j\}$ with j . We assume that there are $C, a, b > 0$ and $\alpha \in (0, 1]$ such that, for all $j \geq 0$,

$$|\phi_j(x)| = \beta_j \leq C j^b, \quad x \in D. \quad (10.20a)$$

$$|\phi_j(x) - \phi_j(y)| \leq C j^a |x - y|^\alpha, \quad x, y \in D. \quad (10.20b)$$

We also assume that $a > b$ as, since $\|\phi_j\|_{L^2} = 1$, it is natural that the pre-multiplication constant in the Hölder estimate on the $\{\phi_j\}$ grows in j at least as fast as the bound on the functions themselves.

Theorem 6. Assume that u is given by (10.19) and (10.17) with ξ_1 drawn from a centred q -exponential distribution. Suppose also that (10.20) hold and that $s > d(b + q^{-1} + \frac{1}{2}\theta(a - b))$ for some $\theta \in (0, 2)$. Then \mathbb{P} -a.s. we have $u \in C^{0,\beta}(\mathbb{T}^d)$ for all $\beta < \frac{\alpha\theta}{2}$.

Proof. We apply Corollary 5 of the Kolmogorov continuity theorem and S_1 and S_2 are as defined there. We use θ in place of the parameter δ appearing in Corollary 5 in order to avoid confusion with δ appearing in Theorem 2 and (10.17) above. Let $f_j = \gamma_j \phi_j$ and note that

$$\begin{aligned} S_1 &= \sum_{j=1}^{\infty} |\gamma_j|^2 \beta_j^2 \lesssim \sum_{j=1}^{\infty} j^{-c_1} \\ S_2 &= \sum_{j=1}^{\infty} |\gamma_j|^{2-\theta} \beta_j^{2-\theta} \gamma_j^\theta j^{a\theta} \lesssim \sum_{j=1}^{\infty} j^{-c_2}. \end{aligned}$$

Short calculation shows that

$$\begin{aligned} c_1 &= \frac{2s}{d} + 1 - \frac{2}{q} - 2b, \\ c_2 &= \frac{2s}{d} + 1 - \frac{2}{q} - 2b - \theta(a - b). \end{aligned}$$

We require $c_1 > 1$ and $c_2 > 1$ and since $a > b$ satisfaction of the second of these will imply the first. Satisfaction of the second gives the desired lower bound on s .

We note that the result of Theorem 6 holds true when the mean function is nonzero if it satisfies

$$|m_0(x)| \leq C, \quad x \in D.$$

$$|m_0(x) - m_0(y)| \leq C|x - y|^\alpha, \quad x, y \in D.$$

We have the following sharper result if the family $\{\phi_j\}$ is regular enough to be a basis for B'_{qq} instead of satisfying (10.20):

Theorem 7. Assume that u is given by (10.19) and (10.17) with ξ_1 drawn from a centred q -exponential distribution. Suppose also that $\{\phi_j\}_{j \in \mathbb{N}}$ form a basis for B'_{qq} for some $t < s - \frac{d}{q}$. Then $u \in C^{0,t}(\mathbb{T}^d)$ \mathbb{P} -almost surely.

Proof. For any $m \geq 1$, using the definition of $X^{t,q}$ -norm, we can write

$$\|u\|_{B_{mq,mq}^t}^{mq} = (\frac{1}{\delta})^m \sum_{j=1}^{\infty} j^{\frac{mqt}{d} + \frac{mq}{2} - 1} j^{-mq(\frac{s}{d} + \frac{1}{2} - \frac{1}{q})} |\xi_j|^{mq}.$$

For every $m \in \mathbb{N}$, there exists a constant C_m with $\mathbb{E}|\xi_j|^{mq} = C_m$. Since each term of the above series is measurable, we can swap the sum and the integration and write

$$\mathbb{E}\|u\|_{B_{mq,mq}^t}^{mq} = C_m (\frac{1}{\delta})^m \sum_{j=1}^{\infty} j^{\frac{mq}{d}(t-s) + m - 1} \leq \tilde{C}_m,$$

noting that the exponent of j is smaller than -1 (since $t < s - d/q$). Now for a given $t < s - d/q$, one can choose m large enough so that $\frac{d}{mq} < s - d/q - t$. Then the embedding $B_{mq,mq}^{t_1} \subset C^t$ for any t_1 satisfying $t + \frac{d}{mq} < t_1 < s - d/q$ implies that $\mathbb{E}\|u\|_{C^t(\mathbb{T}^d)}^{mq} < \infty$. It follows that $u \in C^t$ \mathbb{P} -almost surely.

If the mean function m_0 is t -Hölder continuous, the result of the above theorem holds for a random series with nonzero mean function as well.

2.4 Gaussian Priors

Let X be a Hilbert space \mathcal{H} of real-valued functions on bounded open $D \subset \mathbb{R}^d$ with Lipschitz boundary and with inner product and norm denoted by $\langle \cdot, \cdot \rangle$ and $\|\cdot\|$, respectively; for example, $\mathcal{H} = L^2(D; \mathbb{R})$. Assume that $\{\phi_j\}_{j=1}^{\infty}$ is an orthonormal basis for \mathcal{H} . We study the Gaussian case where $\xi_1 \sim N(0, 1)$, and then equation (10.11) with $u_j = \gamma_j \xi_j$ generates random draws from the Gaussian measure $N(m_0, C)$ on \mathcal{H} where the covariance operator C depends on the sequence $\gamma = \{\gamma_j\}_{j=1}^{\infty}$. See the Appendix for background on Gaussian measures in a Hilbert space. As in Sect. 2.3, we consider the setting in which $m_0 = 0$ so that the function u is given by (10.16) and has mean zero. We thus focus on identifying C from the random series (10.16) and studying the regularity of random draws from $N(0, C)$.

Define the Hilbert scale of spaces \mathcal{H}^t as in Sect. A.1.3 with, recall, norm

$$\|u\|_{\mathcal{H}^t}^2 = \sum_{j=1}^{\infty} j^{\frac{2t}{d}} |u_j|^2.$$

We choose $\xi_1 \sim N(0, 1)$ and study convergence of the series (10.18) for u^N to a limit function u given by (10.19); the spaces in which this convergence occurs will depend upon the sequence γ . To understand the sequence of functions $\{u^N\}$, it is useful to introduce the following function space:

$$L^2_{\mathbb{P}}(\Omega; \mathcal{H}') := \left\{ v : D \times \Omega \rightarrow \mathbb{R} \mid \mathbb{E}(\|v\|_{\mathcal{H}'})^2 < \infty \right\}.$$

This is in fact a Hilbert space, although we will not use the Hilbert space structure. We will only use the fact that $L^2_{\mathbb{P}}$ is a Banach space when equipped with the norm $(\mathbb{E}(\|v\|_{\mathcal{H}^t}^2))^{\frac{1}{2}}$ and that hence every Cauchy sequence is convergent.

Theorem 8. Assume that $\gamma_j \asymp j^{-\frac{s}{d}}$. Then the sequence of functions $\{u^N\}_{N=1}^\infty$ given by (10.18) is Cauchy in the Hilbert space $L^2_{\mathbb{P}}(\Omega; \mathcal{H}^t)$, $t < s - \frac{d}{2}$. Thus, the infinite series (10.19) exists as an $L^2_{\mathbb{P}}$ limit and takes values in \mathcal{H}^t almost surely, for $t < s - \frac{d}{2}$.

Proof. For $N > M$,

$$\begin{aligned}\mathbb{E}\|u^N - u^M\|_{\mathcal{H}^t}^2 &= \mathbb{E} \sum_{j=M+1}^N j^{\frac{2t}{d}} |u_j|^2 \\ &\asymp \sum_{j=M+1}^N j^{\frac{2(t-s)}{d}} \leq \sum_{j=M+1}^\infty j^{\frac{2(t-s)}{d}}.\end{aligned}$$

The sum on the right-hand side tends to 0 as $M \rightarrow \infty$, provided $\frac{2(t-s)}{d} < -1$, by the dominated convergence theorem. This completes the proof. \square

Remarks 2. We make the following remarks concerning the Gaussian random functions constructed in the preceding theorem.

- The preceding theorem shows that the sum (10.18) has an $L^2_{\mathbb{P}}$ limit in \mathcal{H}^t when $t < s - d/2$, as one can also see from the following direct calculation

$$\begin{aligned}\mathbb{E}\|u\|_{\mathcal{H}^t}^2 &= \sum_{j=1}^\infty j^{\frac{2t}{d}} \mathbb{E}(\gamma_j^2 \xi_j^2) \\ &= \sum_{j=1}^\infty j^{\frac{2t}{d}} \gamma_j^2 \\ &\asymp \sum_{j=1}^\infty j^{\frac{2(t-s)}{d}} < \infty.\end{aligned}$$

Thus $u \in \mathcal{H}^t$ a.s., for $t < s - \frac{d}{2}$.

- From the preceding theorem, we see that, provided $s > \frac{d}{2}$, the random function in (10.19) generates a mean-zero Gaussian measure on \mathcal{H} . The expression (10.19) is known as the *Karhunen-Loève expansion* and the eigenfunctions $\{\phi_j\}_{j=1}^\infty$ as the *Karhunen-Loève basis*.

- The covariance operator \mathcal{C} of a measure μ on \mathcal{H} may then be viewed as a bounded linear operator from \mathcal{H} into itself defined to satisfy

$$\mathcal{C}\ell = \int_{\mathcal{H}} \langle \ell, u \rangle u \mu(du), \quad (10.24)$$

for all $\ell \in \mathcal{H}$. Thus

$$\mathcal{C} = \int_{\mathcal{H}} u \otimes u \mu(du). \quad (10.25)$$

The following formal calculation, which can be made rigorous if \mathcal{C} is trace class on \mathcal{H} , gives an expression for the covariance operator:

$$\begin{aligned} \mathcal{C} &= \mathbb{E} u \otimes u \\ &= \mathbb{E} \left(\sum_{j=1}^{\infty} \sum_{k=1}^{\infty} \gamma_j \gamma_k \xi_j \xi_k \phi_j \otimes \phi_k \right) \\ &= \left(\sum_{j=1}^{\infty} \sum_{k=1}^{\infty} \gamma_j \gamma_k \mathbb{E}(\xi_j \xi_k) \phi_j \otimes \phi_k \right) \\ &= \left(\sum_{j=1}^{\infty} \sum_{k=1}^{\infty} \gamma_j \gamma_k \delta_{jk} \phi_j \otimes \phi_k \right) \\ &= \sum_{j=1}^{\infty} \gamma_j^2 \phi_j \otimes \phi_j. \end{aligned}$$

From this expression for the covariance, we may find eigenpairs explicitly:

$$\begin{aligned} \mathcal{C}\phi_k &= \left(\sum_{j=1}^{\infty} \gamma_j^2 \phi_j \otimes \phi_j \right) \phi_k \\ &= \sum_{j=1}^{\infty} \gamma_j^2 \langle \phi_j, \phi_k \rangle \phi_j = \sum_{j=1}^{\infty} \gamma_j^2 \delta_{jk} \phi_k = \gamma_k^2 \phi_k. \end{aligned}$$

- The Gaussian measure is denoted by $\mu_0 := N(0, \mathcal{C})$, a Gaussian with mean function 0 and covariance operator \mathcal{C} . The eigenfunctions of \mathcal{C} , $\{\phi_j\}_{j=1}^{\infty}$, are known as the *Karhunen-Loëve* basis for measure μ_0 . The γ_j^2 are the eigenvalues associated with this eigenbasis, and thus γ_j is the standard deviation of the Gaussian measure in the direction ϕ_j .

In the case where $\mathcal{H} = \dot{L}^2(\mathbb{T}^d)$, we are in the setting of Sect. 2.3 and we briefly consider this case. We assume that the $\{\phi_j\}_{j=1}^\infty$ constitute the Fourier basis. Let $A = -\Delta$ denote the negative Laplacian equipped with periodic boundary conditions on $[0, 1]^d$ and restricted to functions which integrate to zero over $[0, 1]^d$. This operator is positive self-adjoint and has eigenvalues which grow like $j^{2/d}$, analogously to Assumption 1 made in the case of Dirichlet boundary conditions. It then follows that $\mathcal{H}' = \mathcal{D}(A^{t/2}) = \dot{H}^t(\mathbb{T}^d)$, the Sobolev space of periodic functions on $[0, 1]^d$ with spatial mean equal to zero and t (possibly negative or fractional) square integrable derivatives. Thus, by the preceding Remarks 2, u defined by (10.19) is in the space \dot{H}^t a.s., $t < s - \frac{d}{2}$. In fact we can say more about regularity, using the Kolmogorov continuity test and Corollary 4; this we now do.

Theorem 9. *Consider the Karhunen-Loëve expansion (10.19) so that u is a sample from the measure $N(0, \mathcal{C})$ in the case where $\mathcal{C} = A^{-s}$ with $A = -\Delta$, $\mathcal{D}(A) = \dot{H}^2(\mathbb{T}^d)$ and $s > \frac{d}{2}$. Then, \mathbb{P} -a.s., $u \in \dot{H}^t$, $t < s - \frac{d}{2}$, and $u \in C^{0,t}(\mathbb{T}^d)$ a.s., $t < 1 \wedge (s - \frac{d}{2})$.*

Proof. Because of the stated properties of the eigenvalues of the Laplacian, it follows that the eigenvalues of \mathcal{C} satisfy $\gamma_j^2 \asymp j^{-\frac{2s}{d}}$ and the eigenbasis $\{\phi_j\}$ is the Fourier basis. Thus we may apply the conclusions stated in Remarks 2 to deduce that $u \in \dot{H}^t$, $t < \alpha - \frac{d}{2}$. Furthermore we may apply Corollary 5 to obtain Hölder regularity of u . To do this, we note that the $\{\phi_j\}$ are bounded in $L^\infty(\mathbb{T}^d)$ and are Lipschitz with constants which grow like $j^{1/d}$. We apply that corollary with $\alpha = 1$ and obtain

$$S_1 = \sum_{j=1}^{\infty} \gamma_j^2, \quad S_2 = \sum_{j=1}^{\infty} \gamma_j^2 j^{\delta/d}.$$

The corollary delivers the desired result after noting that any $\delta < 2s - d$ will make S_2 , and hence S_1 , summable.

The previous example illustrates the fact that, although we have constructed Gaussian measures in a Hilbert space setting, and that they are naturally defined on a range of Hilbert (Sobolev-like) spaces defined through fractional powers of the Laplacian, they may also be defined on Banach spaces, such as the space of Hölder continuous functions. We now return to the setting of the general domain D , rather than the d -dimensional torus. In this general context, it is important to highlight the Fernique theorem, here restated from the Appendix because of its importance:

Theorem 10 (Fernique Theorem). *Let μ_0 be a Gaussian measure on the separable Banach space X . Then there exists $\beta_c \in (0, \infty)$ such that, for all $\beta \in (0, \beta_c)$,*

$$\mathbb{E}^{\mu_0} \exp(\beta \|u\|_X^2) < \infty.$$

Remarks 3. We make two remarks concerning the Fernique theorem.

- Theorem 10, when combined with Theorem 9, shows that, with β sufficiently small, $\mathbb{E}^{\mu_0} \exp(\beta \|u\|_X^2) < \infty$ for both $X = \dot{H}^t$ and $X = C^{0,t}(\mathbb{T}^d)$, if $t < s - \frac{d}{2}$.
- Let $\mu_0 = N(0, A^{-s})$ where A is as in Theorem 9. Then Theorem 5 proves the Fernique theorem 10 for $X = X^{t,2} = \dot{H}^t$, if $t < s - \frac{d}{2}$; the proof in the case of the torus is very different from the general proof of the result in the abstract setting of Theorem 10.
- Theorem 5(ii) gives, in the Gaussian case, the Fernique theorem in the case that X is the Hilbert space $X^{t,2}$. Furthermore, the constant β_c is specified explicitly in that setting. More explicit versions of the general Fernique Theorem 10 are possible, but the characterization of β_c is more involved.

Example 3. Consider the random function (10.11) in the case where $\mathcal{H} = \dot{L}^2(\mathbb{T}^d)$ and $\mu_0 = N(0, A^{-s})$, $s > \frac{d}{2}$ as in the preceding example. Then we know that, μ_0 -a.s., $u \in C^{0,t}$, $t < 1 \wedge (s - \frac{d}{2})$. Set $\kappa = e^u$ in the elliptic PDE (10.7) so that the coefficient κ and hence the solution p are random variables on the probability space $(\Omega, \mathcal{F}, \mathbb{P})$. Then κ_{\min} given in (10.6) satisfies

$$\kappa_{\min} \geq \exp(-\|u\|_\infty).$$

By Lemma 2 we obtain

$$\|p\|_V \leq \exp(\|u\|_\infty) \|f\|_{V^*}.$$

Since $C^{0,t} \subset L^\infty(\mathbb{T}^d)$, $t \in (0, 1)$, we deduce that

$$\|u\|_{L^\infty} \leq K_1 \|u\|_{C^{0,t}}.$$

Furthermore, for any $\epsilon > 0$, there is constant $K_2 = K_2(\epsilon)$ such that $\exp(K_1 r x) \leq K_2 \exp(\epsilon x^2)$ for all $x \geq 0$. Thus

$$\begin{aligned} \|p\|_V^r &\leq \exp(K_1 r \|u\|_{C^{0,t}}) \|f\|_{V^*}^r \\ &\leq K_2 \exp(\epsilon \|u\|_{C^{0,t}}^2) \|f\|_{V^*}^r. \end{aligned}$$

Hence, by Theorem 10, we deduce that

$$\mathbb{E}\|p\|_V^r < \infty, \quad \text{i.e.} \quad p \in L_{\mathbb{P}}^r(\Omega; V) \quad \forall r \in \mathbb{Z}^+.$$

This result holds for any $r \geq 0$. Thus, when the coefficient of the elliptic PDE is *log normal*, that is, κ is the exponential of a Gaussian function, moments of all orders exist for the random variable p . However, unlike the case of the uniform prior, we cannot obtain exponential moments on $\mathbb{E} \exp(\alpha \|p\|_V^r)$ for any $(r, \alpha) \in \mathbb{Z}^+ \times (0, \infty)$.

This is because the coefficient κ , while positive a.s., does not satisfy a uniform positive lower bound across the probability space. \square

2.5 Random Field Perspective

In this subsection we link the preceding constructions of random functions, through randomized series, to the notion of *random fields*. Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space, with expectation denoted by \mathbb{E} , and $D \subseteq \mathbb{R}^d$ an open set. For the random series constructions developed in the preceding Subsections, $\Omega = \mathbb{R}^\infty$ and $\mathcal{F} = \mathbf{B}(\Omega)$; however, the development of the general theory of random fields does not require this specific choice. A *random field* on D is a measurable mapping $u : D \times \Omega \rightarrow \mathbb{R}^n$. Thus, for any $x \in D$, $u(x; \cdot)$ is an \mathbb{R}^n -valued random variable; on the other hand, for any $\omega \in \Omega$, $u(\cdot; \omega) : D \rightarrow \mathbb{R}^n$ is a vector field. In the construction of random fields, it is commonplace to first construct the *finite-dimensional distributions*. These are found by choosing any integer $K \geq 1$, and any set of points $\{x_k\}_{k=1}^K$ in D , and then considering the random vector $(u(x_1; \cdot)^*, \dots, u(x_K; \cdot)^*)^* \in \mathbb{R}^{nK}$. From the finite-dimensional distributions of this collection of random vectors, we would like to be able to make sense of the probability measure μ on X , a separable Banach space equipped with the Borel σ -algebra $\mathbf{B}(X)$, via the formula

$$\mu(A) = \mathbb{P}(u(\cdot; \omega) \in A), \quad A \in \mathbf{B}(X), \quad (10.26)$$

where ω is taken from a common probability space on which the random element $u \in X$ is defined. It is thus necessary to study the joint distribution of a set of K \mathbb{R}^n -valued random variables, all on a common probability space. Such \mathbb{R}^{nK} -valued random variables are, of course, only defined up to a set of zero measure. It is desirable that all such finite-dimensional distributions are defined on a common subset $\Omega_0 \subset \Omega$ with full measure, so that u may be viewed as a function $u : D \times \Omega_0 \rightarrow \mathbb{R}^n$; such a choice of random field is termed a *modification*. When reinterpreting the previous subsections in terms of random fields, statements about almost sure (regularity) properties should be viewed as statements concerning the existence of a modification possessing of the stated almost sure regularity property.

We may define the space of functions

$$L_{\mathbb{P}}^q(\Omega; X) := \left\{ v : D \times \Omega \rightarrow \mathbb{R}^n \mid \mathbb{E}(\|v\|_X^q) < \infty \right\}.$$

This is a Banach space, when equipped with the norm $(\mathbb{E}(\|v\|_X^q))^{1/q}$. We have used such spaces in the preceding subsections when demonstrating convergence of the randomized series. Note that we often simply write $u(x)$, suppressing the explicit dependence on the probability space.

A *Gaussian random field* is one where, for any integer $K \geq 1$, and any set of points $\{x_k\}_{k=1}^K$ in D , the random vector $(u(x_1; \cdot)^*, \dots, u(x_K; \cdot)^*)^* \in \mathbb{R}^{nK}$ is a Gaussian random vector. The *mean function* of a Gaussian random field is $m(x) = \mathbb{E}u(x)$. The *covariance function* is $c(x, y) = \mathbb{E}(u(x) - m(x))(u(y) - m(y))^*$. For Gaussian random fields, the mean function $m : D \rightarrow \mathbb{R}^n$ and the covariance function $c : D \times D \rightarrow \mathbb{R}^{n \times n}$ together completely specify the joint probability distribution for $(u(x_1; \cdot)^*, \dots, u(x_K)^*)^* \in \mathbb{R}^{nK}$. Furthermore, if we view the Gaussian random field as a Gaussian measure on $L^2(D; \mathbb{R}^n)$, then the covariance operator can be constructed from the covariance function as follows. Without loss of generality, we consider the mean-zero case; the more general case follows by shift of origin. Since the field has mean zero, we have, from (10.24), that for all $h_1, h_2 \in L^2(D; \mathbb{R}^n)$,

$$\begin{aligned}\langle h_1, \mathcal{C}h_2 \rangle &= \mathbb{E}\langle h_1, u \rangle \langle u, h_2 \rangle \\ &= \mathbb{E} \int_D \int_D h_1(x)^*(u(x)u(y)^*)h_2(y)dydx \\ &= \mathbb{E} \int_D h_1(x)^* \left(\int_D (u(x)u(y)^*)h_2(y)dy \right) dx \\ &= \int_D h_1(x)^* \left(\int_D c(x, y)h_2(y)dy \right) dx\end{aligned}$$

and we deduce that, for all $\psi \in L^2(D; \mathbb{R}^n)$,

$$(\mathcal{C}\psi)(x) = \int_D c(x, y)\psi(y)dy. \quad (10.27)$$

Thus the covariance operator of a Gaussian random field is an integral operator with kernel given by the covariance function. As such we may also view the covariance function as the Green's function of the inverse covariance, or *precision*.

A mean-zero Gaussian random field is termed *stationary* if $c(x, y) = s(x - y)$ for some matrix-valued function s , so that shifting the field by a fixed random vector does not change the statistics. It is *isotropic* if it is stationary and, in addition, $s(\cdot) = \iota(|\cdot|)$, for some matrix-valued function ι .

In the previous subsection, we demonstrated how the regularity of random fields maybe established from the properties of the sequences γ (deterministic, with decay) and ξ (i.i.d. random). Here we show similar results but express them in terms of properties of the covariance function and covariance operator.

Theorem 11. *Consider an \mathbb{R}^n -valued Gaussian random field u on $D \subset \mathbb{R}^d$ with mean zero and with isotropic correlation function $c : D \times D \rightarrow \mathbb{R}^{n \times n}$. Assume that D is bounded and that $\text{Tr } c(x, y) = k(|x - y|)$ where $k : \mathbb{R}^+ \rightarrow \mathbb{R}$ is Hölder with any exponent $\alpha \leq 1$. Then u is almost surely Hölder continuous on D with any exponent smaller than $\frac{1}{2}\alpha$.*

Proof. We have

$$\begin{aligned}\mathbb{E}|u(x) - u(y)|^2 &= \mathbb{E}|u(x)|^2 + \mathbb{E}|u(y)|^2 - 2\mathbb{E}\langle u(x), u(y) \rangle \\ &= \text{Tr}\left(c(x, x) + c(y, y) - 2c(x, y)\right) \\ &= 2\left(k(0) - k(|x - y|)\right) \\ &\leq C|x - y|^\alpha.\end{aligned}$$

Since u is Gaussian, it follows that, for any integer $r > 0$,

$$\mathbb{E}|u(x) - u(y)|^{2r} \leq C_r|x - y|^{\alpha r}.$$

Let $p = 2r$ and noting that

$$\alpha r = p\left(\frac{\alpha}{2} - \frac{d}{p}\right) + d$$

we deduce from Corollary 4 that u is Hölder continuous on D with any exponent smaller than

$$\sup_{p \in \mathbb{N}} \min\left\{1, \frac{\alpha}{2} - \frac{d}{p}\right\} = \frac{\alpha}{2},$$

which is precisely what we claimed.

It is often convenient both algorithmically and theoretically to define the covariance operator through fractional inverse powers of a differential operator. Indeed in the previous subsection, we showed that our assumptions on the random series construction we used could be interpreted as having a covariance operator which was an inverse fractional power of the Laplacian on zero spatial average functions with periodic boundary conditions. We now generalize this perspective and consider covariance operators which are a fractional power of an operator A satisfying the following.

Assumption 2. *The operator A , densely defined on the Hilbert space $\mathcal{H} = L^2(D; \mathbb{R}^n)$, satisfies the following properties:*

1. *A is positive definite, self-adjoint and invertible;*
2. *the eigenfunctions $\{\phi_j\}_{j \in \mathbb{N}}$ of A form an orthonormal basis for \mathcal{H} ;*

3. the eigenvalues of A satisfy $\alpha_j \asymp j^{2/d}$;
4. there is $C > 0$ such that

$$\sup_{j \in \mathbb{N}} \left(\|\phi_j\|_{L^\infty} + \frac{1}{j^{1/d}} \text{Lip}(\phi_j) \right) \leq C.$$

These properties are satisfied by the Laplacian on a torus, when applied to functions with spatial mean zero. But they are in fact satisfied for a much wider range of differential operators which are *Laplacian-like*. For example, the Dirichlet Laplacian on a bounded open set D in \mathbb{R}^d , together with various Laplacian operators perturbed by lower order terms, for example, Schrödinger operators. Inspection of the proof of Theorem 9 reveals that it only uses the properties of Assumption 2. Thus we have:

Theorem 12. *Let u be a sample from the measure $N(0, \mathcal{C})$ in the case where $\mathcal{C} = A^{-s}$ with A satisfying Assumptions 2 and $s > \frac{d}{2}$. Then, \mathbb{P} -a.s., $u \in \dot{H}^t$, for $t < s - \frac{d}{2}$, and $u \in C^{0,t}(D)$, for $t < 1 \wedge (s - \frac{d}{2})$.*

Example 4. Consider the case $d = 2, n = 1$ and $D = [0, 1]^2$. Define the Gaussian random field through the measure $\mu = N(0, (-\Delta)^{-\alpha})$ where Δ is the Laplacian with domain $H_0^1(D) \cap H^2(D)$. Then Assumption 2 is satisfied by $-\Delta$. By Theorem 12 it follows that choosing $\alpha > 1$ suffices to ensure that draws from μ are almost surely in $L^2(D)$. It also follows that, in fact, draws from μ are almost surely in $C(D)$.

2.6 Summary

In the preceding four subsections, we have shown how to create random functions by randomizing the coefficients of a series of functions. Using these random series, we have also studied the regularity properties of the resulting functions. Furthermore we have extended our perspective in the Gaussian case to determine regularity properties from the properties of the covariance function or the covariance operator.

For the uniform prior, we have shown that the random functions all live in a subset of $X = L^\infty$ characterized by the upper and lower bounds given in Theorem 2 and found as the closure of the linear span of the set of functions $(m_0, \{\phi_j\}_{j=1}^\infty)$; denote this subset, which is a separable Banach space, by X' . For the Besov priors, we have shown in Theorem 5 that the random functions live in the separable Banach spaces $X^{t,q}$ for all $t < s - d/q$; denote any one of these Banach spaces by X' . And finally for the Gaussian priors, we have shown in Theorem 8 that the random function exists as an L^2 limit in any of the Hilbert spaces \mathcal{H}' for $t < s - d/2$. Furthermore, we have indicated that, by use of the Kolmogorov continuity theorem, we can also show that the Gaussian random functions lie in certain Hölder spaces; these Hölder spaces are not separable but, by the discussion in Sect. A.1.2, we

can embed the spaces $C^{0,\gamma'}$ in the separable uniform Hölder spaces $C_0^{0,\gamma}$ for any $\gamma < \gamma'$; since the upper bound on the range of Hölder exponents established by use of Kolmogorov continuity theorem is open, this means we can work in the same range of Hölder exponents, but restricted to uniform Hölder spaces, thereby regaining separability. In this Gaussian case, we denote any of the separable Hilbert or Banach spaces where the Gaussian random function lives almost surely by X' .

Thus, in all of these examples, we have created a probability measure μ_0 which is the pushforward of the measure \mathbb{P} on the i.i.d. sequence ξ under the map which takes the sequence into the random function. The resulting measure lives on the separable Banach space X' , and we will often write $\mu_0(X') = 1$ to denote this fact. This is shorthand for saying that functions drawn from μ_0 are in X' almost surely. Separability of X' naturally leads to the use of the Borel σ -algebra to define a canonical measurable space and to the development of an integration theory – Bochner integration – which is natural on this space; see Sect. A.2.2.

2.7 Bibliographic Notes

- Section 2.1. For general discussion of the properties of random functions constructed via randomization of coefficients in a series expansion, see [49]. The construction of probability measure on infinite sequences of i.i.d. random variables may be found in [27].
- Section 2.2. These uniform priors have been extensively studied in the context of the field of uncertainty quantification, and the reader is directed to [18, 19] for more details. Uncertainty quantification in this context does not concern inverse problems, but rather studies the effect, on the solution of an equation, of randomizing the input data. Thus, the interest is in the pushforward of a measure on input parameter space onto a measure on solution space, for a differential equation. Recently, however, these priors have been used to study the inverse problem; see [90].
- Section 2.3. Besov priors were introduced in the paper [69] and Theorem 5 is taken from that paper. We notice that the theorem constitutes a special case of the Fernique theorem in the Gaussian case $q = 2$; it is restricted to a specific class of Hilbert space norms, however, whereas the Fernique theorem in full generality applies in all norms on Banach spaces which have full Gaussian measure. See [35, 40] for proof of the Fernique theorem. A more general Fernique-like property of the Besov measures is proved in [24], but it remains open to determine the appropriate complete generalization of the Fernique theorem to Besov measures. For proof of Lemma 3, see [54, Chapter 4]. For properties of families of functions that can form a basis for a Besov space and examples of such families, see [31, 74].
- Section 2.4. The general theory of Gaussian measures on Banach spaces is contained in [14, 67]. The text [28], concerning the theory of stochastic PDEs, also has a useful overview of the subject. The Karhunen-Loëve expansion (10.19) is contained in [1]. The formal calculation concerning the covariance operator

of the Gaussian measure which follows Theorem 8 leads to the answer which may be rigorously justified by using characteristic functions; see, for example, Proposition 2.18 in [28]. All three texts include statement and proof of the Fernique theorem in the generality given here. The Kolmogorov continuity theorem is discussed in [28] and [1]. Proof of Hölder regularity adapted to the case of the periodic setting may be found in [40] and [92, Chapter 6]. For further reading on Gaussian measures, see [27].

- Section 2.5. A key tool in making the random field perspective rigorous is the Kolmogorov Extension Theorem 29.
- Section 2.6. For a discussion of measure theory on general spaces, see [15]. The notion of Bochner integral is introduced in [13]; we discuss it in Sect. A.2.2.

3 Posterior Distribution

In this section we prove a Bayes' theorem appropriate for combining a likelihood with prior measures on separable Banach spaces as constructed in the previous section. In Sect. 3.1, we start with some general remarks about conditioned random variables. Section 3.2 contains our statement and proof of a Bayes' theorem and specifically its application to Bayesian inversion. We note here that, in our setting, the posterior μ^y will always be absolutely continuous with respect to the prior μ_0 , and we use the standard notation $\mu^y \ll \mu_0$ to denote this. It is possible to construct examples, for instance, in the purely Gaussian setting, where the posterior is not absolutely continuous with respect to the prior. Thus, it is certainly not necessary to work in the setting where $\mu^y \ll \mu_0$. However, it is quite natural, from a modeling point of view, to work in this setting: absolute continuity ensures that almost sure properties built into the prior will be inherited by the posterior. For these almost sure properties to be changed by the data would require that the data contains an infinite amount of information, something which is unnatural in most applications.

In Sect. 3.3, we study the example of the heat equation, introduced in Sect. 1.2, from the perspective of Bayesian inversion, and in Sect. 3.4 we do the same for the elliptic inverse problem of Sect. 1.3.

3.1 Conditioned Random Variables

Key to the development of Bayes' Theorem, and the posterior distribution, is the notion of conditional random variables. In this section we state an important theorem concerning conditioning.

Let (X, A) and (Y, B) denote a pair of measurable spaces, and let ν and π be probability measures on $X \times Y$. We assume that $\nu \ll \pi$. Thus there exists π -measurable $\phi : X \times Y \rightarrow \mathbb{R}$ with $\phi \in L_\pi^1$ (see Sect. A.1.4 for definition of L_π^1) and

$$\frac{d\nu}{d\pi}(x, y) = \phi(x, y). \quad (10.28)$$

That is, for $(x, y) \in X \times Y$,

$$\mathbb{E}^v f(x, y) = \mathbb{E}^\pi(\phi(x, y)f(x, y)),$$

or, equivalently,

$$\int_{X \times Y} f(x, y)v(dx, dy) = \int_{X \times Y} \phi(x, y)f(x, y)\pi(dx, dy).$$

Theorem 13. Assume that the conditional random variable $x|y$ exists under π with probability distribution denoted $\pi^y(dx)$. Then the conditional random variable $x|y$ under v exists, with probability distribution denoted by $v^y(dx)$. Furthermore, $v^y \ll \pi^y$ and if $c(y) := \int_X \phi(x, y)d\pi^y(x) > 0$, then

$$\frac{d v^y}{d \pi^y}(x) = \frac{1}{c(y)}\phi(x, y).$$

Example 5. Let $X = C([0, 1]; \mathbb{R})$, $Y = \mathbb{R}$. Let π denote the measure on $X \times Y$ induced by the random variable $(w(\cdot), w(1))$, where w is a draw from standard unit Wiener measure on \mathbb{R} , starting from $w(0) = z$. Let π^y denote measure on X found by conditioning Brownian motion to satisfy $w(1) = y$, thus π^y is a Brownian bridge measure with $w(0) = z, w(1) = y$.

Assume that $v \ll \pi$ with

$$\frac{d v}{d \pi}(x, y) = \exp(-\Phi(x, y)).$$

Assume further that

$$\sup_{x \in X} \Phi(x, y) = \Phi^+(y) < \infty$$

for every $y \in \mathbb{R}$. Then

$$c(y) = \int_{\mathbb{R}} \exp(-\Phi(x, y))d\pi^y(x) > \exp(-\Phi^+(y)) > 0.$$

Thus $v^y(dx)$ exists and

$$\frac{d v^y}{d \pi^y}(x) = \frac{1}{c(y)} \exp(-\Phi(x, y)). \quad \square$$

We will use the preceding theorem to go from a construction of the joint probability distribution on unknown and data to the conditional distribution of the unknown, given data. In constructing the joint probability distribution, we will need to establish measurability of the likelihood, for which the following will be useful:

Lemma 4. Let (Z, B) be a Borel measurable topological space and assume that $G \in C(Z; \mathbb{R})$ and that $\pi(Z) = 1$ for some probability measure π on (Z, B) . Then G is a π -measurable function.

3.2 Bayes' Theorem for Inverse Problems

Let X and Y be separable Banach spaces, equipped with the Borel σ -algebra, and $G : X \rightarrow Y$ a measurable mapping. We wish to solve the inverse problem of finding u from y where

$$y = G(u) + \eta \quad (10.29)$$

and $\eta \in Y$ denotes noise. We employ a Bayesian approach to this problem in which we let $(u, y) \in X \times Y$ be a random variable and compute $u|y$. We specify the random variable (u, y) as follows:

- **Prior:** $u \sim \mu_0$ measure on X .
- **Noise:** $\eta \sim \mathbb{Q}_0$ measure on Y , and (recalling that \perp denotes independence) $\eta \perp u$.

The random variable $y|u$ is then distributed according to the measure \mathbb{Q}_u , the translate of \mathbb{Q}_0 by $G(u)$. We *assume* throughout the following that $\mathbb{Q}_u \ll \mathbb{Q}_0$ for u μ_0 -a.s. Thus, for some **potential** $\Phi : X \times Y \rightarrow \mathbb{R}$,

$$\frac{d\mathbb{Q}_u}{d\mathbb{Q}_0}(y) = \exp(-\Phi(u; y)). \quad (10.30)$$

Thus, for fixed u , $\Phi(u; \cdot) : Y \rightarrow \mathbb{R}$ is measurable and $\mathbb{E}^{\mathbb{Q}_0} \exp(-\Phi(u; y)) = 1$. For given instance of the data y , $-\Phi(\cdot; y)$ is termed the **log likelihood**.

Define v_0 to be the product measure

$$v_0(du, dy) = \mu_0(du)\mathbb{Q}_0(dy). \quad (10.31)$$

We *assume* in what follows that $\Phi(\cdot, \cdot)$ is v_0 measurable. Then the random variable $(u, y) \in X \times Y$ is distributed according to measure $v(du, dy) = \mu_0(du)\mathbb{Q}_u(dy)$. Furthermore, it then follows that $v \ll v_0$ with

$$\frac{d\nu}{dv_0}(u, y) = \exp(-\Phi(u; y)).$$

We have the following infinite-dimensional analogue of Theorem 1.

Theorem 14 (Bayes' Theorem). *Assume that $\Phi : X \times Y \rightarrow \mathbb{R}$ is v_0 measurable and that, for y \mathbb{Q}_0 -a.s.,*

$$Z := \int_X \exp(-\Phi(u; y))\mu_0(du) > 0. \quad (10.32)$$

Then the conditional distribution of $u|y$ exists under ν and is denoted by μ^y . Furthermore $\mu^y \ll \mu_0$ and, for y ν -a.s.,

$$\frac{d\mu^y}{d\mu_0}(u) = \frac{1}{Z} \exp(-\Phi(u; y)). \quad (10.33)$$

Proof. First note that the positivity of Z holds for y ν_0 -almost surely, and hence by absolute continuity of ν with respect to ν_0 , for y ν -almost surely. The proof is an application of Theorem 13 with π replaced by ν_0 , $\phi(x, y) = \exp(-\Phi(u, y))$ and $(x, y) = (u, y)$. Since $\nu_0(du, dy)$ has product form, the conditional distribution of $u|y$ under ν_0 is simply μ_0 . The result follows. \square

Remarks 4. In order to implement the derivation of Bayes' formula (10.33), four essential steps are required:

- Define a suitable prior measure μ_0 and noise measure \mathbb{Q}_0 whose independent product form the reference measure ν_0 .
- Determine the potential Φ such that formula (10.30) holds.
- Show that Φ is ν_0 measurable.
- Show that the normalization constant Z given by (10.32) is positive almost surely with respect to $y \sim \mathbb{Q}_0$.

We will show how to carry out this program for two examples in the following subsections. The following remark will also be used in studying one of the examples.

Remarks 5. The following comments on the setup above may be useful.

- In formula (10.33) we can shift $\Phi(u, y)$ by any constant $c(y)$, independent of u , provided the constant is finite \mathbb{Q}_0 -a.s. and hence ν -a.s. Such a shift can be absorbed into a redefinition of the normalization constant Z .
- Our Bayes' Theorem only asserts that the posterior is absolutely continuous with respect to the prior μ_0 . In fact equivalence (mutual absolute continuity) will occur when $\Phi(\cdot; y)$ is finite everywhere in X .

3.3 Heat Equation

We apply Bayesian inversion to the heat equation from Sect. 1.2. Recall that for $G(u) = e^{-A}u$, we have the relationship

$$y = G(u) + \eta,$$

which we wish to invert. Let $X = H$ and define

$$\mathcal{H}^t = \mathcal{D}(A^{t/2}) = \left\{ w \mid w = A^{-t/2}w_0, w_0 \in H \right\}.$$

Under Assumption 1, we have $\alpha_j \asymp j^{\frac{2}{d}}$ so that this family of spaces is identical with the Hilbert scale of spaces \mathcal{H}^t as defined in Sects. 1.2 and 2.4.

We choose the prior $\mu_0 = N(0, A^{-\alpha})$, $\alpha > \frac{d}{2}$. Thus $\mu_0(X) = \mu_0(H) = 1$. Indeed the analysis in Sect. 2.4 shows that $\mu_0(\mathcal{H}^t) = 1$, $t < \alpha - \frac{d}{2}$. For the likelihood we assume that $\eta \perp u$ with $\eta \sim \mathbb{Q}_0 = N(0, A^{-\beta})$, and $\beta \in \mathbb{R}$. This measure satisfies $\mathbb{Q}_0(\mathcal{H}^t) = 1$ for $t < \beta - \frac{d}{2}$ and we thus choose $Y = \mathcal{H}^t$ for some $t' < \beta - \frac{d}{2}$. Notice that our analysis includes the case of white observational noise, for which $\beta = 0$. The Cameron-Martin Theorem 32, together with the fact that $e^{-\lambda A}$ commutes with arbitrary fractional powers of A , can be used to show that $y|u \sim \mathbb{Q}_u := N(G(u), A^{-\beta})$ where $\mathbb{Q}_u \ll \mathbb{Q}_0$ with

$$\frac{d\mathbb{Q}_u}{d\mathbb{Q}_0}(y) = \exp(-\Phi(u; y)),$$

and

$$\Phi(u; y) = \frac{1}{2} \|A^{\frac{\beta}{2}} e^{-A} u\|^2 - \langle A^{\frac{\beta}{2}} e^{-\frac{A}{2}} y, A^{\frac{\beta}{2}} e^{-\frac{A}{2}} u \rangle.$$

In the following we repeatedly use the fact that $A^\gamma e^{-\lambda A}$, $\lambda > 0$, is a bounded linear operator from \mathcal{H}^a to \mathcal{H}^b , any $a, b, \gamma \in \mathbb{R}$. Recall that $\nu_0(du, dy) = \mu_0(du)\mathbb{Q}_0(dy)$. Note that $\nu_0(H \times \mathcal{H}^{t'}) = 1$. Using the boundedness of $A^\gamma e^{-\lambda A}$, it may be shown that

$$\Phi : H \times \mathcal{H}^{t'} \rightarrow \mathbb{R}$$

is continuous and hence ν_0 -measurable by Lemma 4.

Theorem 14 shows that the posterior is given by μ^y where

$$\frac{d\mu^y}{d\mu_0}(u) = \frac{1}{Z} \exp(-\Phi(u; y)),$$

$$Z = \int_H \exp(-\Phi(u; y)) \mu_0(du),$$

provided that $Z > 0$ for y \mathbb{Q}_0 -a.s. We establish this positivity in the remainder of the proof. Since $y \in \mathcal{H}^t$ for any $t < \beta - \frac{d}{2}$, \mathbb{Q}_0 -a.s., we have that $y = A^{-t'/2} w_0$ for some $w_0 \in H$ and $t' < \beta - \frac{d}{2}$. Thus we may write

$$\Phi(u; y) = \frac{1}{2} \|A^{\frac{\beta}{2}} e^{-A} u\|^2 - \langle A^{\frac{\beta-t'}{2}} e^{-\frac{A}{2}} w_0, A^{\frac{\beta}{2}} e^{-\frac{A}{2}} u \rangle. \quad (10.34)$$

Then, using the boundedness of $A^\gamma e^{-\lambda A}$, $\lambda > 0$, together with (10.34), we have

$$\Phi(u; y) \leq C(\|u\|^2 + \|w_0\|^2)$$

where $\|w_0\|$ is finite \mathbb{Q}_0 -a.s. Thus,

$$Z \geq \int_{\|u\|^2 \leq 1} \exp(-C(1 + \|w_0\|^2)) \mu_0(du)$$

and, since $\mu_0(\|u\|^2 \leq 1) > 0$ (by Theorem 33 all balls have positive measure for Gaussians on a separable Banach space), the required positivity follows.

3.4 Elliptic Inverse Problem

We consider the elliptic inverse problem from Sect. 1.3 from the Bayesian perspective. We consider the use of both uniform and Gaussian priors. Before studying the inverse problem, however, it is important to derive some continuity properties of the forward problem. Throughout this section, we consider equation (10.7) under the assumption that $f \in V^*$.

3.4.1 Forward Problem

Recall that in Sect. 1.3, equation (10.10), we defined

$$X^+ = \left\{ v \in L^\infty(D) \mid \text{ess inf}_{x \in D} v(x) > 0 \right\}. \quad (10.35)$$

Then the map $\mathcal{R} : X^+ \rightarrow V$ by $\mathcal{R}(v) = p$. This map is well-defined by Lemma 2 and we have the following result.

Lemma 5. *For $i = 1, 2$, let*

$$\begin{aligned} -\nabla \cdot (\kappa_i \nabla p_i) &= f, \quad x \in D, \\ p_i &= 0, \quad x \in \partial D. \end{aligned}$$

Then

$$\|p_1 - p_2\|_V \leq \frac{1}{\kappa_{\min}^2} \|f\|_{V^*} \|\kappa_1 - \kappa_2\|_{L^\infty}$$

where we assume that

$$\kappa_{\min} := \text{ess inf}_{x \in D} \kappa_1(x) \wedge \text{ess inf}_{x \in D} \kappa_2(x) > 0.$$

Thus the function $\mathcal{R} : X^+ \rightarrow V$ is locally Lipschitz.

Proof. Let $e = \kappa_1 - \kappa_2$, $r = p_1 - p_2$. Then

$$\begin{aligned} -\nabla \cdot (\kappa_1 \nabla r) &= \nabla \cdot ((\kappa_1 - \kappa_2) \nabla p_2), \quad x \in D \\ r &= 0, \quad x \in \partial D. \end{aligned}$$

Multiplying by r and integrating by parts on both sides of the identity gives

$$\kappa_{\min} \int_D |\nabla r|^2 dx \leq \|(\kappa_2 - \kappa_1) \nabla p_2\| \|\nabla r\|.$$

Using the fact that $\|\varphi\|_V = \|\nabla \varphi\|$, and applying Lemma 2 to bound p_2 in V , we find that

$$\begin{aligned} \|r\|_V &\leq \|(\kappa_2 - \kappa_1) \nabla p_2\| / \kappa_{\min} \\ &\leq \|\kappa_2 - \kappa_1\|_{L^\infty} \|p_2\|_V / \kappa_{\min} \\ &\leq \frac{1}{\kappa_{\min}^2} \|f\|_{V^*} \|e\|_{L^\infty}. \end{aligned}$$

□

3.4.2 Uniform Priors

We now study the inverse problem of finding κ from a finite set of continuous linear functionals $\{l_j\}_{j=1}^J$ on V , representing measurements of p ; thus $l_j \in V^*$. To match the notation from Sect. 3.2, we take $\kappa = u$ and we define the separable Banach space X' as in Sect. 2.2. It is straightforward to see that Lemma 5 extends to the case where X^+ given by (10.35) is replaced by

$$X^+ = \left\{ v \in X' \mid \text{ess inf}_{x \in D} v(x) > 0 \right\} \quad (10.36)$$

since $X' \subset L^\infty(D)$. When considering uniform priors for the elliptic problem, we work with this definition of X^+ .

We define $G : X^+ \rightarrow \mathbb{R}^J$ by

$$G_j(u) = l_j(\mathcal{R}(u)), \quad j = 1, \dots, J$$

where, recall, the l_j are elements of V^* : bounded linear functionals on V . Then $G(u) = (G_1(u), \dots, G_J(u))$ and we are interested in the inverse problem of finding $u \in X^+$ from y where

$$y = G(u) + \eta$$

and η is the noise. We assume $\eta \sim N(0, \Gamma)$, for positive symmetric $\Gamma \in \mathbb{R}^{J \times J}$. (Use of other statistical assumptions on η is a straightforward extension of what follows whenever η has a smooth density on \mathbb{R}^J .)

Let μ_0 denote the prior measure constructed in Sect. 2.2. Then μ_0 -almost surely we have, by Theorem 2,

$$u \in X_0^+ := \left\{ v \in X' \mid \frac{1}{1+\delta} m_{\min} \leq v(x) \leq m_{\max} + \frac{\delta}{1+\delta} m_{\min} \quad \text{a.e. } x \in D \right\}. \quad (10.37)$$

Thus $\mu_0(X_0^+) = 1$.

The likelihood is defined as follows. Since $\eta \sim N(0, \Gamma)$, it follows that $\mathbb{Q}_0 = N(0, \Gamma)$, $\mathbb{Q}_u = N(G(u), \Gamma)$ and

$$\begin{aligned} \frac{d\mathbb{Q}_u}{d\mathbb{Q}_0}(y) &= \exp(-\Phi(u; y)), \\ \Phi(u; y) &= \frac{1}{2} |\Gamma^{-\frac{1}{2}}(y - G(u))|^2 - \frac{1}{2} |\Gamma^{-\frac{1}{2}}y|^2. \end{aligned}$$

Recall that $\nu_0(dy, du) = \mathbb{Q}_0(dy)\mu_0(du)$. Since $G : X^+ \rightarrow \mathbb{R}^J$ is locally Lipschitz by Lemma 5, Lemma 4 implies that $\Phi : X^+ \times Y \rightarrow \mathbb{R}$ is ν_0 -measurable. Thus Theorem 14 shows that $u|y \sim \mu^y$ where

$$\frac{d\mu^y}{d\mu_0}(u) = \frac{1}{Z} \exp(-\Phi(u; y)) \quad (10.38)$$

$$Z = \int_{X^+} \exp(-\Phi(u; y)) \mu_0(du),$$

provided $Z > 0$ for y \mathbb{Q}_0 -almost surely. To see that $Z > 0$, note that

$$Z = \int_{X_0^+} \exp(-\Phi(u; y)) \mu_0(du),$$

since $\mu_0(X_0^+) = 1$. On X_0^+ we have that $\mathcal{R}(\cdot)$ is bounded in V , and hence G is bounded in \mathbb{R}^J . Furthermore y is finite \mathbb{Q}_0 -almost surely. Thus \mathbb{Q}_0 -almost surely with respect to y , $\Phi(\cdot; y)$ is bounded on X_0^+ ; we denote the resulting bound by $M = M(y) < \infty$. Hence

$$Z \geq \int_{X_0^+} \exp(-M) \mu_0(du) = \exp(-M) > 0.$$

and the result is proved.

We may use Remark 5 to shift Φ by $\frac{1}{2}|\Gamma^{-\frac{1}{2}}y|^2$, since this is almost surely finite under \mathbb{Q}_0 and hence under $v(du, dy) = \mathbb{Q}_u(dy)\mu_0(du)$. We then obtain the equivalent form for the posterior distribution μ^y :

$$\frac{d\mu^y}{d\mu_0}(u) = \frac{1}{Z} \exp\left(-\frac{1}{2}|\Gamma^{-\frac{1}{2}}(y - G(u))|^2\right), \quad (10.39a)$$

$$Z = \int_X \exp\left(-\frac{1}{2}|\Gamma^{-\frac{1}{2}}(y - G(u))|^2\right) \mu_0(du). \quad (10.39b)$$

3.4.3 Gaussian Priors

We conclude this subsection by discussing the same inverse problem, but using Gaussian priors from Sect. 2.4. We now set $X = C(\overline{D})$ and $Y = \mathbb{R}^J$ and we note that X embeds continuously into $L^\infty(D)$. We assume that we can find an operator A which satisfies Assumption 2. We now take $\kappa = \exp(u)$ and define $G : X \rightarrow \mathbb{R}^J$ by

$$G_j(u) = l_j(\mathcal{R}(\exp(u))), \quad j = 1, \dots, J.$$

We take as prior on u the measure $N(0, A^{-s})$ with $s > d/2$. Then Theorem 12 shows that $\mu(X) = 1$. The likelihood is unchanged by the prior, since it concerns y given u , and is hence identical to that in the case of the uniform prior, although the mean shift from \mathbb{Q}_0 to \mathbb{Q}_u by $G(u)$ now has a different interpretation since $\kappa = \exp(u)$ rather than $\kappa = u$. Thus we again obtain (10.38) for the posterior distribution (albeit with a different definition of $G(u)$) provided that we can establish that, \mathbb{Q}_0 -a.s.,

$$Z = \int_X \exp\left(\frac{1}{2}|\Gamma^{-\frac{1}{2}}y|^2 - \frac{1}{2}|\Gamma^{-\frac{1}{2}}(y - G(u))|^2\right) \mu_0(du) > 0.$$

To this end, we use the fact that the unit ball in X , denoted B , has positive measure by Theorem 33 and that on this ball $\mathcal{R}(\exp(u))$ is bounded in V by $e^{-a}\|f\|_{V^*}$, by Lemma 2, for some finite positive constant a . This follows from the continuous embedding of X into L^∞ and since the infimum of $\kappa = \exp(u)$ is bounded below by $e^{-\|u\|_{L^\infty}}$. Thus G is bounded on B and, noting that y is \mathbb{Q}_0 -a.s. finite, we have for some $M = M(y) < \infty$,

$$\sup_{u \in B} \left(\frac{1}{2}|\Gamma^{-\frac{1}{2}}(y - G(u))|^2 - \frac{1}{2}|\Gamma^{-\frac{1}{2}}y|^2 \right) < M.$$

Hence

$$Z \geq \int_B \exp(-M) \mu_0(du) = \exp(-M) \mu_0(B) > 0$$

since all balls have positive measure for Gaussian measure on a separable Banach space. Thus we again obtain (10.39) for the posterior measure, now with the new definition of G , and hence Φ .

3.5 Bibliographic Notes

- Section 3.1. Theorem 13 is taken from [43] where it is used to compute expressions for the measure induced by various conditionings applied to SDEs. The existence of regular conditional probability distributions is discussed in [54], Theorem 6.3. Example 5, concerning end-point conditioning of measures defined via a density with respect to Wiener measure, finds application to problems from molecular dynamics in [82, 83]. Further material concerning the equivalence of posterior with respect to the prior may be found in [92, Chapters 3 and 6], [3, 4]. The equivalence of Gaussian measures is studied via the Feldman-Hájek theorem; see [28] and the Appendix. A proof of Lemma 4 can be found in [88, Chapter 1, Theorem 1.12]. See also [54, Lemma 1.5].
- Section 3.2. General development of Bayes' Theorem for inverse problems on function space, along the lines described here, may be found in [17, 92]. The reader is also directed to the papers [61, 62] for earlier related material and to [63–65] for recent developments.
- Section 3.3. The inverse problem for the heat equation was one of the first infinite-dimensional inverse problems to receive Bayesian treatment (see [36]), leading to further developments in [68, 71]. The problem is worked through in detail in [92]. To fully understand the details, the reader will need to study the Cameron-Martin theorem (concerning shifts in the mean of Gaussian measures) and the Feldman-Hájek theorem (concerning equivalence of Gaussian measures); both of these may be found in [14, 28, 67] and are also discussed in [92].
- Section 3.4. The elliptic inverse problem with the uniform prior is studied in [90]. A Gaussian prior is adopted in [25] and a Besov prior in [24].

4 Common Structure

In this section we discuss various common features of the posterior distribution arising from the Bayesian approach to inverse problems. We start, in Sect. 4.1, by studying the continuity properties of the posterior with respect to changes in data, proving a form of well posedness; indeed, we show that the posterior is Lipschitz in the data with respect to the Hellinger metric. In Sect. 4.2 we use similar ideas to study the effect of approximation on the posterior distribution, showing that small changes in the potential Φ lead to small changes in the posterior distribution, again in the Hellinger metric; this work may be used to translate error analysis pertaining to the forward problem into estimates on errors in the posterior distribution. In the final Sect. 4.3, we study an important link between the Bayesian approach to inverse problems and classical regularization techniques for inverse problems;

specifically we link the Bayesian MAP estimator to a Tikhonov-Phillips regularized least squares problem. The first two subsections work with general priors, while the final one is concerned with Gaussians only.

4.1 Well Posedness

In many classical inverse problems, small changes in the data can induce arbitrarily large changes in the solution, and some form of regularization is needed to counteract this ill posedness. We illustrate this effect with the inverse heat equation example. We then proceed to show that the Bayesian approach to inversion has the property that small changes in the data lead to small changes in the posterior distribution. Thus working with probability measures on the solution space, and adopting suitable priors, provides a form of regularization.

Example 6. Consider the heat equation introduced in Sect. 1.2 and both perfect data $y = e^{-A}u$, derived from the forward model with no noise, and noisy data $y' = e^{-A}u + \eta$. Consider the case where $\eta = \epsilon\varphi_j$ with ϵ small and φ_j a normalized eigenfunction of A . Thus $\|\eta\| = \epsilon$. Obviously application of the inverse of e^{-A} to y returns the point u which gave rise to the perfect data. It is natural to apply the inverse of e^{-A} to both y and to y' to understand the effect of the noise. Doing so yields the identity

$$\|e^A y - e^A y'\| = \|e^A(y - y')\| = \|e^A \eta\| = \epsilon \|e^A \varphi_j\| = \epsilon e^{\alpha_j}.$$

Recall Assumption 1 which gives $\alpha_j \asymp j^{2/d}$. Now fix any $a > 0$ and choose j large enough to ensure that $\alpha_j = (a+1)\log(\epsilon^{-1})$. It then follows that $\|y - y'\| = \mathcal{O}(\epsilon)$ while $\|e^A y - e^A y'\| = \mathcal{O}(\epsilon^{-a})$. This is a manifestation of ill posedness. Furthermore, since $a > 0$ is arbitrary, the ill posedness can be made arbitrarily bad by considering $a \rightarrow \infty$. \square

Our aim in this section is to show that this ill-posedness effect does not occur in the Bayesian posterior distribution: small changes in the data y lead to small changes in the measure μ^y . Let X and Y be separable Banach spaces, equipped with the Borel σ -algebra, and μ_0 a measure on X . We will work under assumptions which enable us to make sense of the following measure $\mu^y \ll \mu_0$ defined, for some $\Phi : X \times Y \rightarrow \mathbb{R}$, by

$$\frac{d\mu^y}{d\mu_0}(u) = \frac{1}{Z(y)} \exp(-\Phi(u; y)), \quad (10.40a)$$

$$Z(y) = \int_X \exp(-\Phi(u; y)) \mu_0(du). \quad (10.40b)$$

We make the following assumptions concerning Φ :

Assumptions 1. Let $X' \subseteq X$ and assume that $\Phi \in C(X' \times Y; \mathbb{R})$. Assume further that there are functions $M_i : \mathbb{R}^+ \times \mathbb{R}^+ \rightarrow \mathbb{R}^+$, $i = 1, 2$, monotonic non-decreasing separately in each argument, and with M_2 strictly positive, such that for all $u \in X'$, $y, y_1, y_2 \in B_Y(0, r)$,

$$\begin{aligned}\Phi(u; y) &\geq -M_1(r, \|u\|_X), \\ |\Phi(u; y_1) - \Phi(u; y_2)| &\leq M_2(r, \|u\|_X) \|y_1 - y_2\|_Y.\end{aligned}\quad \square$$

In order to measure the effect of changes in y on the measure μ^y , we need a metric on measures. We use the Hellinger metric defined in Sect. A.2.4.

Theorem 15. Let Assumptions 1 hold. Assume that $\mu_0(X') = 1$ and that $\mu_0(X' \cap B) > 0$ for some bounded set B in X . Assume additionally that, for every fixed $r > 0$,

$$\exp(M_1(r, \|u\|_X)) \in L_{\mu_0}^1(X; \mathbb{R}).$$

Then, for every $y \in Y$, $Z(y)$ given by (10.40b) is positive and finite and the probability measure μ^y given by (10.40) is well defined.

Proof. The boundedness of $Z(y)$ follows directly from the lower bound on Φ in Assumption 1, together with the assumed integrability condition in the theorem. Since $u \sim \mu_0$ satisfies $u \in X'$ a.s., we have

$$Z(y) = \int_{X'} \exp(-\Phi(u; y)) \mu_0(du).$$

Note that $B' = X' \cap B$ is bounded in X . Define

$$R_1 := \sup_{u \in B'} \|u\|_X < \infty.$$

Since $\Phi : X' \times Y \rightarrow \mathbb{R}$ is continuous, it is finite at every point in $B' \times \{y\}$. Thus, by the continuity of $\Phi(\cdot; \cdot)$ implied by Assumptions 1, we see that

$$\sup_{(u,y) \in B' \times B_Y(0,r)} \Phi(u; y) = R_2 < \infty.$$

Hence

$$Z(y) \geq \int_{B'} \exp(-R_2) \mu_0(du) = \exp(-R_2) \mu_0(B') > 0. \quad (10.41)$$

Since $\mu_0(B')$ is assumed positive and R_2 is finite, we deduce that $Z(y) > 0$. \square

Remarks 6. The following remarks apply to the preceding and following theorem.

- In the preceding theorem, we are not explicitly working in a Bayesian setting: we are showing that, under the stated conditions on Φ , the measure is well defined and normalizable. In Theorem 14, we did not need to check normalizability because μ^y was defined as a regular conditional probability, via Theorem 13, and therefore automatically normalizable.
- The lower bound (10.41) is used repeatedly in what follows, without comment.
- Establishing the integrability conditions for both the preceding and following theorem is often achieved for Gaussian μ_0 by appealing to the Fernique theorem.

Theorem 16. *Let Assumptions 1 hold. Assume that $\mu_0(X') = 1$ and that $\mu_0(X' \cap B) > 0$ for some bounded set B in X . Assume additionally that, for every fixed $r > 0$,*

$$\exp(M_1(r, \|u\|_X)) \left(1 + M_2(r, \|u\|_X)^2\right) \in L_{\mu_0}^1(X; \mathbb{R}).$$

Then there is $C = C(r) > 0$ such that, for all $y, y' \in B_Y(0, r)$

$$d_{\text{Hell}}(\mu^y, \mu^{y'}) \leq C \|y - y'\|_Y.$$

Proof. Throughout this proof, we use C to denote a constant independent of u , but possibly depending on the fixed value of r ; it may change from occurrence to occurrence. We use the fact that, since $M_2(r, \cdot)$ is monotonic non-decreasing and strictly positive on $[0, \infty)$,

$$\exp(M_1(r, \|u\|_X)) M_2(r, \|u\|_X) \leq \exp(M_1(r, \|u\|_X)) \left(1 + M_2(r, \|u\|_X)^2\right), \quad (10.42a)$$

$$\exp(M_1(r, \|u\|_X)) \leq \exp(M_1(r, \|u\|_X)) \left(1 + M_2(r, \|u\|_X)^2\right). \quad (10.42b)$$

Let $Z = Z(y)$ and $Z' = Z(y')$ denote the normalization constants for μ^y and $\mu^{y'}$ so that, by Theorem 15,

$$Z = \int_{X'} \exp(-\Phi(u; y)) \mu_0(du) > 0,$$

$$Z' = \int_{X'} \exp(-\Phi(u; y')) \mu_0(du) > 0.$$

Then, using the local Lipschitz property of the exponential and the assumed Lipschitz continuity of $\Phi(u; \cdot)$, together with (10.42a), we have

$$\begin{aligned} |Z - Z'| &\leq \int_{X'} |\exp(-\Phi(u; y)) - \exp(-\Phi(u; y'))| \mu_0(du) \\ &\leq \int_{X'} \exp(M_1(r, \|u\|_X)) |\Phi(u; y) - \Phi(u; y')| \mu_0(du) \\ &\leq \left(\int_{X'} \exp(M_1(r, \|u\|_X)) M_2(r, \|u\|_X) \mu_0(du) \right) \|y - y'\|_Y \\ &\leq \left(\int_{X'} \exp(M_1(r, \|u\|_X)) (1 + M_2(r, \|u\|_X)^2) \mu_0(du) \right) \|y - y'\|_Y \\ &\leq C \|y - y'\|_Y. \end{aligned}$$

The last line follows because the integrand is in $L^1_{\mu_0}$ by assumption. From the definition of Hellinger distance, we have

$$\left(d_{\text{Hell}}(\mu^y, \mu^{y'}) \right)^2 \leq I_1 + I_2,$$

where

$$\begin{aligned} I_1 &= \frac{1}{Z} \int_{X'} \left(\exp\left(-\frac{1}{2}\Phi(u; y)\right) - \exp\left(-\frac{1}{2}\Phi(u; y')\right) \right)^2 \mu_0(du), \\ I_2 &= |Z^{-\frac{1}{2}} - (Z')^{-\frac{1}{2}}|^2 \int_{X'} \exp(-\Phi(u; y')) \mu_0(du). \end{aligned}$$

Note that, again using similar Lipschitz calculations to those above, using the fact that $Z > 0$ and Assumptions 1,

$$\begin{aligned} I_1 &\leq \frac{1}{4Z} \int_{X'} \exp(M_1(r, \|u\|_X)) |\Phi(u; y) - \Phi(u; y')|^2 \mu_0(du) \\ &\leq \frac{1}{Z} \left(\int_{X'} \exp(M_1(r, \|u\|_X)) M_2(r, \|u\|_X)^2 \mu_0(du) \right) \|y - y'\|_Y^2 \\ &\leq C \|y - y'\|_Y^2. \end{aligned}$$

Also, using Assumptions 1, together with (10.42b),

$$\begin{aligned} \int_{X'} \exp(-\Phi(u; y')) \mu_0(du) &\leq \int_{X'} \exp(M_1(r, \|u\|_X)) \mu_0(du) \\ &< \infty. \end{aligned}$$

Hence

$$I_2 \leq C(Z^{-3} \vee (Z')^{-3})|Z - Z'|^2 \leq C\|y - y'\|_Y^2.$$

The result is complete. \square

Remark 1. The Hellinger metric has the very desirable property that it translates directly into bounds on expectations. For functions f which are in $L_{\mu^y}^2(X; \mathbb{R})$ and $L_{\mu^{y'}}^2(X; \mathbb{R})$, the closeness of the Hellinger metric implies closeness of expectations of f . To be precise, for $y, y' \in B_Y(0, r)$, we have

$$|\mathbb{E}^{\mu^y} f(u) - \mathbb{E}^{\mu^{y'}} f(u)| \leq C d_{\text{Hell}}(\mu^y, \mu^{y'})$$

where constant C depends on r and on the expectations of $|f|^2$ under μ^y and $\mu^{y'}$. It follows that

$$|\mathbb{E}^{\mu^y} f(u) - \mathbb{E}^{\mu^{y'}} f(u)| \leq C \|y - y'\|,$$

for a possibly different constant C which also depends on r and on the expectations of $|f|^2$ under μ^y and $\mu^{y'}$.

4.2 Approximation

In this section we concentrate on continuity properties of the posterior measure with respect to approximation of the potential Φ . The methods used are very similar to those in the previous subsection, and we establish a continuity property of the posterior distribution, in the Hellinger metric, with respect to small changes in the potential Φ .

Because the data y plays no explicit role in this discussion, we drop explicit reference to it. Let X be a Banach space and μ_0 a measure on X . Assume that μ and μ^N are both absolutely continuous with respect to μ_0 and given by

$$\frac{d\mu}{d\mu_0}(u) = \frac{1}{Z} \exp(-\Phi(u)), \quad (10.43a)$$

$$Z = \int_X \exp(-\Phi(u)) \mu_0(du) \quad (10.43b)$$

and

$$\frac{d\mu^N}{d\mu_0}(u) = \frac{1}{Z^N} \exp(-\Phi^N(u)), \quad (10.44a)$$

$$Z^N = \int_X \exp(-\Phi^N(u)) \mu_0(du) \quad (10.44b)$$

respectively. The measure μ^N might arise, for example, through an approximation of the forward map G underlying an inverse problem of the form (10.29). It is natural to ask whether closeness of the forward map and its approximation imply closeness of the posterior measures. We now address this question.

Assumptions 2. Let $X' \subseteq X$ and assume that $\Phi \in C(X'; \mathbb{R})$. Assume further that there are functions $M_i : \mathbb{R}^+ \rightarrow \mathbb{R}^+$, $i = 1, 2$, independent of N and monotonic non-decreasing separately in each argument, and with M_2 strictly positive, such that for all $u \in X'$,

$$\begin{aligned}\Phi(u) &\geq -M_1(\|u\|_X), \\ \Phi^N(u) &\geq -M_1(\|u\|_X), \\ |\Phi(u) - \Phi^N(u)| &\leq M_2(\|u\|_X)\psi(N),\end{aligned}$$

where $\psi(N) \rightarrow 0$ as $N \rightarrow \infty$. \square

The following two theorems are very similar to Theorems 15 and 16, and the proofs are adapted to estimate changes in the posterior caused by changes in the potential Φ , rather than the data y .

Theorem 17. Let Assumptions 2 hold. Assume that $\mu_0(X') = 1$ and that $\mu_0(X' \cap B) > 0$ for some bounded set B in X . Assume additionally that, for every fixed $r > 0$,

$$\exp(M_1(r, \|u\|_X)) \in L_{\mu_0}^1(X; \mathbb{R}).$$

Then Z and Z^N given by (10.43b) and (10.44b) are positive and finite and the probability measures μ and μ^N given by (10.43) and (10.44) are well defined. Furthermore, for sufficiently large N , Z^N given by (10.44b) is bounded below by a positive constant independent of N .

Proof. Finiteness of the normalization constants Z and Z^N follows from the lower bounds on Φ and Φ^N given in Assumptions 2, together with the integrability condition in the theorem. Since $u \sim \mu_0$ satisfies $u \in X'$ a.s., we have

$$Z = \int_{X'} \exp(-\Phi(u)) \mu_0(du).$$

Note that $B' = X' \cap B$ is bounded in X . Thus

$$R_1 := \sup_{u \in B'} \|u\|_X < \infty.$$

Since $\Phi : X' \rightarrow \mathbb{R}$ is continuous, it is finite at every point in B' . Thus, by the properties of $|\Phi(\cdot) - \Phi^N(\cdot)|$ implied by Assumptions 2, we see that

$$\sup_{u \in B'} \Phi(u) = R_2 < \infty.$$

Hence

$$Z \geq \int_{B'} \exp(-R_2) \mu_0(du) = \exp(-R_2) \mu_0(B').$$

Since $\mu_0(B')$ is assumed positive and R_2 is finite, we deduce that $Z > 0$. By Assumption 2, we may choose N large enough so that

$$\sup_{u \in B'} |\Phi(u) - \Phi^N(u)| \leq R_2$$

so that

$$\sup_{u \in B'} \Phi^N(u) \leq 2R_2 < \infty.$$

Hence

$$Z^N \geq \int_{B'} \exp(-2R_2) \mu_0(du) = \exp(-2R_2) \mu_0(B').$$

Since $\mu_0(B')$ is assumed positive and R_2 is finite, we deduce that $Z^N > 0$. Furthermore, the lower bound is independent of N , as required. \square

Theorem 18. *Let Assumptions 2 hold. Assume that $\mu_0(X') = 1$ and that $\mu_0(X' \cap B) > 0$ for some bounded set B in X . Assume additionally that*

$$\exp(M_1(\|u\|_X)) \left(1 + M_2(\|u\|_X)^2\right) \in L^1_{\mu_0}(X; \mathbb{R}).$$

Then there is $C > 0$ such that, for all N sufficiently large,

$$d_{\text{Hell}}(\mu, \mu^N) \leq C \psi(N).$$

Proof. Throughout this proof, we use C to denote a constant independent of u and N ; it may change from occurrence to occurrence. We use the fact that, since $M_2(\cdot)$ is monotonic non-decreasing and since it is strictly positive on $[0, \infty)$,

$$\exp(M_1(\|u\|_X)) M_2(\|u\|_X) \leq \exp(M_1(\|u\|_X)) \left(1 + M_2(\|u\|_X)^2\right), \quad (10.45a)$$

$$\exp(M_1(\|u\|_X)) \leq \exp(M_1(\|u\|_X)) \left(1 + M_2(\|u\|_X)^2\right). \quad (10.45b)$$

Let Z and Z^N denote the normalization constants for μ and μ^N so that for all N sufficiently large, by Theorem 17,

$$Z = \int_{X'} \exp(-\Phi(u)) \mu_0(du) > 0,$$

$$Z^N = \int_{X'} \exp(-\Phi^N(u)) \mu_0(du) > 0,$$

with positive lower bounds independent of N . Then, using the local Lipschitz property of the exponential and the approximation property of $\Phi^N(\cdot)$ from Assumptions 2, together with (10.45a), we have

$$\begin{aligned} |Z - Z^N| &\leq \int_{X'} |\exp(-\Phi(u)) - \exp(-\Phi^N(u))| \mu_0(du) \\ &\leq \int_{X'} \exp(M_1(\|u\|_X)) |\Phi(u) - \Phi^N(u)| \mu_0(du) \\ &\leq \left(\int_{X'} \exp(M_1(\|u\|_X)) M_2(\|u\|_X) \mu_0(du) \right) \psi(N) \\ &\leq \left(\int_{X'} \exp(M_1(\|u\|_X)) (1 + M_2(\|u\|_X)^2) \mu_0(du) \right) \psi(N) \\ &\leq C \psi(N). \end{aligned}$$

The last line follows because the integrand is in $L^1_{\mu_0}$ by assumption. From the definition of Hellinger distance, we have

$$\left(d_{\text{Hell}}(\mu^y, \mu^{y'}) \right)^2 \leq I_1 + I_2,$$

where

$$I_1 = \frac{1}{Z} \int_{X'} \left(\exp\left(-\frac{1}{2}\Phi(u)\right) - \exp\left(-\frac{1}{2}\Phi^N(u)\right) \right)^2 \mu_0(du),$$

$$I_2 = |Z^{-\frac{1}{2}} - (Z^N)^{-\frac{1}{2}}|^2 \int_{X'} \exp(-\Phi^N(u)) \mu_0(du).$$

Note that, again by means of similar Lipschitz calculations to those above, using the fact that $Z, Z^N > 0$ uniformly for N sufficiently large by Theorem 17, and Assumptions 2,

$$\begin{aligned} I_1 &\leq \frac{1}{4Z} \int_{X'} \exp(M_1(\|u\|_X)) |\Phi(u) - \Phi^N(u)|^2 \mu_0(du) \\ &\leq \frac{1}{Z} \left(\int_{X'} \exp(M_1(\|u\|_X)) M_2(\|u\|_X)^2 \mu_0(du) \right) \psi(N)^2 \\ &\leq C \psi(N)^2. \end{aligned}$$

Also, using Assumptions 2, together with (10.45b),

$$\begin{aligned} \int_{X'} \exp(-\Phi^N(u)) \mu_0(du) &\leq \int_{X'} \exp(M_1(\|u\|_X)) \mu_0(du) \\ &< \infty, \end{aligned}$$

and the upper bound is independent of N . Hence

$$I_2 \leq C(Z^{-3} \vee (Z^N)^{-3}) |Z - Z^N|^2 \leq C \psi(N)^2.$$

The result is complete. \square

Remarks 7. The following two remarks are relevant to establishing the conditions of the preceding two theorems and to applying them.

- As mentioned in the previous subsection concerning well posedness, the Fernique theorem can frequently be used to establish integrability conditions, such as those in the two preceding theorems when μ_0 is Gaussian.
- Using the ideas underlying Remark 1, the preceding theorem enables us to translate errors arising from approximation of the forward problem into errors in the Bayesian solution of the inverse problem. Furthermore, the errors in the forward and inverse problems scale the same way with respect to N . For functions f which are in L_μ^2 and $L_{\mu^N}^2$, uniformly with respect to N , the closeness of the Hellinger metric implies closeness of expectations of f :

$$|\mathbb{E}^\mu f(u) - \mathbb{E}^{\mu^N} f(u)| \leq C \psi(N).$$

4.3 MAP Estimators and Tikhonov Regularization

The aim of this section is to connect the probabilistic approach to inverse problems with the classical method of Tikhonov regularization. We consider the setting in which the prior measure μ_0 is a Gaussian measure. We then show that MAP estimators, points of maximal probability, coincide with minimizers of a Tikhonov-Phillips regularized least squares function, with regularization being with respect to the Cameron-Martin norm of the Gaussian prior. The data y plays no explicit role in our developments here, and so we work in the setting of equation (10.43). Recall, however, that in the context of inverse problems, a classical methodology is to simply try and minimize (subject to some regularization) $\Phi(u)$. Indeed for finite data and Gaussian observational noise with Gaussian distribution $N(0, \Gamma)$, we have

$$\Phi(u) = \frac{1}{2} |\Gamma^{-\frac{1}{2}}(y - G(u))|^2.$$

Thus Φ is simply a covariance weighted model-data misfit least squares function.

In this section we show that maximizing probability under μ (in a sense that we will make precise in what follows) is equivalent to minimizing

$$I(u) = \begin{cases} \Phi(u) + \frac{1}{2}\|u\|_E^2 & \text{if } u \in E, \text{ and} \\ +\infty & \text{else.} \end{cases} \quad (10.46)$$

Here $(E, \|\cdot\|_E)$ denotes the Cameron-Martin space associated to the Gaussian prior μ_0 . We view μ_0 as a Gaussian probability measure on a separable Banach space $(X, \|\cdot\|_X)$ so that $\mu_0(X) = 1$. We make the following assumptions about the function Φ :

Assumption 3. *The function $\Phi: X \rightarrow \mathbb{R}$ satisfies the following conditions:*

(i) *For every $\epsilon > 0$, there is an $M = M(\epsilon) \in \mathbb{R}$, such that for all $u \in X$,*

$$\Phi(u) \geq M - \epsilon\|u\|_X^2.$$

(ii) *Φ is locally bounded from above, i.e., for every $r > 0$ there exists $K = K(r) > 0$ such that, for all $u \in X$ with $\|u\|_X < r$, we have*

$$\Phi(u) \leq K.$$

(iii) *Φ is locally Lipschitz continuous, i.e., for every $r > 0$ there exists $L = L(r) > 0$ such that for all $u_1, u_2 \in X$ with $\|u_1\|_X, \|u_2\|_X < r$, we have*

$$|\Phi(u_1) - \Phi(u_2)| \leq L\|u_1 - u_2\|_X.$$

In finite dimensions, for measures which have a continuous density with respect to Lebesgue measure, there is an obvious notion of most likely point(s): simply the point(s) at which the Lebesgue density is maximized. This way of thinking does not translate into the infinite-dimensional context, but there is a way of restating it which does. Fix a small radius $\delta > 0$ and identify centres of balls of radius δ which have maximal probability. Letting $\delta \rightarrow 0$ then recovers the preceding definition, when there is a continuous Lebesgue density. We adopt this small ball approach in the infinite-dimensional setting.

For $z \in E$, let $B^\delta(z) \subset X$ be the open ball centred at $z \in X$ with radius δ in X . Let

$$J^\delta(z) = \mu(B^\delta(z))$$

be the mass of the ball $B^\delta(z)$ under the measure μ . Similarly we define

$$J_0^\delta(z) = \mu_0(B^\delta(z))$$

the mass of the ball $B^\delta(z)$ under the Gaussian prior. Recall that all balls in a separable Banach space have positive Gaussian measure, by Theorem 33; it thus follows that $J_0^\delta(z)$ is finite and positive for any $z \in E$. By Assumptions 3(i) and (ii) together with the Fernique Theorem 10, the same is true for $J^\delta(z)$. Our first theorem encapsulates the idea that probability is maximized where I is minimized. To see this, fix any point z_2 in the Cameron-Martin space E and notice that the probability of the small ball at z_1 is maximized, asymptotically as the radius of the ball tends to zero, at minimizers of I .

Theorem 19. *Let Assumptions 3 hold and assume that $\mu_0(X) = 1$. Then the function I defined by (10.46) satisfies, for any $z_1, z_2 \in E$,*

$$\lim_{\delta \rightarrow 0} \frac{J^\delta(z_1)}{J^\delta(z_2)} = \exp(I(z_2) - I(z_1)).$$

Proof. Since $J^\delta(z)$ is finite and positive for any $z \in E$, the ratio of interest is finite and positive. The key estimate in the proof is given in Theorem 35:

$$\lim_{\delta \rightarrow 0} \frac{J_0^\delta(z_1)}{J_0^\delta(z_2)} = \exp\left(\frac{1}{2}\|z_2\|_E^2 - \frac{1}{2}\|z_1\|_E^2\right). \quad (10.47)$$

This estimate transfers questions about probability, naturally asked on the space X of full measure under μ_0 , into statements concerning the Cameron-Martin norm of μ_0 ; note that under this norm, a random variable distributed as μ_0 is almost surely infinite so the result is nontrivial.

We have

$$\begin{aligned} \frac{J^\delta(z_1)}{J^\delta(z_2)} &= \frac{\int_{B^\delta(z_1)} \exp(-\Phi(u)) \mu_0(du)}{\int_{B^\delta(z_2)} \exp(-\Phi(v)) \mu_0(dv)} \\ &= \frac{\int_{B^\delta(z_1)} \exp(-\Phi(u) + \Phi(z_1)) \exp(-\Phi(z_1)) \mu_0(du)}{\int_{B^\delta(z_2)} \exp(-\Phi(v) + \Phi(z_2)) \exp(-\Phi(z_2)) \mu_0(dv)}. \end{aligned}$$

By Assumption 3 (iii), there is $L = L(r)$ such that, for all $u, v \in X$ with $\max\{\|u\|_X, \|v\|_X\} < r$,

$$-L\|u - v\|_X \leq \Phi(u) - \Phi(v) \leq L\|u - v\|_X.$$

If we define $L_1 = L(\|z_1\|_X + \delta)$ and $L_2 = L(\|z_2\|_X + \delta)$, then we have

$$\begin{aligned} \frac{J^\delta(z_1)}{J^\delta(z_2)} &\leq e^{\delta(L_1 + L_2)} \frac{\int_{B^\delta(z_1)} \exp(-\Phi(z_1)) \mu_0(du)}{\int_{B^\delta(z_2)} \exp(-\Phi(z_2)) \mu_0(dv)} \\ &= e^{\delta(L_1 + L_2)} e^{-\Phi(z_1) + \Phi(z_2)} \frac{\int_{B^\delta(z_1)} \mu_0(du)}{\int_{B^\delta(z_2)} \mu_0(dv)}. \end{aligned}$$

Now, by (10.47), we have

$$\frac{J^\delta(z_1)}{J^\delta(z_2)} \leq r_1(\delta) e^{\delta(L_2 + L_1)} e^{-I(z_1) + I(z_2)}$$

with $r_1(\delta) \rightarrow 1$ as $\delta \rightarrow 0$. Thus

$$\limsup_{\delta \rightarrow 0} \frac{J^\delta(z_1)}{J^\delta(z_2)} \leq e^{-I(z_1) + I(z_2)}. \quad (10.48)$$

Similarly we obtain

$$\frac{J^\delta(z_1)}{J^\delta(z_2)} \geq \frac{1}{r_2(\delta)} e^{-\delta(L_2 + L_1)} e^{-I(z_1) + I(z_2)}$$

with $r_2(\delta) \rightarrow 1$ as $\delta \rightarrow 0$ and deduce that

$$\liminf_{\delta \rightarrow 0} \frac{J^\delta(z_1)}{J^\delta(z_2)} \geq e^{-I(z_1) + I(z_2)} \quad (10.49)$$

Inequalities (10.48) and (10.49) give the desired result.

We have thus linked the Bayesian approach to inverse problems with a classical regularization technique. We conclude the subsection by showing that, under the prevailing Assumption 3, the minimization problem for I is well defined. We first recall a basic definition and lemma from the calculus of variations.

Definition 1. The function $I : E \rightarrow \mathbb{R}$ is *weakly lower semicontinuous* if

$$\liminf_{n \rightarrow \infty} I(u_n) \geq I(u)$$

whenever $u_n \rightharpoonup u$ in E . The function $I : E \rightarrow \mathbb{R}$ is *weakly continuous* if

$$\lim_{n \rightarrow \infty} I(u_n) = I(u)$$

whenever $u_n \rightharpoonup u$ in E . \square

Clearly weak continuity implies weak lower semicontinuity.

Lemma 6. If $(E, \langle \cdot, \cdot \rangle_E)$ is a Hilbert space with induced norm $\|\cdot\|_E$, then the quadratic form $J(u) := \frac{1}{2}\|u\|_E^2$ is weakly lower semicontinuous.

Proof. The result follows from the fact that

$$\begin{aligned} J(u_n) - J(u) &= \frac{1}{2} \|u_n\|_E^2 - \frac{1}{2} \|u\|_E^2 \\ &= \frac{1}{2} \langle u_n - u, u_n + u \rangle_E \\ &= \frac{1}{2} \langle u_n - u, 2u \rangle_E + \frac{1}{2} \|u_n - u\|_E^2 \\ &\geq \frac{1}{2} \langle u_n - u, 2u \rangle_E. \end{aligned}$$

But the right-hand side tends to zero since $u_n \rightarrow u$ in E . Hence, the result follows.

Theorem 20. Suppose that Assumption 3 hold and let E be a Hilbert space compactly embedded in X . Then there exists $\bar{u} \in E$ such that

$$I(\bar{u}) = \bar{I} := \inf\{I(u) : u \in E\}.$$

Furthermore, if $\{u_n\}$ is a minimizing sequence satisfying $I(u_n) \rightarrow I(\bar{u})$, then there is a subsequence $\{u_{n'}\}$ that converges strongly to \bar{u} in E .

Proof. Compactness of E in X implies that, for some universal constant C ,

$$\|u\|_X^2 \leq C \|u\|_E^2.$$

Hence, by Assumption 3(i), it follows that, for any $\epsilon > 0$, there is $M(\epsilon) \in \mathbb{R}$ such that

$$\left(\frac{1}{2} - C\epsilon\right) \|u\|_E^2 + M(\epsilon) \leq I(u).$$

By choosing ϵ sufficiently small, we deduce that there is $M \in \mathbb{R}$ such that, for all $u \in E$,

$$\frac{1}{4} \|u\|_E^2 + M \leq I(u). \quad (10.50)$$

Let u_n be an infimizing sequence satisfying $I(u_n) \rightarrow \bar{I}$ as $n \rightarrow \infty$. For any $\delta > 0$ there is $N = N_1(\delta)$:

$$\bar{I} \leq I(u_n) \leq \bar{I} + \delta, \quad \forall n \geq N_1. \quad (10.51)$$

Using (10.50) we deduce that the sequence $\{u_n\}$ is bounded in E and, since E is a Hilbert space, there exists $\bar{u} \in E$ such that $u_n \rightharpoonup \bar{u}$ in E . By the compact embedding

of E in X we deduce that $u_n \rightarrow \bar{u}$, strongly in X . By the Lipschitz continuity of Φ in X (Assumption 3(iii)), we deduce that $\Phi(u_n) \rightarrow \Phi(\bar{u})$. Thus, Φ is weakly continuous on E . The functional $J(u) := \frac{1}{2}\|u\|_E^2$ is weakly lower semicontinuous on E by Lemma 6. Hence $I(u) = J(u) + \Phi(u)$ is weakly lower semicontinuous on E . Using this fact in (10.51), it follows that, for any $\delta > 0$,

$$\bar{I} \leq I(\bar{u}) \leq \bar{I} + \delta.$$

Since δ is arbitrary, the first result follows.

By passing to a further subsequence, and for $n, \ell \geq N_2(\delta)$,

$$\begin{aligned} \frac{1}{4}\|u_n - u_\ell\|_E^2 &= \frac{1}{2}\|u_n\|_E^2 + \frac{1}{2}\|u_\ell\|_E^2 - \frac{1}{4}\|u_n + u_\ell\|_E^2 \\ &= I(u_n) + I(u_\ell) - 2I\left(\frac{1}{2}(u_n + u_\ell)\right) - \Phi(u_n) - \Phi(u_\ell) + 2\Phi\left(\frac{1}{2}(u_n + u_\ell)\right) \\ &\leq 2(\bar{I} + \delta) - 2\bar{I} - \Phi(u_n) - \Phi(u_\ell) + 2\Phi\left(\frac{1}{2}(u_n + u_\ell)\right) \\ &\leq 2\delta - \Phi(u_n) - \Phi(u_\ell) + 2\Phi\left(\frac{1}{2}(u_n + u_\ell)\right). \end{aligned}$$

But u_n, u_ℓ and $\frac{1}{2}(u_n + u_\ell)$ all converge strongly to \bar{u} in X . Thus, by continuity of Φ , we deduce that for all $n, \ell \geq N_3(\delta)$,

$$\frac{1}{4}\|u_n - u_\ell\|_E^2 \leq 3\delta.$$

Hence the sequence is Cauchy in E and converges strongly and the proof is complete.

Corollary 1. *Suppose that Assumptions 3 hold and the Gaussian measure μ_0 with Cameron-Martin space E satisfies $\mu_0(X) = 1$. Then there exists $\bar{u} \in E$ such that*

$$I(\bar{u}) = \bar{I} := \inf\{I(u) : u \in E\}.$$

Furthermore, if $\{u_n\}$ is a minimizing sequence satisfying $I(u_n) \rightarrow I(\bar{u})$, then there is a subsequence $\{u_{n'}\}$ that converges strongly to \bar{u} in E .

Proof. By Theorem 34, E is compactly embedded in X . Hence the result follows by Theorem 20.

4.4 Bibliographic Notes

- Section 4.1. The well-posedness theory described here was introduced in the papers [17] and [92]. Relationships between the Hellinger distance on probability measures and the total variation distance and Kullback-Leibler divergence may be found in [38] and Pollard (Distances and affinities between measures. Unpublished manuscript, <http://www.stat.yale.edu/~pollard/Books/Asymptopia/Metrics.pdf>), as well as in [92].
- Section 4.2. Generalization of the well-posedness theory to study the effect of numerical approximation of the forward model on the inverse problem may be found in [20]. The relationship between expectations and Hellinger distance, as used in Remark 7, is demonstrated in [92].
- Section 4.3. The connection between Tikhonov-Phillips regularization and MAP estimators is widely appreciated in computational Bayesian inverse problems; see [53]. Making the connection rigorous in the separable Banach space setting is the subject of the paper [30]; further references to the historical development of the subject may be found therein. Related to Lemma 6, see also [23, Chapter 3].

5 Measure Preserving Dynamics

The aim of this section is to study Markov processes, in continuous time, and Markov chains, in discrete time, which preserve the measure μ given by (10.43). The overall setting is described in Sect. 5.1 and introduces the role of detailed balance and reversibility in constructing measure-preserving Markov chains/processes. Section 5.2 concerns Markov chain Monte Carlo (MCMC) methods; these are Markov chains which are invariant with respect to μ . Metropolis-Hastings methods are introduced and the role of detailed balance in their construction is explained. The benefit of conceiving MCMC methods which are defined on the infinite-dimensional space is emphasized. In particular, the idea of using proposals which preserve the prior, more specifically which are prior reversible, is introduced as an example. In Sect. 5.3 we show how sequential Monte Carlo (SMC) methods can be used to construct approximate samples from the measure μ given by (10.43). Again our perspective is to construct algorithms which are probably well defined on the infinite-dimensional space, and in fact we find an upper bound for the approximation error of the SMC method which proves its convergence on an infinite-dimensional space. The MCMC methods from the previous section play an important role in the construction of these SMC methods. Sections 5.4–5.6 concern continuous time μ -reversible processes. In particular they concern derivation and study of a Langevin equation which is invariant with respect to the measure μ . (Note that this is called the overdamped Langevin equation for a physicist and the plain Langevin equation for a statistician.) In continuous time we work entirely in the case of Gaussian prior measure $\mu_0 = N(0, \mathcal{C})$ on Hilbert space \mathcal{H} with inner product and norm denoted by $\langle \cdot, \cdot \rangle$ and $\| \cdot \|$, respectively; however, in discrete time our analysis is more general, applying on a separable Banach space $(X, \| \cdot \|)$ and for quite general prior measure.

5.1 General Setting

This section is devoted to Banach space valued Markov chains or processes which are invariant with respect to the posterior measure μ^y constructed in Sect. 3.2. Within this section, the data y arising in the inverse problems plays no explicit role; indeed the theory applies to a wide range of measures μ on separable Banach space X . Thus the discussion in this chapter includes, but is not limited to, Bayesian inverse problems. All of the Markov chains we construct will exploit structure in a reference measure μ_0 with respect to which the measure μ is absolutely continuous; thus μ has a density with respect to μ_0 . In continuous time we will explicitly use the Gaussianity of μ_0 , but in discrete time we will be more general.

Let μ_0 be a reference measure on the separable Banach space X equipped with the Borel σ -algebra $\mathcal{B}(X)$. We assume that $\mu \ll \mu_0$ is given by

$$\frac{d\mu}{d\mu_0}(u) = \frac{1}{Z} \exp(-\Phi(u)), \quad (10.52a)$$

$$Z = \int_X \exp(-\Phi(u)) \mu_0(du), \quad (10.52b)$$

where $Z \in (0, \infty)$. In the following we let $P(u, dv)$ denote a Markov transition kernel so that $P(u, \cdot)$ is a probability measure on $(X, \mathcal{B}(X))$ for each $u \in X$. Our interest is in probability kernels which preserve μ .

Definition 2. The Markov chain with transition kernel P is *invariant* with respect to μ if

$$\int_X \mu(du) P(u, \cdot) = \mu(\cdot)$$

as measures on $(X, \mathcal{B}(X))$. The Markov kernel is said to satisfy *detailed balance* with respect to μ if

$$\mu(du) P(u, dv) = \mu(dv) P(v, du)$$

as measures on $(X \times X, \mathcal{B}(X) \otimes \mathcal{B}(X))$. The resulting Markov chain is then said to be *reversible* with respect to μ . \square

It is straightforward to see, by integrating the detailed balance condition with respect to u and using the fact that $P(v, du)$ is a Markov kernel, the following:

Lemma 7. A Markov chain which is reversible with respect to μ is also invariant with respect to μ .

Reversible Markov chains and processes arise naturally in many physical systems which are in statistical equilibrium. They are also important, however, as a means of

constructing Markov chains which are invariant with respect to a given probability measure. We demonstrate this in Sect. 5.2 where we consider the Metropolis-Hastings variant of MCMC methods. Then, in Sects. 5.4, 5.5 and 5.6, we move to continuous time Markov processes. In particular we show that the equation

$$\frac{du}{dt} = -u - \mathcal{C}D\Phi(u) + \sqrt{2}\frac{dW}{dt}, \quad u(0) = u_0, \quad (10.53)$$

preserves the measure μ , where W is a \mathcal{C} -Wiener process, defined below in Sect. A.4. Precisely we show that if $u_0 \sim \mu$, independently of the driving Wiener process, then $\mathbb{E}\varphi(u(t)) = \mathbb{E}\varphi(u_0)$ for all $t > 0$ for continuous bounded φ defined on an appropriately chosen subspaces, under boundedness conditions on Φ and its derivatives.

Example 7. Consider the (measurable) Hilbert space $(\mathcal{H}, \mathbf{B}(\mathcal{H}))$ equipped, as usual, with the Borel σ -algebra. Let μ denote the Gaussian measure $N(0, \mathcal{C})$ on \mathcal{H} and, for fixed u , let $P(u, dv)$ denote the Gaussian measure $N((1 - \beta^2)^{\frac{1}{2}}u, \beta^2\mathcal{C})$, also viewed as a probability measure on \mathcal{H} . Thus $v \sim P(u, dv)$ can be expressed as $v = (1 - \beta^2)^{\frac{1}{2}}u + \beta\xi$ where $\xi \sim N(0, \mathcal{C})$ is independent of u . We show that P is reversible, and hence invariant, with respect to μ . To see this we note that $\mu(du)P(u, dv)$ is a centred Gaussian measure on $\mathcal{H} \times \mathcal{H}$, equipped with the σ -algebra $\mathbf{B}(\mathcal{H}) \otimes \mathbf{B}(\mathcal{H})$. The covariance of the jointly varying random variable is characterized by the identities

$$\mathbb{E}u \otimes u = \mathcal{C}, \quad \mathbb{E}v \otimes v = \mathcal{C}, \quad \mathbb{E}u \otimes v = (1 - \beta^2)^{\frac{1}{2}}\mathcal{C}. \quad (10.54)$$

Indeed, letting $v(du, dv) := \mu(du)P(u, dv)$, and with $\langle \cdot, \cdot \rangle$ and $\|\cdot\|$, the inner product and norm on \mathcal{H} , respectively, we can write, using (10.115),

$$\begin{aligned} \hat{v}(d\xi, d\eta) &= \int_{\mathcal{H} \times \mathcal{H}} e^{i\langle u, \xi \rangle + i\langle v, \eta \rangle} \mu(du)P(u, dv) \\ &= \int_{\mathcal{H}} e^{i\langle u, \xi \rangle} \int_{\mathcal{H}} e^{i\langle v, \eta \rangle} P(u, dv) \mu(du) \\ &= \int_{\mathcal{H}} e^{i\langle u, \xi \rangle} e^{i\sqrt{1-\beta^2}\langle u, \eta \rangle - \frac{1}{2}\|\beta\mathcal{C}^{\frac{1}{2}}\eta\|^2} \mu(du) \\ &= e^{-\frac{\beta^2}{2}\|\mathcal{C}^{\frac{1}{2}}\eta\|^2} \int_{\mathcal{H}} e^{i\langle u, \sqrt{1-\beta^2}\eta + \xi \rangle} \mu(du) \\ &= e^{-\frac{\beta^2}{2}\|\mathcal{C}^{\frac{1}{2}}\eta\|^2} e^{-\frac{1}{2}\|\mathcal{C}^{\frac{1}{2}}(\sqrt{1-\beta^2}\eta + \xi)\|^2} \\ &= \exp\left(-\frac{1}{2}\|\mathcal{C}^{\frac{1}{2}}\eta\|^2 - \frac{1}{2}\|\mathcal{C}^{\frac{1}{2}}\xi\|^2 - (1 - \beta^2)^{\frac{1}{2}}\langle \mathcal{C}^{\frac{1}{2}}\xi, \mathcal{C}^{\frac{1}{2}}\eta \rangle\right). \end{aligned}$$

Hence, by Lemma 19 and equation (10.115), $\mu(du)P(u, dv)$ is a centred Gaussian measure with the covariance operator given by (10.54). Since the expression in the last line of the above equation is symmetric in ξ and η , $\mu(dv)P(v, du)$ is a centred Gaussian measure with the same covariance as $\mu(du)P(u, dv)$ and so the reversibility is proved. \square

Example 8. Consider the equation

$$\frac{du}{dt} = -u + \sqrt{2} \frac{dW}{dt}, \quad u(0) = u_0, \quad (10.55)$$

where W is a \mathcal{C} -Wiener process (defined in Sect. A.4 below). Then

$$u(t) = e^{-t}u_0 + \sqrt{2} \int_0^t e^{-(t-s)} dW(s).$$

Use of the Itô isometry demonstrates that $u(t)$ is distributed according to the Gaussian $N(e^{-t}u_0, (1-e^{-2t})\mathcal{C})$. Setting $\beta^2 = 1 - e^{-2t}$ and employing the previous example shows that the Markov process is reversible since, for every $t > 0$, the transition kernel of the process is reversible. \square

5.2 Metropolis-Hastings Methods

In this section we study Metropolis-Hastings methods designed to sample from the probability measure μ given by (10.52). The perspective that we have described on inverse problems, specifically the formulation of Bayesian inversion on function space, leads to new sampling methods which are specifically tailored to the high-dimensional problems which arise from discretization of the infinite-dimensional setting. In particular it leads naturally to the philosophy that it is advantageous to design algorithms which, in principle, make sense in infinite dimensions; it is these methods which will perform well under refinement of finite-dimensional approximations. Most Metropolis-Hastings methods which are defined in finite dimensions will not make sense in the infinite-dimensional limit. This is because the acceptance probability for Metropolis-Hastings methods is defined as the Radon-Nikodym derivative between two measures describing the behavior of the Markov chain in stationarity. Since measures in infinite dimensions have a tendency to be mutually singular, only carefully designed methods will have interpretations in infinite dimensions. To simplify the presentation, we work with the following assumptions throughout:

Assumptions 3. *The function $\Phi : X \rightarrow \mathbb{R}$ is bounded on bounded subsets of X .*

\square

We now consider the following prototype Metropolis-Hastings method which accepts and rejects proposals from a Markov kernel Q to produce a Markov chain with kernel P which is reversible with respect to μ .

Algorithm 1

Given $a : X \times X \rightarrow [0, 1]$ generate $\{u^{(k)}\}_{k \geq 0}$ as follows:

- 1 Set $k = 0$ and pick $u^{(0)} \in X$.
 - 2 Propose $v^{(k)} \sim Q(u^{(k)}, dv)$.
 - 3 Set $u^{(k+1)} = v^{(k)}$ with probability $a(u^{(k)}, v^{(k)})$, independently of $(u^{(k)}, v^{(k)})$.
 - 4 Set $u^{(k+1)} = u^{(k)}$ otherwise.
 - 5 $k \rightarrow k + 1$ and return to 2. □
-

Given a proposal kernel Q , a key question in the design of MCMC methods is the question of how to choose $a(u, v)$ to ensure that $P(u, dv)$ satisfies detailed balance with respect to μ . If the resulting Markov chain is ergodic, this then yields an algorithm which, asymptotically, samples from μ and can be used to estimate expectations against μ .

To determine conditions on a which are necessary and sufficient for detailed balance, we first note that the Markov kernel which arises from accepting/rejecting proposals from Q is given by

$$P(u, dv) = Q(u, dv)a(u, v) + \delta_u(dv) \int_X (1 - a(u, w))Q(u, dw). \quad (10.56)$$

Notice that

$$\int_X P(u, dv) = 1$$

as required. Substituting the expression for P into the detailed balance condition from Definition 2, we obtain

$$\begin{aligned} & \mu(du)Q(u, dv)a(u, v) + \mu(du)\delta_u(dv) \int_X (1 - a(u, w))Q(u, dw) \\ &= \\ & \mu(dv)Q(v, du)a(v, u) + \mu(dv)\delta_v(du) \int_X (1 - a(v, w))Q(v, dw). \end{aligned}$$

We now note that the measure $\mu(du)\delta_u(dv)$ is in fact symmetric in the pair (u, v) and that $u = v$ almost surely under it. As a consequence the identity reduces to

$$\mu(du)Q(u, dv)a(u, v) = \mu(dv)Q(v, du)a(v, u). \quad (10.57)$$

Our aim now is to identify choices of a which ensure that (10.57) is satisfied. This will then ensure that the prototype algorithm does indeed lead to a Markov chain for which μ is invariant. To this end we define the measures

$$\nu(du, dv) = \mu(du)Q(u, dv)$$

and

$$\nu^T(du, dv) = \mu(dv)Q(v, du)$$

on $(X \times X, \mathcal{B}(X) \otimes \mathcal{B}(X))$. The following theorem determines a necessary and sufficient condition for the choice of a to make the algorithm μ reversible and identifies the canonical Metropolis-Hastings choice.

Theorem 21. *Assume that ν and ν^T are equivalent as measures on $X \times X$, equipped with the σ -algebra $\mathcal{B}(X) \otimes \mathcal{B}(X)$, and that $\nu(du, dv) = r(u, v)\nu^T(du, dv)$. Then the probability kernel (10.56) satisfies detailed balance if and only if*

$$r(u, v)a(u, v) = a(v, u), \quad \nu\text{-a.s.} \quad (10.58)$$

In particular the choice $\alpha_{\text{mh}}(u, v) = \min\{1, r(v, u)\}$ will imply detailed balance.

Proof. Since ν and ν^T are equivalent (10.57) holds if and only if

$$\frac{d\nu}{d\nu^T}(u, v)a(u, v) = a(v, u).$$

This is precisely (10.58). Now note that $\nu(du, dv) = r(u, v)\nu^T(du, dv)$ and $\nu^T(du, dv) = r(v, u)\nu(du, dv)$ since ν and ν^T are equivalent. Thus $r(u, v)r(v, u) = 1$. It follows that

$$\begin{aligned} r(u, v)\alpha_{\text{mh}}(u, v) &= \min\{r(u, v), r(u, v)r(v, u)\} \\ &= \min\{r(u, v), 1\} \\ &= \alpha_{\text{mh}}(v, u) \end{aligned}$$

as required.

A good example of the resulting methodology arises in the case where $Q(u, dv)$ is reversible with respect to μ_0 :

Theorem 22. *Let Assumption 3 hold. Consider Algorithm 5 applied to (10.52) in the case where the proposal kernel Q is reversible with respect to the prior μ_0 . Then the resulting Markov kernel P given by (10.56) is reversible with respect to μ if $a(u, v) = \min\{1, \exp(\Phi(u) - \Phi(v))\}$.*

Proof. Prior reversibility implies that

$$\mu_0(d u) Q(u, d v) = \mu_0(d v) Q(v, d u).$$

Multiplying both sides by $\exp(-\Phi(u))$ gives

$$\mu(d u) Q(u, d v) = \exp(-\Phi(u)) \mu_0(d v) Q(v, d u)$$

and then multiplication by $\exp(-\Phi(v))$ gives

$$\exp(-\Phi(v)) \mu(d u) Q(u, d v) = \exp(-\Phi(u)) \mu(d v) Q(v, d u).$$

This is the statement that

$$\exp(-\Phi(v)) v(d u, d v) = \exp(-\Phi(u)) v^\top(d u, d v).$$

Since Φ is bounded on bounded sets by Assumption 3, we deduce that

$$\frac{d v}{d v^\top}(u, v) = r(u, v) = \exp(\Phi(v) - \Phi(u)).$$

Theorem 21 gives the desired result.

We provide two examples of prior reversible proposals, the first applying in the general Banach space setting and the second when the prior is a Gaussian measure.

Algorithm 2 Independence Sampler

The independence sampler arises when $Q(u, d v) = \mu_0(d v)$ so that proposals are independent draws from the prior. Clearly prior reversibility is satisfied. The following algorithm results. Define

$$a(u, v) = \min\{1, \exp(\Phi(u) - \Phi(v))\}$$

and generate $\{u^{(k)}\}_{k \geq 0}$ as follows:

1. Set $k = 0$ and pick $u^{(0)} \in X$.
2. Propose $v^{(k)} \sim \mu_0$ independently of $u^{(k)}$.
3. Set $u^{(k+1)} = v^{(k)}$ with probability $a(u^{(k)}, v^{(k)})$, independently of $(u^{(k)}, v^{(k)})$.
4. Set $u^{(k+1)} = u^{(k)}$ otherwise.
5. $k \rightarrow k + 1$ and return to 2.

□

The preceding algorithm works well when the likelihood is not *too* informative; however, when the information in the likelihood is substantial, and $\Phi(\cdot)$ varies significantly depending on where it is evaluated, the independence sampler will

not work well. In such a situation, it is typically the case that *local* proposals are needed, with a parameter controlling the degree of locality; this parameter can then be optimized by choosing it as large as possible, consistent with achieving a reasonable acceptance probability. The following algorithm is an example of this concept, with parameter β playing the role of the locality parameter. The algorithm may be viewed as the natural generalization of the random walk Metropolis method, for targets defined by density with respect to Lebesgue measure, to the situation where the targets are defined by density with respect to Gaussian measure. The name pCN is used because of the original derivation of the algorithm via a Crank-Nicolson discretization of the Hilbert space valued SDE (10.55).

Algorithm 3 pCN Method

Assume that X is a Hilbert space $(\mathcal{H}, \mathcal{B}(\mathcal{H}))$ and that $\mu_0 = N(0, \mathcal{C})$ is a Gaussian prior on \mathcal{H} .

Now define $Q(u, dv)$ to be the Gaussian measure $N((1 - \beta^2)^{\frac{1}{2}}u, \beta^2\mathcal{C})$, also on \mathcal{H} . Example 7 shows that Q is μ_0 reversible. The following algorithm results.

Define

$$a(u, v) = \min\{1, \exp(\Phi(u) - \Phi(v))\}$$

and generate $\{u^{(k)}\}_{k \geq 0}$ as follows:

1. Set $k = 0$ and pick $u^{(0)} \in X$.
2. Propose $v^{(k)} = \sqrt{(1 - \beta^2)}u^{(k)} + \beta\xi^{(k)}$, $\xi^{(k)} \sim N(0, \mathcal{C})$.
3. Set $u^{(k+1)} = v^{(k)}$ with probability $a(u^{(k)}, v^{(k)})$, independently of $(u^{(k)}, \xi^{(k)})$.
4. Set $u^{(k+1)} = u^{(k)}$ otherwise.
5. $k \rightarrow k + 1$ and return to 2.

□

Example 9. Example 8 shows that using the proposal from Example 7 within a Metropolis-Hastings context may be viewed as using a proposal based on the μ -measure-preserving equation (10.53), but with the $D\Phi$ term dropped. The accept-reject mechanism of Algorithm 3, which is based on differences of Φ , then compensates for the missing $D\Phi$ term.

5.3 Sequential Monte Carlo Methods

In this section we introduce sequential Monte Carlo methods and show how these may be viewed as a generic tool for sampling the posterior distribution arising in Bayesian inverse problems. These methods have their origin in filtering of dynamical systems but, as we will demonstrate, have the potential as algorithms for probing a very wide class of probability measures. The key idea is to introduce

a sequence of measures which evolve the prior distribution into the posterior distribution. Particle filtering methods are then applied to this sequence of measures in order to evolve a set of particles that are prior distributed into a set of particles that are approximately posterior distributed. From a practical perspective, a key step in the construction of these methods is the use of MCMC methods which preserve the measure of interest and other measures closely related to it; furthermore, our interest is in designing SMC methods which, in principle, are well defined on the infinite-dimensional space; for these two reasons, the MCMC methods from the previous subsection play a central role in what follows.

Given integer J , let $h = J^{-1}$, and for nonnegative integer $j \leq J$, define the sequence of measures $\mu_j \ll \mu_0$ by

$$\frac{d\mu_j}{d\mu_0}(u) = \frac{1}{Z_j} \exp(-jh\Phi(u)), \quad (10.59a)$$

$$Z_j = \int_X \exp(-jh\Phi(u)) \mu_0(du). \quad (10.59b)$$

Then $\mu_J = \mu$ given by (10.52); thus, our interest is in approximating μ_J , and we will achieve this by approximating the sequence of measures $\{\mu_j\}_{j=0}^J$, using information about μ_j to inform approximation of μ_{j+1} . To simplify the analysis, we assume that Φ is bounded above and below on X so that there is $\phi^\pm \in \mathbb{R}$ such that

$$\phi^- \leq \Phi(u) \leq \phi^+ \quad \forall u \in X. \quad (10.60)$$

Without loss of generality, we assume that $\phi^- \leq 0$ and that $\phi^+ \geq 0$, which may be achieved by normalization. Note that then the family of measures $\{\mu_j\}_{j=0}^J$ are mutually absolutely continuous and, furthermore,

$$\frac{d\mu_{j+1}}{d\mu_j}(u) = \frac{Z_j}{Z_{j+1}} \exp(-h\Phi(u)). \quad (10.61)$$

An important idea here is that, while μ_0 and μ may be quite far apart as measures, the pair of measures μ_j, μ_{j+1} can be quite close, for sufficiently small h . This fact can be used to incrementally evolve samples from μ_0 into approximate samples of μ_J .

Let L denote the operator on probability measures which corresponds to application of Bayes' theorem with likelihood proportional to $\exp(-h\Phi(u))$, and let P_j denote any Markov kernel which preserves the measure μ_j ; such kernels arise, for example, from the MCMC methods of the previous subsection. These considerations imply that

$$\mu_{j+1} = \mathsf{L}P_j\mu_j. \quad (10.62)$$

Sequential Monte Carlo methods proceed by approximating the sequence $\{\mu_j\}$ by a set of Dirac measures, as we now describe. It is useful to break up the iteration (10.62) and write it as

$$\hat{\mu}_{j+1} = P_j \mu_j, \quad (10.63a)$$

$$\mu_{j+1} = \mathcal{L}\hat{\mu}_{j+1}. \quad (10.63b)$$

We approximate each of the two steps in (10.63) separately. To this end it helps to note that, since P_j preserves μ_j ,

$$\frac{d\mu_{j+1}}{d\hat{\mu}_{j+1}}(u) = \frac{Z_j}{Z_{j+1}} \exp(-h\Phi(u)). \quad (10.64)$$

To define the method, we write an N -particle Dirac measure approximation of the form

$$\mu_j \approx \mu_j^N := \sum_{n=1}^N w_j^{(n)} \delta(v_j - v_j^{(n)}). \quad (10.65)$$

The approximate distribution is completely defined by particle positions $v_j^{(n)}$ and weights $w_j^{(n)}$, respectively. Thus the objective of the method is to find an update rule for $\{v_j^{(n)}, w_j^{(n)}\}_{n=1}^N \mapsto \{v_{j+1}^{(n)}, w_{j+1}^{(n)}\}_{n=1}^N$. The weights must sum to one. To do this we proceed as follows. First each particle $v_j^{(n)}$ is updated by proposing a new candidate particle $\hat{v}_{j+1}^{(n)}$ according to the Markov kernel P_j ; this corresponds to (10.63a) and creates an approximation to $\hat{\mu}_{j+1}$. (See the last two parts of Remark 8 for a discussion on the role of P_j in the algorithm.) We can think of this approximation as a prior distribution for application of Bayes' rule in the form (10.63b), or equivalently (10.64). Secondly, each new particle is re-weighted according to the desired distribution μ_{j+1} given by (10.64). The required calculations are very straightforward because of the assumed form of the measures as sums of Dirac's, as we now explain.

The first step of the algorithm has made the approximation

$$\hat{\mu}_{j+1} \approx \hat{\mu}_{j+1}^N = \sum_{n=1}^N w_{j+1}^{(n)} \delta(v_{j+1} - \hat{v}_{j+1}^{(n)}). \quad (10.66)$$

We now apply Bayes' formula in the form (10.64). Using an approximation proportional to (10.66) for $\hat{\mu}_{j+1}$, we obtain

$$\mu_{j+1} \approx \mu_{j+1}^N := \sum_{n=1}^N w_{j+1}^{(n)} \delta(v_{j+1} - \hat{v}_{j+1}^{(n)}). \quad (10.67)$$

where

$$\hat{w}_{j+1}^{(n)} = \exp(-h\Phi(\hat{v}_{j+1}^{(n)}))w_j^{(n)} \quad (10.68)$$

and normalization requires

$$w_{j+1}^{(n)} = \hat{w}_{j+1}^{(n)} / \left(\sum_{n=1}^N \hat{w}_{j+1}^{(n)} \right). \quad (10.69)$$

Practical experience shows that some weights become very small, and for this reason it is desirable to add a *resampling step* to determine the $\{v_{j+1}^{(n)}\}$ by drawing from (10.67); this has the effect of removing particles with very low weights and replacing them with multiple copies of the particles with higher weights. Because the initial measure $\mathbb{P}(v_0)$ is not in Dirac form, it is convenient to place this resampling step at the *start* of each iteration, rather than at the end as we have presented here, as this naturally introduces a particle approximation of the initial measure. This reordering makes no difference to the iteration we have described and results in the following algorithm.

Algorithm 4

1. Let $\mu_0^N = \mu_0$ and set $j = 0$.
2. Draw $v_j^{(n)} \sim \mu_j^N, n = 1, \dots, N$.
3. Set $w_j^{(n)} = 1/N, n = 1, \dots, N$ and define μ_j^N by (10.65).
4. Draw $\hat{v}_{j+1}^{(n)} \sim P_j(v_j^{(n)}, \cdot)$.
5. Define $w_{j+1}^{(n)}$ by (10.68), (10.69) and μ_{j+1}^N by (10.67).
6. $j \rightarrow j + 1$ and return to 2.

□

We define S^N to be the mapping between probability measures defined by sampling N i.i.d. points from a measure and approximating that measure by an equally weighted sum of Dirac's at the sample points. Then the preceding algorithm may be written as

$$\mu_{j+1}^N = \mathsf{L} S^N P_j \mu_j^N. \quad (10.70)$$

Although we have written the sampling step S^N *after* application of P_j , some reflection shows that this is well justified: applying P_j followed by S^N can be shown, by first conditioning on the initial point and sampling with respect to P_j and then sampling over the distribution of the initial point, to be the algorithm as defined. The sequence of distributions that we wish to approximate simply satisfies

the iteration (10.62). Thus, analyzing the particle filter requires estimation of the error induced by application of S^N (the *resampling error*) together with estimation of the rate of accumulation of this error in time.

The operators L , P_j and S^N map the space $\mathsf{P}(X)$ of probability measures on X into itself according to the following:

$$(\mathsf{L}\mu)(dv) = \frac{\exp(-h\Phi(v))\mu(dv)}{\int_X \exp(-h\Phi(v))\mu(dv)},$$

$$(P_j\mu)(dv) = \int_X P_j(v', dv)\mu(dv'),$$

$$(S^N\mu)(dv) = \frac{1}{N} \sum_{n=1}^N \delta(v - v^{(n)})dv, \quad v^{(n)} \sim \mu \text{ i.i.d.}$$

where P_j is the kernel associated with the μ_j -invariant Markov chain.

Let $\mu = \mu^{(\omega)}$ denote, for each ω , an element of $\mathsf{P}(X)$. If we assume that ω is a random variable and let \mathbb{E}^ω denote expectation over ω , then we may define a distance $d(\cdot, \cdot)$ between two random probability measures $\mu^{(\omega)}$ and $\nu^{(\omega)}$, as follows:

$$d(\mu, \nu) = \sup_{|f|_\infty \leq 1} \sqrt{\mathbb{E}^\omega |\mu(f) - \nu(f)|^2},$$

with $|f|_\infty := \sup_{v \in X} |f(v)|$, and where we have used the convention that $\mu(f) = \int_X f(v)\mu(dv)$ for measurable $f : X \rightarrow \mathbb{R}$, and similar for ν . This distance does indeed generate a metric and, in particular, satisfies the triangle inequality. In fact it is simply the total variation distance in the case of measures which are not random.

With respect to this distance between random probability measures, we may prove that the SMC method generates a good approximation of the true measure μ , in the limit $N \rightarrow \infty$. We use the fact that, under (10.60), we have

$$\exp(-h\phi^+) < \exp(-h\Phi(v)) < \exp(-h\phi^-).$$

Since $\phi^- \leq 0$ and $\phi^+ \geq 0$, we deduce that there exists $\kappa \in (0, 1)$ such that for all $v \in X$,

$$\kappa < \exp(-h\Phi(v)) < \kappa^{-1}.$$

This constant κ appears in the following.

Theorem 23. *We assume in the following that (10.60) holds. Then*

$$d(\mu_J^N, \mu_J) \leq \sum_{j=1}^J (2\kappa^{-2})^j \frac{1}{\sqrt{N}}.$$

Proof. The desired result is a consequence of the following three facts, whose proof we postpone to three lemmas at the end of the subsection:

$$\begin{aligned} \sup_{\mu \in \mathcal{P}(X)} d(S^N \mu, \mu) &\leq \frac{1}{\sqrt{N}}, \\ d(P_j v, P_j \mu) &\leq d(v, \mu), \\ d(\mathsf{L}v, \mathsf{L}\mu) &\leq 2\kappa^{-2} d(v, \mu). \end{aligned}$$

By the triangle inequality, we have, for $v_j^N = P_j \mu_j^N$,

$$\begin{aligned} d(\mu_{j+1}^N, \mu_{j+1}) &= d(\mathsf{L}S^N P_j \mu_j^N, \mathsf{L}P_j \mu_j) \\ &\leq d(\mathsf{L}P_j \mu_j^N, \mathsf{L}P_j \mu_j) + d(\mathsf{L}S^N P_j \mu_j^N, \mathsf{L}P_j \mu_j^N) \\ &\leq 2\kappa^{-2} \left(d(\mu_j^N, \mu_j) + d(S^N v_j^N, v_j^N) \right) \\ &\leq 2\kappa^{-2} \left(d(\mu_j^N, \mu_j) + \frac{1}{\sqrt{N}} \right). \end{aligned}$$

Iterating, after noting that $\mu_0^N = \mu_0$, gives the desired result.

Remarks 8. This theorem shows that the sequential particle filter actually reproduces the true posterior distribution $\mu = \mu_J$, in the limit $N \rightarrow \infty$. We make some comments about this.

- The measure $\mu = \mu_J$ is well approximated by μ_j^N in the sense that, as the number of particles $N \rightarrow \infty$, the approximating measure converges to the true measure. The result holds in the infinite-dimensional setting. As a consequence the algorithm as stated is robust to finite-dimensional approximation.
- Note that $\kappa = \kappa(J)$ and that $\kappa \rightarrow 1$ as $J \rightarrow \infty$. Using this fact shows that the error constant in Theorem 23 behaves as $\sum_{j=1}^J (2\kappa^{-2})^j \asymp J 2^J$. Optimizing this upper bound does not give a useful rule of thumb for choosing J and in fact suggests choosing $J = 1$. In any case in applications Φ is not bounded from above, or even below in general, and a more refined analysis is then required.
- In principle the theory applies even if the Markov kernel P_j is simply the identity mapping on probability measures. However, moving the particles according to a nontrivial μ_j -invariant measure is absolutely essential for the methodology to work in practice. This can be seen by noting that if P_j is indeed taken to be the identity map on measures, then the particle positions will be unchanged as j changes, meaning that the measure $\mu = \mu_J$ is approximated by weighted samples from the prior, clearly undesirable in general.
- In fact, if the Markov kernel P_j is ergodic, then it is sometimes possible to obtain bounds which are *uniform* in J .

We now prove the three lemmas which underlie the convergence proof.

Lemma 8. *The sampling operator satisfies*

$$\sup_{\mu \in \mathbb{P}(X)} d(S^N \mu, \mu) \leq \frac{1}{\sqrt{N}}.$$

Proof. Let ν be an element of $\mathbb{P}(X)$ and $\{v^{(k)}\}_{k=1}^N$ a set of i.i.d. samples with $v^{(1)} \sim \nu$; the randomness entering the probability measures is through these samples, expectation with respect to which we denote by \mathbb{E}^ω in what follows. Then

$$S^N \nu(f) = \frac{1}{N} \sum_{k=1}^N f(v^{(k)})$$

and, defining $\bar{f} = f - \nu(f)$, we deduce that

$$S^N \nu(f) - \nu(f) = \frac{1}{N} \sum_{k=1}^N \bar{f}(v^{(k)}).$$

It is straightforward to see that

$$\mathbb{E}^\omega \bar{f}(v^{(k)}) \bar{f}(v^{(l)}) = \delta_{kl} \mathbb{E}^\omega |\bar{f}(v^{(k)})|^2.$$

Furthermore, for $|f|_\infty \leq 1$,

$$\mathbb{E}^\omega |\bar{f}(v^{(1)})|^2 = \mathbb{E}^\omega |f(v^{(1)})|^2 - |\mathbb{E}^\omega f(v^{(1)})|^2 \leq 1.$$

It follows that, for $|f|_\infty \leq 1$,

$$\mathbb{E}^\omega |\nu(f) - S^N \nu(f)|^2 = \frac{1}{N^2} \sum_{k=1}^N \mathbb{E}^\omega |\bar{f}(v^{(k)})|^2 \leq \frac{1}{N}.$$

Since the result is independent of ν , we may take the supremum over all probability measures and obtain the desired result.

Lemma 9. *Since P_j is a Markov kernel, we have*

$$d(P_j \nu, P_j \nu') \leq d(\nu, \nu').$$

Proof. The result is generic for any Markov kernel P , so we drop the index j on P_j for the duration of the proof. Define

$$q(v') = \int_X P(v', dv) f(v),$$

that is the expected value of f under one step of the Markov chain started from v' . Clearly, since

$$|q(v')| \leq \left(\int_X P(v', dv) \right) \sup_v |f(v)| = \sup_v |f(v)|$$

it follows that

$$\sup_v |q(v)| \leq \sup_v |f(v)|.$$

Also, since

$$Pv(f) = \int_X f(v) \left(\int_X P(v', dv) v(dv') \right),$$

exchanging the order of integration shows that

$$|Pv(f) - Pv'(f)| = |v(q) - v'(q)|.$$

Thus

$$\begin{aligned} d(Pv, Pv') &= \sup_{\|f\|_\infty \leq 1} \left(\mathbb{E}^\omega |Pv(f) - Pv'(f)|^2 \right)^{\frac{1}{2}} \\ &\leq \sup_{\|q\|_\infty \leq 1} \left(\mathbb{E}^\omega |v(q) - v'(q)|^2 \right)^{\frac{1}{2}} \\ &= d(v, v') \end{aligned}$$

as required.

Lemma 10. *Under the Assumptions of Theorem 23, we have*

$$d(\mathsf{L}v, \mathsf{L}\mu) \leq 2\kappa^{-2} d(v, \mu).$$

Proof. Define $g(v) = \exp(-h\Phi(v))$. Notice that for $|f|_\infty < \infty$, we can rewrite

$$\begin{aligned} (\mathbb{L}\nu)(f) - (\mathbb{L}\mu)(f) &= \frac{\nu(fg)}{\nu(g)} - \frac{\mu(fg)}{\mu(g)} \\ &= \frac{\nu(fg)}{\nu(g)} - \frac{\mu(fg)}{\nu(g)} + \frac{\mu(fg)}{\nu(g)} - \frac{\mu(fg)}{\mu(g)} \\ &= \frac{\kappa^{-1}}{\nu(g)} [\nu(\kappa fg) - \mu(\kappa fg)] + \frac{\mu(fg)}{\mu(g)} \frac{\kappa^{-1}}{\nu(g)} [\mu(\kappa g) - \nu(\kappa g)]. \end{aligned}$$

Now notice that $\nu(g)^{-1} \leq \kappa^{-1}$ and that, for $|f|_\infty \leq 1$, $\mu(fg)/\mu(g) \leq 1$ since the expression corresponds to an expectation with respect to measure found from μ by reweighting with likelihood proportional to g . Thus

$$|(\mathbb{L}\nu)(f) - (\mathbb{L}\mu)(f)| \leq \kappa^{-2} |\nu(\kappa fg) - \mu(\kappa fg)| + \kappa^{-2} |\nu(\kappa g) - \mu(\kappa g)|.$$

Since $|\kappa g| \leq 1$, it follows that

$$\mathbb{E}^\omega |(\mathbb{L}\nu)(f) - (\mathbb{L}\mu)(f)|^2 \leq 4\kappa^{-4} \sup_{|f|_\infty \leq 1} \mathbb{E}^\omega |\nu(f) - \mu(f)|^2$$

and the desired result follows.

5.4 Continuous Time Markov Processes

In the remainder of this section, we shift our attention to continuous time processes which preserve μ ; these are important in the construction of proposals for MCMC methods and also as diffusion limits for MCMC. Our main goal is to show that the equation (10.53) preserves μ . Our setting is to work in the separable Hilbert space \mathcal{H} with Inner product and norm denoted by $\langle \cdot, \cdot \rangle$ and $\| \cdot \|$, respectively. We assume that the prior μ_0 is a Gaussian on \mathcal{H} and, furthermore, we specify the space $X \subset \mathcal{H}$ that will play a central role in this continuous time setting. This choice of space X will link the properties of the reference measure μ_0 and the potential Φ . We assume that \mathcal{C} has eigendecomposition

$$\mathcal{C}\phi_j = \gamma_j^2 \phi_j \tag{10.74}$$

where $\{\phi_j\}_{j=1}^\infty$ forms an orthonormal basis for \mathcal{H} and where $\gamma_j \asymp j^{-s}$. Necessarily $s > \frac{1}{2}$ since \mathcal{C} must be trace class to be a covariance on \mathcal{H} . We define the following scale of Hilbert subspaces, defined for $r > 0$, by

$$\mathcal{X}^r = \left\{ u \in \mathcal{H} \mid \sum_{j=1}^{\infty} j^{2r} |\langle u, \phi_j \rangle|^2 < \infty \right\}$$

and then extend to superspaces $r < 0$ by duality. We use $\|\cdot\|_r$ to denote the norm induced by the inner product

$$\langle u, v \rangle_r = \sum_{j=1}^{\infty} j^{2r} u_j v_j$$

for $u_j = \langle u, \phi_j \rangle$ and $v_j = \langle v, \phi_j \rangle$. Application of Theorem 5 with $d = 1$ and $q = 2$ shows that $\mu_0(\mathcal{X}^r) = 1$ for all $r \in [0, s - \frac{1}{2}]$. In what follows we will take $X = \mathcal{X}^t$ for some fixed $t \in [0, s - \frac{1}{2}]$.

Notice that we have not assumed that the underlying Hilbert space is comprised of L^2 functions mapping $D \subset \mathbb{R}^d$ into \mathbb{R} , and hence we have not introduced the dimension d of an underlying physical space \mathbb{R}^d into either the decay assumptions on the γ_j or the spaces \mathcal{X}^r . However, note that the spaces \mathcal{H}^t introduced in Sect. 2.4 are, in the case where $\mathcal{H} = L^2(D; \mathbb{R})$, the same as the spaces $\mathcal{X}^{t/d}$.

We now break our developments into introductory discussion of the finite-dimensional setting, in Sect. 5.5, and into the Hilbert space setting in Sect. 5.6. In Sect. 5.5.1, we introduce a family of Langevin equations which are invariant with respect to a given measure with smooth Lebesgue density. Using this, in Sect. 5.5.2, we motivate equation (10.53) showing that, in finite dimensions, it corresponds to a particular choice of Langevin equation. In Sect. 5.6.1, for the infinite-dimensional setting, we describe the precise assumptions under which we will prove invariance of measure μ under the dynamics (10.53). Section 5.6.2 describes the elements of the finite-dimensional approximation of (10.53) which will underlie our proof of invariance. Finally, Sect. 5.6.3 contains statement of the measure invariance result as Theorem 27, together with its proof; this is preceded by Theorem 26 which establishes existence and uniqueness of a solution to (10.53), as well as continuous dependence of the solution on the initial condition and Brownian forcing. Theorems 25 and 24 are the finite-dimensional analogues of Theorems 27 and 26, respectively, and play a useful role in motivating the infinite-dimensional theory.

5.5 Finite-Dimensional Langevin Equation

5.5.1 Background Theory

Before setting up the (rather involved) technical assumptions required for our proof of measure invariance, we give some finite-dimensional intuition. Recall that $|\cdot|$

denotes the Euclidean norm on \mathbb{R}^n , and we also use this notation for the induced matrix norm on \mathbb{R}^n . We assume that

$$I \in C^2(\mathbb{R}^n, \mathbb{R}^+), \quad \int_{\mathbb{R}^n} e^{-I(u)} du = 1.$$

Thus $\rho(u) = e^{-I(u)}$ is the Lebesgue density corresponding to a random variable on \mathbb{R}^n . Let μ be the corresponding measure.

Let \mathbb{W} denote standard Wiener measure on \mathbb{R}^n . Thus $B \sim \mathbb{W}$ is a standard Brownian motion in $C([0, \infty); \mathbb{R}^n)$. Let $u \in C([0, \infty); \mathbb{R}^n)$ satisfy the SDE

$$\frac{du}{dt} = -A DI(u) + \sqrt{2A} \frac{dB}{dt}, \quad u(0) = u_0 \quad (10.75)$$

where $A \in \mathbb{R}^{n \times n}$ is symmetric and strictly positive definite and $DI \in C^1(\mathbb{R}^n, \mathbb{R}^n)$ is the gradient of I . Assume that $\exists M > 0 : \forall u \in \mathbb{R}^n$, the Hessian of I satisfies

$$|D^2 I(u)| \leq M.$$

We refer to equations of the form (10.75) as *Langevin equations* (as mentioned earlier, they correspond to overdamped Langevin equations in the physics literature and to Langevin equations in the statistics literature) and the matrix A as a *preconditioner*.

Theorem 24. *For every $u_0 \in \mathbb{R}^n$ and \mathbb{W} -a.s., equation (10.75) has a unique global in time solution $u \in C([0, \infty); \mathbb{R}^n)$.*

Proof. A solution of the SDE is a solution of the integral equation

$$u(t) = u_0 - \int_0^t A DI(u(s)) ds + \sqrt{2A} B(t). \quad (10.76)$$

Define $X = C([0, T]; \mathbb{R}^n)$ and $\mathcal{F} : X \rightarrow X$ by

$$(\mathcal{F}v)(t) = u_0 - \int_0^t A DI(v(s)) ds + \sqrt{2A} B(t). \quad (10.77)$$

Thus $u \in X$ solving (10.76) is a fixed point of \mathcal{F} . We show that \mathcal{F} has a unique fixed point, for T sufficiently small. To this end we study a contraction property of \mathcal{F} :

$$\begin{aligned}
\|(\mathcal{F}v_1) - (\mathcal{F}v_2)\|_X &= \sup_{0 \leq t \leq T} \left| \int_0^t \left(A DI(v_1(s)) - A DI(v_2(s)) \right) ds \right| \\
&\leq \int_0^T \left| A DI(v_1(s)) - A DI(v_2(s)) \right| ds \\
&\leq \int_0^T |A|M|v_1(s) - v_2(s)| ds \\
&\leq T|A|M\|v_1 - v_2\|_X.
\end{aligned}$$

Choosing $T : T|A|M < 1$ shows that \mathcal{F} is a contraction on X . This argument may be repeated on successive intervals $[T, 2T], [2T, 3T], \dots$ to obtain a unique global solution in $C([0, \infty); \mathbb{R}^n)$.

Remark 2. Note that, since A is positive-definite symmetric, its eigenvectors e_j form an orthonormal basis for \mathbb{R}^n . We write $Ae_j = \alpha_j^2 e_j$. Thus

$$B(t) = \sum_{j=1}^n \beta_j(t) e_j$$

where the $\{\beta_j\}_{j=1}^n$ are an i.i.d. collection of standard unit Brownian motions on \mathbb{R} . Thus we obtain

$$\sqrt{A}B(t) = \sum_{j=1}^n \alpha_j \beta_j e_j =: W(t).$$

We refer to W as an A -Wiener process. Such a process is Gaussian with mean zero and covariance structure

$$\mathbb{E}W(t) \otimes W(s) = A(t \wedge s).$$

The equation (10.75) may be written as

$$\frac{du}{dt} = -ADI(u) + \sqrt{2} \frac{dW}{dt}, \quad u(0) = u_0. \quad (10.78)$$

Theorem 25. Let $u(t)$ solve (10.75). If $u_0 \sim \mu$, then $u(t) \sim \mu$ for all $t > 0$. More precisely, for all $\varphi : \mathbb{R}^n \rightarrow \mathbb{R}^+$ bounded and continuous, $u_0 \sim \mu$ implies

$$\mathbb{E}\varphi(u(t)) = \mathbb{E}\varphi(u_0), \quad \forall t > 0.$$

Proof. Consider the additive noise SDE, for additive noise with strictly positive-definite diffusion matrix Σ ,

$$\frac{du}{dt} = f(u) + \sqrt{2\Sigma} \frac{dB}{dt}, \quad u(0) = u_0 \sim \nu_0.$$

If ν_0 has pdf ρ_0 , then the Fokker-Planck equation for this SDE is

$$\begin{aligned} \frac{\partial \bar{\rho}}{\partial t} &= \nabla \cdot (-f \bar{\rho} + \Sigma \nabla \bar{\rho}), \quad (u, t) \in \mathbb{R}^n \times \mathbb{R}^+, \\ \bar{\rho}|_{t=0} &= \rho_0. \end{aligned}$$

At time $t > 0$ the solution of the SDE is distributed according to measure $\nu(t)$ with density $\bar{\rho}(u, t)$ solving the Fokker-Planck equation. Thus the initial measure ν_0 is preserved if

$$\nabla \cdot (-f \rho_0 + \Sigma \nabla \rho_0) = 0$$

and then $\bar{\rho}(\cdot, t) = \rho_0$, $\forall t \geq 0$.

We apply this Fokker-Planck equation to show that μ is invariant for equation (10.76). We need to show that

$$\nabla \cdot (ADI(u)\rho + A \nabla \rho) = 0$$

if $\rho = e^{-I(u)}$. With this choice of ρ we have

$$\nabla \rho = -DI(u)e^{-I(u)} = -DI(u)\rho.$$

Thus

$$A DI(u)\rho + A \nabla \rho = A DI(u)\rho - A DI(u)\rho = 0,$$

so that

$$\nabla \cdot (A DI(u)\rho + A \nabla \rho) = \nabla \cdot (0) = 0.$$

Hence the proof is complete.

5.5.2 Motivation for Equation (10.53)

Using the preceding finite-dimensional development, we now motivate the form of equation (10.53). For (10.52) we have, if \mathcal{H} is \mathbb{R}^n ,

$$\mu(du) = \exp(-I(u)) du, \quad I(u) = \frac{1}{2}|\mathcal{C}^{-\frac{1}{2}}u|^2 + \Phi(u) + \ln Z.$$

Thus

$$DI(u) = \mathcal{C}^{-1}u + D\Phi(u)$$

and equation (10.75), which preserves μ , is

$$\frac{du}{dt} = -A(\mathcal{C}^{-1}u + D\Phi(u)) + \sqrt{2A}\frac{dB}{dt}.$$

Choosing the preconditioner $A = \mathcal{C}$ gives

$$\frac{du}{dt} = -u - \mathcal{C}D\Phi(u) + \sqrt{2\mathcal{C}}\frac{dB}{dt}.$$

This is exactly (10.53) provided $W = \sqrt{\mathcal{C}}B$, where B is a Brownian motion with covariance \mathcal{I} . Then W is a Brownian motion with covariance \mathcal{C} . This is the finite-dimensional analogue of the construction of a \mathcal{C} -Wiener process in the Appendix. We are now in a position to prove Theorems 26 and 27 which are the infinite-dimensional analogues of Theorems 24 and 25.

5.6 Infinite-Dimensional Langevin Equation

5.6.1 Assumptions on Change of Measure

Recall that $\mu_0(\mathcal{X}^r) = 1$ for all $r \in [0, s - \frac{1}{2}]$. The functional $\Phi(\cdot)$ is assumed to be defined on \mathcal{X}^t for some $t \in [0, s - \frac{1}{2})$, and indeed we will assume appropriate bounds on the first and second derivatives, building on this assumption. (Thus, in this Sect. 5.6.1, t does not denote time; instead we use τ to denote the generic time argument.) These regularity assumptions on $\Phi(\cdot)$ ensure that the probability distribution μ is not too different from μ_0 , when projected into directions associated with ϕ_j for j large.

For each $u \in \mathcal{X}^t$, the derivative $D\Phi(u)$ is an element of the dual $(\mathcal{X}^t)^*$ of \mathcal{X}^t comprising continuous linear functionals on \mathcal{X}^t . However, we may identify $(\mathcal{X}^t)^*$ with \mathcal{X}^{-t} and view $D\Phi(u)$ as an element of \mathcal{X}^{-t} for each $u \in \mathcal{X}^t$. With this identification, the following identity holds

$$\|D\Phi(u)\|_{\mathcal{L}(\mathcal{X}^t, \mathbb{R})} = \|D\Phi(u)\|_{-t}$$

and the second derivative $D^2\Phi(u)$ can be identified as an element of $\mathcal{L}(\mathcal{X}^t, \mathcal{X}^{-t})$. To avoid technicalities, we assume that $\Phi(\cdot)$ is quadratically bounded, with first derivative linearly bounded and second derivative globally bounded. Weaker assumptions could be dealt with by use of stopping time arguments.

Assumptions 4. There exist constants $M_i \in \mathbb{R}^+, i \leq 4$ and $t \in [0, s - 1/2)$ such that, for all $u \in \mathcal{X}^t$, the functional $\Phi : \mathcal{X}^t \rightarrow \mathbb{R}$ satisfies

$$\begin{aligned} -M_1 &\leq \Phi(u) \leq M_2 \left(1 + \|u\|_t^2\right); \\ \|D\Phi(u)\|_{-t} &\leq M_3 \left(1 + \|u\|_t\right); \\ \|D^2\Phi(u)\|_{\mathcal{L}(\mathcal{X}^t, \mathcal{X}^{-t})} &\leq M_4. \end{aligned}$$

□

Example 10. The functional $\Phi(u) = \frac{1}{2}\|u\|_t^2$ satisfies Assumptions 4. To see this note that we may write $\Phi(u) = \frac{1}{2}\langle u, \mathcal{K}u \rangle$ where

$$\mathcal{K} = \frac{1}{2} \sum_{j=1}^{\infty} j^{2t} \phi_j \phi_j^*.$$

The functional $\Phi : \mathcal{X}^t \rightarrow \mathbb{R}^+$ is clearly well defined by definition. Its derivative at $u \in \mathcal{X}^t$ is given by $\mathcal{K}u = D\Phi(u) = \sum_{j \geq 1} j^{2t} u_j \phi_j$, where $u_j = \langle \phi_j, u \rangle$. Furthermore $D\Phi(u) \in \mathcal{X}^{-t}$ with $\|D\Phi(u)\|_{-t} = \|u\|_t$. The second derivative $D^2\Phi(u) \in \mathcal{L}(\mathcal{X}^t, \mathcal{X}^{-t})$ is the linear operator \mathcal{K} that is the operator that maps $u \in \mathcal{X}^t$ to $\sum_{j \geq 1} j^{2t} \langle u, \phi_j \rangle \phi_j \in \mathcal{X}^t$: its norm satisfies $\|D^2\Phi(u)\|_{\mathcal{L}(\mathcal{X}^t, \mathcal{X}^{-t})} = 1$ for any $u \in \mathcal{X}^t$. □

Since the eigenvalues γ_j^2 of \mathcal{C} decrease as $\gamma_j \asymp j^{-s}$, the operator \mathcal{C} has a smoothing effect: $\mathcal{C}^\alpha h$ gains $2\alpha s$ orders of regularity in the sense that the \mathcal{X}^β -norm of $\mathcal{C}^\alpha h$ is controlled by the $\mathcal{X}^{\beta-2\alpha s}$ -norm of $h \in \mathcal{H}$. Indeed it is straightforward to show the following:

Lemma 11. Under Assumption 4, the following estimates hold:

1. The operator \mathcal{C} satisfies

$$\|\mathcal{C}^\alpha h\|_\beta \asymp \|h\|_{\beta-2\alpha s}.$$

2. The function $\mathcal{CD}\Phi : \mathcal{X}^t \rightarrow \mathcal{X}^t$ is globally Lipschitz on \mathcal{X}^t : there exists a constant $M_5 > 0$ such that

$$\|\mathcal{CD}\Phi(u) - \mathcal{CD}\Phi(v)\|_t \leq M_5 \|u - v\|_t \quad \forall u, v \in \mathcal{X}^t. \quad (10.79)$$

3. The function $F : \mathcal{X}^t \rightarrow \mathcal{X}^t$ defined by

$$F(u) = -u - \mathcal{CD}\Phi(u) \quad (10.80)$$

is globally Lipschitz on \mathcal{X}^t .

4. The functional $\Phi(\cdot) : \mathcal{X}^t \rightarrow \mathbb{R}$ satisfies a second-order Taylor formula (for which we extend $\langle \cdot, \cdot \rangle$ from an inner product on \mathcal{X} to the dual pairing between \mathcal{X}^{-t} and \mathcal{X}^t). There exists a constant $M_6 > 0$ such that

$$\Phi(v) - \left(\Phi(u) + \langle D\Phi(u), v - u \rangle \right) \leq M_6 \|u - v\|_t^2 \quad \forall u, v \in \mathcal{X}^t. \quad (10.81)$$

5.6.2 Finite-Dimensional Approximation

Our analysis now proceeds as follows. First we introduce an approximation of the measure μ , denoted by μ^N . To this end we let P^N denote orthogonal projection in \mathcal{H} onto $X^N := \text{span}\{\phi_1, \dots, \phi_N\}$ and denote by Q^N orthogonal projection in \mathcal{H} onto $X^\perp := \text{span}\{\phi_{N+1}, \phi_{N+2}, \dots\}$. Thus $Q^N = I - P^N$. Then define the measure μ^N by

$$\frac{d\mu^N}{d\mu_0}(u) = \frac{1}{Z^N} \exp(-\Phi(P^N u)), \quad (10.82a)$$

$$Z^N = \int_{X'} \exp(-\Phi(P^N u)) \mu_0(du). \quad (10.82b)$$

This is a specific example of the approximating family in (10.44) if we define

$$\Phi^N := \Phi \circ P^N. \quad (10.83)$$

Indeed if we take $X = \mathcal{X}^\tau$ for any $\tau \in (t, s - \frac{1}{2})$, we see that $\|P^N\|_{\mathcal{L}(X, X)} = 1$ and that, for any $u \in X$,

$$\begin{aligned} \|\Phi(u) - \Phi^N(u)\| &= \|\Phi(u) - \Phi(P^N u)\| \\ &\leq M_3(1 + \|u\|_t) \|(I - P^N)u\|_t \\ &\leq CM_3(1 + \|u\|_\tau) \|u\|_\tau N^{-(\tau-t)}. \end{aligned}$$

Since Φ and hence Φ^N are bounded below by $-M_1$, and since the function $1 + \|u\|_\tau^2$ is integrable by the Fernique theorem 10, the approximation Theorem 18 applies. We deduce that the Hellinger distance between μ and μ^N is bounded above by $\mathcal{O}(N^{-r})$ for any $r < s - \frac{1}{2} - t$ since $\tau - t \in (0, s - \frac{1}{2} - t)$.

We will not use this explicit convergence rate in what follows, but we will use the idea that μ^N converges to μ in order to prove invariance of the measure μ under the SDE (10.53). The measure μ^N has a product structure that we will exploit in the following. We note that any element $u \in \mathcal{H}$ is uniquely decomposed as $u = p + q$ where $p \in X^N$ and $q \in X^\perp$. Thus we will write $\mu^N(du) = \mu^N(dp, dq)$, and similar expressions for μ_0 and so forth, in what follows.

Lemma 12. Define $\mathcal{C}^N = P^N \mathcal{C} P^N$ and $\mathcal{C}^\perp = Q^N \mathcal{C} Q^N$. Then μ_0 factors as the product of measures $\mu_{0,P} = N(0, \mathcal{C}^N)$ and $\mu_{0,Q} = N(0, \mathcal{C}^\perp)$ on X^N and X^\perp ,

respectively. Furthermore μ^N itself also factors as a product measure on $X^N \oplus X^\perp$: $\mu^N(dp, dq) = \mu_P(dp)\mu_Q(dq)$ with $\mu_Q = \mu_{0,Q}$ and

$$\frac{d\mu_P}{d\mu_{0,P}}(u) \propto \exp(-\Phi(p)).$$

Proof. Because P^N and Q^N commute with \mathcal{C} , and because $P^N Q^N = Q^N P^N = 0$, the factorization of the reference measure μ_0 follows automatically. The factorization of the measure μ follows from the fact that $\Phi^N(u) = \Phi(p)$ and hence does not depend on q .

To facilitate the proof of the desired measure preservation property, we introduce the equation

$$\frac{du^N}{dt} = -u^N - \mathcal{C}P^N D\Phi^N(u^N) + \sqrt{2}\frac{dW}{dt}. \quad (10.84)$$

By using well-known properties of finite-dimensional SDEs, we will show that if $u^N(0) \sim \mu^N$, then $u^N(t) \sim \mu^N$ for any $t > 0$. By passing to the limit $N = \infty$, we will deduce that for (10.53), if $u(0) \sim \mu$, then $u(t) \sim \mu$ for any $t > 0$.

The next lemma gathers various regularity estimates on the functional $\Phi^N(\cdot)$ that are repeatedly used in the sequel; they follow from the analogous properties of Φ by using the structure $\Phi^N = \Phi \circ P^N$.

Lemma 13. *Under Assumption 4, the following estimates hold with all constants uniform in N :*

1. *The estimates of Assumption 4 hold with Φ replaced by Φ^N .*
2. *The function $\mathcal{CD}\Phi^N : \mathcal{X}^t \rightarrow \mathcal{X}^t$ is globally Lipschitz on \mathcal{X}^t : there exists a constant $M_5 > 0$ such that*

$$\|\mathcal{CD}\Phi^N(u) - \mathcal{CD}\Phi^N(v)\|_t \leq M_5 \|u - v\|_t \quad \forall u, v \in \mathcal{X}^t.$$

3. *The function $F^N : \mathcal{X}^t \rightarrow \mathcal{X}^t$ defined by*

$$F^N(u) = -u - \mathcal{C}P^N D\Phi^N(u) \quad (10.85)$$

is globally Lipschitz on \mathcal{X}^t .

4. *The functional $\Phi^N(\cdot) : \mathcal{X}^t \rightarrow \mathbb{R}$ satisfies a second-order Taylor formula (for which we extend $\langle \cdot, \cdot \rangle$ from an inner product on \mathcal{X} to the dual pairing between \mathcal{X}^{-t} and \mathcal{X}^t). There exists a constant $M_6 > 0$ such that*

$$\Phi^N(v) - \left(\Phi^N(u) + \langle D\Phi^N(u), v - u \rangle \right) \leq M_6 \|u - v\|_t^2 \quad \forall u, v \in \mathcal{X}^t. \quad (10.86)$$

5.6.3 Main Theorem and Proof

Fix a function $W \in C([0, T]; \mathcal{X}^t)$. Recalling F defined by (10.80), we define a solution of (10.53) to be a function $u \in C([0, T]; \mathcal{X}^t)$ satisfying the integral equation

$$u(\tau) = u_0 + \int_0^\tau F(u(s)) ds + \sqrt{2} W(\tau) \quad \forall \tau \in [0, T]. \quad (10.87)$$

The solution is said to be *global* if $T > 0$ is arbitrary. For us, W will be a \mathcal{C} -Wiener process and hence random; we look for existence of a global solution, almost surely with respect to the Wiener measure. Similarly a solution of (10.84) is a function $u^N \in C([0, T]; \mathcal{X}^t)$ satisfying the integral equation

$$u^N(\tau) = u_0 + \int_0^\tau F^N(u^N(s)) ds + \sqrt{2} W(\tau) \quad \forall t \in [0, T]. \quad (10.88)$$

Again, the solution is random because W is a \mathcal{C} -Wiener process. Note that the solution to this equation is not confined to X^N , because both u_0 and W have nontrivial components in X^\perp . However, within X^\perp , the behavior is purely Gaussian and within X^N , it is finite dimensional. We will exploit these two facts.

The following establishes basic existence, uniqueness, continuity and approximation properties of the solutions of (10.87) and (10.88).

Theorem 26. *For every $u_0 \in \mathcal{X}^t$ and for almost every \mathcal{C} -Wiener process W , equation (10.87) (respectively, (10.88)) has a unique global solution. For any pair $(u_0, W) \in \mathcal{X}^t \times C([0, T]; \mathcal{X}^t)$, we define the Itô map*

$$\Theta: \mathcal{X}^t \times C([0, T]; \mathcal{X}^t) \rightarrow C([0, T]; \mathcal{X}^t)$$

which maps (u_0, W) to the unique solution u (resp. u^N for (10.88)) of the integral equation (10.87) (resp. Θ^N for (10.88)). The map Θ (respectively, Θ^N) is globally Lipschitz continuous. Finally we have that $\Theta^N(u_0, W) \rightarrow \Theta(u_0, W)$ strongly in $C([0, T]; \mathcal{X}^t)$ for every pair $(u_0, W) \in \mathcal{X}^t \times C([0, T]; \mathcal{X}^t)$.

Proof. The existence and uniqueness of local solutions to the integral equation (10.87) is a simple application of the contraction mapping principle, following arguments similar to those employed in the proof of Theorem 24. Extension to a global solution may be achieved by repeating the local argument on successive intervals.

Now let $u^{(i)}$ solve

$$u^{(i)} = u_0^{(i)} + \int_0^\tau F(u^{(i)})(s) ds + \sqrt{2} W^{(i)}(\tau), \quad \tau \in [0, T],$$

for $i = 1, 2$. Subtracting and using the Lipschitz property of F shows that $e = u^{(1)} - u^{(2)}$ satisfies

$$\begin{aligned}\|e(\tau)\|_t &\leq \|u_0^{(1)} - u_0^{(2)}\|_t + L \int_0^\tau \|e(s)\|_t ds + \sqrt{2} \|W^{(1)}(\tau) - W^{(2)}(\tau)\|_t \\ &\leq \|u_0^{(1)} - u_0^{(2)}\|_t + L \int_0^\tau \|e(s)\|_t ds + \sqrt{2} \sup_{0 \leq s \leq T} \|W^{(1)}(s) - W^{(2)}(s)\|_t.\end{aligned}$$

By application of the Gronwall inequality, we find that

$$\sup_{0 \leq \tau \leq T} \|e(\tau)\|_t \leq C(T) (\|u_0^{(1)} - u_0^{(2)}\|_t + \sup_{0 \leq s \leq T} \|W^{(1)}(s) - W^{(2)}(s)\|_t)$$

and the desired continuity is established.

Now we prove pointwise convergence of Θ^N to Θ . Let $e = u - u^N$ where u and u^N solve (10.87) and (10.88), respectively. The pointwise convergence of Θ^N to Θ is established by proving that $e \rightarrow 0$ in $C([0, T]; \mathcal{X}')$. Note that

$$F(u) - F^N(u^N) = (F^N(u) - F^N(u^N)) + (F(u) - F^N(u)).$$

Also, by Lemma 13, $\|F^N(u) - F^N(u^N)\|_t \leq L \|e\|_t$. Thus we have

$$\|e\|_t \leq L \int_0^\tau \|e(s)\|_t ds + \int_0^\tau \|F(u(s)) - F^N(u(s))\|_t ds.$$

Thus, by Gronwall, it suffices to show that

$$\delta^N := \sup_{0 \leq s \leq T} \|F(u(s)) - F^N(u(s))\|_t$$

tends to zero as $N \rightarrow \infty$. Note that

$$\begin{aligned}F(u) - F^N(u) &= \mathcal{C}D\Phi(u) - \mathcal{C}P^N D\Phi(P^N u) \\ &= (I - P^N)\mathcal{C}D\Phi(u) + P^N(\mathcal{C}D\Phi(u) - \mathcal{C}D\Phi(P^N u)).\end{aligned}$$

Thus, since $\mathcal{C}D\Phi$ is globally Lipschitz on \mathcal{X}' , by Lemma 11, and P^N has norm one as a mapping from \mathcal{X}' into itself,

$$\|F(u) - F^N(u)\|_t \leq \|(I - P^N)\mathcal{C}D\Phi(u)\|_t + C \|(I - P^N)u\|_t.$$

By dominated convergence $\|(I - P_N)a\|_t \rightarrow 0$ for any fixed element $a \in \mathcal{X}'$. Thus, because $\mathcal{C}D\Phi$ is globally Lipschitz, by Lemma 11, and as $u \in C([0, T]; \mathcal{X}')$, we deduce that it suffices to bound $\sup_{0 \leq s \leq T} \|u(s)\|_t$. But such a bound is a consequence of the existence theory outlined at the start of the proof, based on the proof of Theorem 24. \square

The following is a straightforward corollary of the preceding theorem:

Corollary 2. *For any pair $(u_0, W) \in \mathcal{X}^t \times C([0, T]; \mathcal{X}^t)$, we define the point Itô map*

$$\Theta_\tau : \mathcal{X}^t \times C([0, T]; \mathcal{X}^t) \rightarrow \mathcal{X}^t$$

(respectively, Θ_τ^N for (10.88)) which maps (u_0, W) to the unique solution $u(\tau)$ of the integral equation (10.87) (respectively, $u^N(\tau)$ for (10.88)) at time τ . The map Θ_τ (respectively, Θ_τ^N) is globally Lipschitz continuous. Finally we have that $\Theta_\tau^N(u_0, W) \rightarrow \Theta_\tau(u_0, W)$ for every pair $(u_0, W) \in \mathcal{X}^t \times C([0, T]; \mathcal{X}^t)$.

Theorem 27. *Let Assumption 4 hold. Then the measure μ given by (10.43) is invariant for (10.53); for all continuous bounded functions $\varphi : \mathcal{X}^t \rightarrow \mathbb{R}$, it follows that if \mathbb{E} denotes expectation with respect to the product measure found from initial condition $u_0 \sim \mu$ and $W \sim \mathbb{W}$, the C -Wiener measure on \mathcal{X}^t , then $\mathbb{E}\varphi(u(\tau)) = \mathbb{E}\varphi(u_0)$.*

Proof. We have that

$$\mathbb{E}\varphi(u(\tau)) = \int \varphi(\Theta_\tau(u_0, W))\mu(d u_0)\mathbb{W}(d W), \quad (10.89)$$

$$\mathbb{E}\varphi(u_0) = \int \varphi(u_0)\mu(d u_0). \quad (10.90)$$

If we solve equation (10.84) with $u_0 \sim \mu^N$, then, using \mathbb{E}^N with the obvious notation,

$$\mathbb{E}^N\varphi(u^N(\tau)) = \int \varphi(\Theta_\tau^N(u_0, W))\mu^N(d u_0)\mathbb{W}(d W), \quad (10.91)$$

$$\mathbb{E}^N\varphi(u_0) = \int \varphi(u_0)\mu^N(d u_0). \quad (10.92)$$

Lemma 14 below shows that, in fact,

$$\mathbb{E}^N\varphi(u^N(\tau)) = \mathbb{E}^N\varphi(u_0).$$

Thus it suffices to show that

$$\mathbb{E}^N\varphi(u^N(\tau)) \rightarrow \mathbb{E}\varphi(u(\tau)) \quad (10.93)$$

and

$$\mathbb{E}^N\varphi(u_0) \rightarrow \mathbb{E}\varphi(u_0). \quad (10.94)$$

Both of these facts follow from the dominated convergence theorem as we now show. First note that

$$\mathbb{E}^N \varphi(u_0) = \int \varphi(u_0) e^{-\Phi(P^N u_0)} \mu_0(du_0).$$

Since $\varphi(\cdot) e^{-\Phi \circ P^N}$ is bounded independently of N , by $(\sup \varphi) e^{M_1}$, and since $(\Phi \circ P^N)(u)$ converges pointwise to $\Phi(u)$ on \mathcal{X}' , we deduce that

$$\mathbb{E}^N \varphi(u_0) \rightarrow \int \varphi(u_0) e^{-\Phi(u_0)} \mu_0(du_0) = \mathbb{E} \varphi(u_0)$$

so that (10.94) holds. The convergence in (10.93) holds by a similar argument. From (10.91) we have

$$\mathbb{E}^N \varphi(u^N(\tau)) = \int \varphi(\Theta_\tau^N(u_0, W)) e^{-\Phi(P^N u_0)} \mu_0(du_0) \mathbb{W}(dW). \quad (10.95)$$

The integrand is again dominated by $(\sup \varphi) e^{M_1}$. Using the pointwise convergence of Θ_τ^N to Θ_τ on $\mathcal{X}' \times C([0, T]; \mathcal{X}')$, as proved in Corollary 2, as well as the pointwise convergence of $(\Phi \circ P^N)(u)$ to $\Phi(u)$, the desired result follows from dominated convergence: we find that

$$\mathbb{E}^N \varphi(u^N(\tau)) \rightarrow \int \varphi(\Theta_\tau(u_0, W)) e^{-\Phi(u_0)} \mu_0(du_0) \mathbb{W}(dW) = \mathbb{E} \varphi(u(\tau)).$$

The desired result follows. \square

Lemma 14. *Let Assumptions 4 hold. Then the measure μ^N given by (10.82) is invariant for (10.84); for all continuous bounded functions $\varphi : \mathcal{X}' \rightarrow \mathbb{R}$, it follows that if \mathbb{E}^N denotes expectation with respect to the product measure found from initial condition $u_0 \sim \mu^N$ and $W \sim \mathbb{W}$, the C-Wiener measure on \mathcal{X}' , then $\mathbb{E}^N \varphi(u^N(\tau)) = \mathbb{E}^N \varphi(u_0)$.*

Proof. Recall from Lemma 12 that measure μ^N given by (10.82) factors as the independent product of two measures on μ_P on X^N and μ_Q on X^\perp . On X^\perp the measure is simply the Gaussian $\mu_Q = \mathcal{N}(0, \mathcal{C}^\perp)$, while on X^N the measure μ_P is finite dimensional with density proportional to

$$\exp \left(-\Phi(p) - \frac{1}{2} \|(\mathcal{C}^N)^{-\frac{1}{2}} p\|^2 \right). \quad (10.96)$$

The equation (10.84) also decouples on the spaces X^N and X^\perp . On X^\perp it gives the integral equation

$$q(\tau) = - \int_0^\tau q(s) + \sqrt{2} Q^N W(\tau) \quad (10.97)$$

while on X^N it gives the integral equation

$$p(\tau) = - \int_0^\tau \left(p(s) + C^N D\Phi(p(s)) \right) ds + \sqrt{2} P^N W(\tau). \quad (10.98)$$

Measure μ_Q is preserved by (10.97), because (10.97) simply gives an integral equation formulation of the Ornstein-Uhlenbeck process with desired Gaussian invariant measure. On the other hand, equation (10.98) is simply an integral equation formulation of the Langevin equation for measure on \mathbb{R}^N with density (10.96), and a calculation with the Fokker-Planck equation, as in Theorem 25, demonstrates the required invariance of μ_P . \square

5.7 Bibliographic Notes

- Section 5.1 describes general background on Markov processes and invariant measures. The book [78] is a good starting point in this area. The book [75] provides a good overview of this subject area, from an applied and computational statistics perspective. For continuous time Markov chains, see [101].
- Section 5.2 concerns MCMC methods. The standard RWM was introduced in [73] and led, via the paper [46], to the development of the more general class of Metropolis-Hastings methods. The paper [94] is a key reference which provides a framework for the study of Metropolis-Hastings methods on general state spaces. The subject of MCMC methods which are invariant with respect to the target measure μ on infinite-dimensional spaces is overviewed in the paper [21]. The specific idea behind the Algorithm 3 is contained in [76, equation (15)], in the finite-dimensional setting. It is possible to show that, in the limit $\beta \rightarrow 0$, suitably interpolated output of Algorithm 3 converges to solution of the equation (10.53): see [82]. Furthermore it is also possible to compute a spectral gap for the Algorithm 3 in the infinite-dimensional setting [44]. This implies the existence of a dimension-independent spectral gap when finite-dimensional approximation is used; in contrast standard Metropolis-Hastings methods, such as random walk Metropolis, have a dimension-dependent spectral gap which shrinks with increasing dimension [99].
- Section 5.3 concerns SMC methods and the foundational work in this area is overviewed in the book [26]. The application of those ideas to the solution of PDE inverse problems was first demonstrated in [50], where the inverse problem is to determine the initial condition of the Navier-Stokes equations from observations. The method is applied to the elliptic inverse problem, with uniform

priors, in [10]. The proof of Theorem 23 follows the very clear exposition given in [84] in the context of filtering for hidden Markov models.

- Sections 5.4–5.6 concern measure preserving continuous time dynamics. The finite-dimensional aspects of this subsection, which we introduce for motivation, are covered in the texts [79] and [37]; the first of these books is an excellent introduction to the basic existence and uniqueness theory, outlined in a simple case in Theorem 24, while the second provides an in-depth treatment of the subject from the viewpoint of the Fokker-Planck equation, as used in Theorem 25. This subject has a long history which is overviewed in the paper [41] where the idea is applied to finding SPDEs which are invariant with respect to the measure generated by a conditioned diffusion process. This idea is generalized to certain conditioned hypoelliptic diffusions in [42]. It is also possible to study deterministic Hamiltonian dynamics which preserves the same measure. This idea is described in [9] in the same setup as employed here; that paper also contains references to the wider literature. Lemma 11 is proved in [72] and Lemma 13 in [82] Lemma 14 requires knowledge of the invariance of Ornstein-Uhlenbeck processes together with invariance of finite-dimensional first order Langevin equations with the form of gradient dynamics subject to additive noise. The invariance of the Ornstein-Uhlenbeck process is covered in [29] and invariance of finite-dimensional SDEs using the Fokker-Planck equation is discussed in [37]. The \mathcal{C} -Wiener process and its properties are described in [28].
- The primary focus of this section has been on the theory of measure-preserving dynamics and its relations to algorithms. The SPDEs are of interest in their own right as a theoretical object, but have particular importance in the construction of MCMC methods and in understanding the limiting behavior of MCMC methods. It is also important to appreciate that MCMC and SMC methods are by no means the only tools available to study the Bayesian inverse problem. In this context we note that computing the expectation with respect to the posterior can be reformulated as computing the ratio of two expectations with respect to the prior, the denominator being the normalization constant. Effectively in some such high-dimensional integration problems, [59] and [77] are general references on the QMC methodology. The paper [57] is a survey on the theory of QMC for bounded integration domains and is relevant for uniform priors. The paper [60] contains theoretical results for unbounded integration domains and is relevant to, for example, Gaussian priors. The use of QMC in plain uncertainty quantification (calculating the pushforward of a measure through a map) is studied for elliptic PDEs with random coefficients in [58] (uniform) and [39] (Gaussian). More sophisticated integration tools can be employed, using polynomial chaos representations of the prior measure, and computing posterior expectations in a manner which exploits sparsity in the map from unknown random coefficients to measured data; see [89, 90]. Much of this work, viewing uncertainty quantification from the point of high-dimensional integration, has its roots in early papers concerning plain uncertainty quantification in elliptic PDEs with random coefficients; the paper [7] was foundational in this area.

6 Conclusions

We have highlighted a theoretical treatment for Bayesian inversion over infinite-dimensional spaces. The resulting framework is appropriate for the mathematical analysis of inverse problems, as well as the development of algorithms. For example, on the analysis side, the idea of MAP estimators, which links the Bayesian approach with classical regularization, developed for Gaussian priors in [30], has recently been extended to other prior models in [47]; the study of contraction of the posterior distribution to a Dirac measure on the truth underlying the data is undertaken in [3, 4, 99]. On the algorithmic side, algorithms for Bayesian inversion in geophysical applications are formulated in [16, 81], and on the computational statistics side, methods for optimal experimental design are formulated in [5, 6]. All of these cited papers build on the framework developed in detail here and first outlined in [92]. It is thus anticipated that the framework herein will form the bedrock of other, related, developments of both the theory and computational practice of Bayesian inverse problems.

A Appendix

A.1 Function Spaces

In this subsection we briefly define the Hilbert and Banach spaces that will be important in our developments of probability and integration in infinite-dimensional spaces. As a consequence we pay particular attention to the issue of separability (the existence of a countable dense subset) which we require in that context. We primarily restrict our discussion to \mathbb{R} - or \mathbb{C} -valued functions, but the reader will easily be able to extend to \mathbb{R}^n -valued or $\mathbb{R}^{n \times n}$ -valued situations, and we discuss Banach space-valued functions at the end of the subsection.

A.1.1 ℓ^p and L^p Spaces

Consider real-valued sequences $u = \{u_j\}_{j=1}^\infty \in \mathbb{R}^\infty$. Let $w \in \mathbb{R}^\infty$ denote a positive sequence so that $w_j > 0$ for each $j \in \mathbb{N}$. For every $p \in [1, \infty)$, we define

$$\ell_w^p = \ell_w^p(\mathbb{N}; \mathbb{R}) = \left\{ u \in \mathbb{R}^\infty \mid \sum_{j=1}^{\infty} w_j |u_j|^p < \infty \right\}.$$

Then ℓ_w^p is a Banach space when equipped with the norm

$$\|u\|_{\ell_w^p} = \left(\sum_{j=1}^{\infty} w_j |u_j|^p \right)^{\frac{1}{p}}.$$

In the case $p = 2$, the resulting spaces are Hilbert spaces when equipped with the inner product

$$\langle u, v \rangle = \sum_{j=1}^{\infty} w_j u_j v_j.$$

These ℓ^p spaces, with $p \in [1, \infty)$, are separable. Throughout we simply write ℓ^p for the spaces ℓ_w^p with $w_j \equiv 1$. In the case $w_j \equiv 1$, we extend the definition of Banach spaces to the case $p = \infty$ by defining

$$\ell^\infty = \ell^\infty(\mathbb{N}; \mathbb{R}) = \left\{ u \in \mathbb{R} \mid \sup_{j \in \mathbb{N}} (|u_j|) < \infty \right\}$$

and

$$\|u\|_{\ell^\infty} = \sup_{j \in \mathbb{N}} (|u_j|).$$

The space ℓ^∞ of bounded sequences is *not* separable. Each element of the sequence u_j is real valued, but the definitions may be readily extended to complex-valued, \mathbb{R}^n -valued, and $\mathbb{R}^{n \times n}$ -valued sequences, replacing $|\cdot|$ by the complex modulus, the vector ℓ^p norm, and the operator ℓ^p norm on matrices, respectively.

We now extend the idea of p -summability to functions and to p -integrability. Let D be a bounded open set in \mathbb{R}^d with Lipschitz boundary and define the space $L^p = L^p(D; \mathbb{R})$ of Lebesgue measurable functions $f : D \rightarrow \mathbb{R}$ with norm $\|\cdot\|_{L^p(D)}$ defined by

$$\|f\|_{L^p(D)} := \begin{cases} \left(\int_D |f|^p dx \right)^{\frac{1}{p}} & \text{for } 1 \leq p < \infty \\ \text{ess sup}_D |f| & \text{for } p = \infty. \end{cases}$$

In the above definition we have used the notation

$$\text{ess sup}_D |f| = \inf \{C : |f| \leq C \text{ a.e. on } D\}.$$

Here *a.e.* is with respect to Lebesgue measure and the integral is, of course, the Lebesgue integral. Sometimes we drop explicit reference to the set D in the norm and simply write $\|\cdot\|_{L^p}$. For Lebesgue measurable functions $f : D \rightarrow \mathbb{R}^n$, the norm is readily extended replacing $|f|$ under the integral by the vector p -norm on \mathbb{R}^n . Likewise we may consider Lebesgue measurable $f : D \rightarrow \mathbb{R}^{n \times n}$, using the operator p -norm on $\mathbb{R}^{n \times n}$. In all these cases, we write $L^p(D)$ as shorthand for $L^p(D; X)$ where $X = \mathbb{R}$, \mathbb{R}^n or $\mathbb{R}^{n \times n}$. Then $L^p(D)$ is the vector space of all (equivalence classes of) measurable functions $f : D \rightarrow \mathbb{R}$ for which $\|f\|_{L^p(D)} < \infty$. The space $L^p(D)$ is separable for $p \in [1, \infty)$, while $L^\infty(D)$ is not separable. We define periodic versions of $L^p(D)$, denoted by $L_{\text{per}}^p(D)$, in the case where D is a unit

cube; these spaces are defined as the completion of C^∞ periodic functions on the unit cube, with respect to the L^p -norm. If we define \mathbb{T}^d to be the d -dimensional unit torus, then we write $L_{\text{per}}^p([0, 1]^d) = L^p(\mathbb{T}^d)$. Again these spaces are separable for $1 \leq p < \infty$, but not for $p = \infty$.

A.1.2 Continuous and Hölder Continuous Functions

Let D be an open and bounded set in \mathbb{R}^d with Lipschitz boundary. We will denote by $C(\overline{D}, \mathbb{R})$, or simply $C(\overline{D})$, the space of continuous functions $f : \overline{D} \rightarrow \mathbb{R}$. When equipped with the supremum norm,

$$\|f\|_{C(\overline{D})} = \sup_{x \in \overline{D}} |f(x)|,$$

$C(\overline{D})$ is a Banach space. Building on this we define the space $C^{0,\gamma}(\overline{D})$ to be the space of functions in $C(\overline{D})$ which are Hölder with any exponent $\gamma \in (0, 1]$ with norm

$$\|f\|_{C^{0,\gamma}(\overline{D})} = \sup_{x \in \overline{D}} |f(x)| + \sup_{x, y \in \overline{D}} \left(\frac{|f(x) - f(y)|}{|x - y|^\gamma} \right). \quad (10.99)$$

The case $\gamma = 1$ corresponds to Lipschitz functions.

We remark that $C(\overline{D})$ is separable since $\overline{D} \subset \mathbb{R}^d$ is compact here. The space of Hölder functions $C^{0,\gamma}(\overline{D}; \mathbb{R})$ is, however, *not* separable. Separability can be recovered by working in the subset of $C^{0,\gamma}(\overline{D}; \mathbb{R})$ where, in addition to (10.99) being finite,

$$\lim_{y \rightarrow x} \frac{|f(x) - f(y)|}{|x - y|^\gamma} = 0,$$

uniformly in x ; we denote the resulting separable space by $C_0^{0,\gamma}(\overline{D}, \mathbb{R})$. This is analogous to the fact that the space of bounded measurable functions is not separable, while the space of continuous functions on a compact domain is. Furthermore it may be shown that $C^{0,\gamma'} \subset C_0^{0,\gamma}$ for every $\gamma' > \gamma$. All of the preceding spaces can be generalized to functions $C^{0,\gamma}(\overline{D}, \mathbb{R}^n)$ and $C_0^{0,\gamma}(\overline{D}, \mathbb{R}^n)$; they may also be extended to periodic functions on the unit torus \mathbb{T}^d found by identifying opposite faces of the unit cube $[0, 1]^d$. The same separability issues arise for these generalizations.

A.1.3 Sobolev Spaces

We define Sobolev spaces of functions with integer number of derivatives, extend to fractional and negative derivatives, and make the connection with Hilbert scales. Here D is a bounded open set in \mathbb{R}^d with Lipschitz boundary. In the context of a function $u \in L^2(D)$, we will use the notation $\frac{\partial u}{\partial x_i}$ to denote the weak derivative with respect to x_i and the notation ∇u for the weak gradient.

The *Sobolev space* $W^{r,p}(D)$ consists of all L^p -integrable functions $u : D \rightarrow \mathbb{R}$ whose α^{th} order weak derivatives exist and are L^p -integrable for all $|\alpha| \leq r$:

$$W^{r,p}(D) = \left\{ u \mid D^\alpha u \in L^p(D) \text{ for } |\alpha| \leq r \right\} \quad (10.100)$$

with norm

$$\|u\|_{W^{r,p}(D)} = \begin{cases} \left(\sum_{|\alpha| \leq r} \|D^\alpha u\|_{L^p(D)}^p \right)^{\frac{1}{p}} & \text{for } 1 \leq p < \infty, \\ \sum_{|\alpha| \leq r} \|D^\alpha u\|_{L^\infty(D)} & \text{for } p = \infty. \end{cases} \quad (10.101)$$

We denote $W^{r,2}(D)$ by $H^r(D)$. We define periodic versions of $H^s(D)$, denoted by $H_{\text{per}}^s(D)$, in the case where D is a unit cube $[0, 1]^d$; these spaces are defined as the completion of C^∞ periodic functions on the unit cube, with respect to the H^s -norm. If we define \mathbb{T}^d to be d -dimensional unit torus, we then write $H^s(\mathbb{T}^d) = H_{\text{per}}^s([0, 1]^d)$.

The spaces $H^s(D)$ with D a bounded open set in \mathbb{R}^d , and $H_{\text{per}}^s([0, 1]^d)$, are separable Hilbert spaces. In particular if we define the inner-product $(\cdot, \cdot)_{L^2(D)}$ on $L^2(D)$ by

$$(u, v)_{L^2(D)} := \int_D u(x)v(x)dx$$

and define the resulting norm $\|\cdot\|_{L^2(D)}$ by the identity

$$\|u\|_{L^2(D)}^2 = (u, u)_{L^2(D)}$$

then the space $H^1(D)$ is a separable Hilbert space with inner product

$$\langle u, v \rangle_{H^1(D)} = (u, v)_{L^2(D)} + (\nabla u, \nabla v)_{L^2(D)}$$

and norm (10.101) with $p = 2$. Likewise the space $H_0^1(D)$ is a separable Hilbert space with inner product

$$\langle u, v \rangle_{H_0^1(D)} = (\nabla u, \nabla v)_{L^2(D)}$$

and norm

$$\|u\|_{H_0^1(D)} = \|\nabla u\|_{L^2(D)}. \quad (10.102)$$

As defined above, Sobolev spaces concern integer numbers of derivatives. However the concept can be extended to fractional derivatives, and there is then a natural connection to Hilbert scales of functions. To explain this we start our

development in the periodic setting. Recall that, given an element u in $L^2(\mathbb{T}^d)$, we can decompose it as a Fourier series:

$$u(x) = \sum_{k \in \mathbb{Z}^d} u_k e^{2\pi i \langle k, x \rangle},$$

where the identity holds for (Lebesgue) almost every $x \in \mathbb{T}^d$. Furthermore, the L^2 norm of u is given by Parseval's identity $\|u\|_{L^2}^2 = \sum |u_k|^2$. The fractional Sobolev space $H^s(\mathbb{T}^d)$ for $s \geq 0$ is given by the subspace of functions $u \in L^2(\mathbb{T}^d)$ such that

$$\|u\|_{H^s}^2 := \sum_{k \in \mathbb{Z}^d} (1 + 4\pi^2 |k|^2)^s |u_k|^2 < \infty. \quad (10.103)$$

Note that this is a separable Hilbert space by virtue of ℓ_w^2 being separable. Note also that $H^0(\mathbb{T}^d) = L^2(\mathbb{T}^d)$ and that, for positive integer s , the definition agrees with the definition $H^s(\mathbb{T}^d) = W^{s,2}(\mathbb{T}^d)$ obtained from (10.100) with the obvious generalization from D to \mathbb{T}^d . For $s < 0$, we define $H^s(\mathbb{T}^d)$ as the closure of L^2 under the norm (10.103). The spaces $H^s(\mathbb{T}^d)$ for $s < 0$ may also be defined via duality. The resulting spaces H^s are separable for all $s \in \mathbb{R}$.

We now link the spaces $H^s(\mathbb{T}^d)$ to a specific Hilbert scale of spaces. Hilbert scales are families of spaces defined by $\mathcal{D}(A^{s/2})$ for A a positive, unbounded, self-adjoint operator on a Hilbert space. To view the fractional Sobolev spaces from this perspective, let $A = I - \Delta$ with domain $H^2(\mathbb{T}^d)$, noting that the eigenvalues of A are simply $1 + 4\pi^2 |k|^2$ for $k \in \mathbb{Z}^d$. We thus see that, by the spectral decomposition theorem, $H^s = \mathcal{D}(A^{s/2})$, and we have $\|u\|_{H^s} = \|A^{s/2}u\|_{L^2}$. Note that we may work in the space of real-valued functions where the eigenfunctions of A , $\{\varphi_j\}_{j=1}^\infty$, comprise sine and cosine functions; the eigenvalues of A , when ordered on a one-dimensional lattice, then satisfy $\alpha_j \asymp j^{2/d}$. This is relevant to the more general perspective of Hilbert scales that we now introduce.

We can now generalize the previous construction of fractional Sobolev spaces to more general domains than the torus. The resulting spaces do not, in general, coincide with Sobolev spaces, because of the effect of the boundary conditions of the operator A used in the construction. On an arbitrary bounded open set $D \subset \mathbb{R}^d$ with Lipschitz boundary, we consider a positive self-adjoint operator A satisfying Assumption 1 so that its eigenvalues satisfy $\alpha_j \asymp j^{2/d}$; then we define the spaces $\mathcal{H}^s = \mathcal{D}(A^{s/2})$ for $s > 0$. Given a Hilbert space $(H, \langle \cdot, \cdot \rangle, \|\cdot\|)$ of real-valued functions on a bounded open set D in \mathbb{R}^d , we recall from Assumption 1 the orthonormal basis for H denoted by $\{\varphi_j\}_{j=1}^\infty$. Any $u \in H$ can be written as

$$u = \sum_{j=1}^{\infty} \langle u, \varphi_j \rangle \varphi_j.$$

Thus

$$\mathcal{H}^s = \left\{ u : D \rightarrow \mathbb{R} \mid \|w\|_{\mathcal{H}^s}^2 < \infty \right\} \quad (10.104)$$

where, for $u_j = \langle u, \varphi_j \rangle$,

$$\|u\|_{\mathcal{H}^s}^2 = \sum_{j=1}^{\infty} j^{\frac{2s}{d}} |u_j|^2.$$

In fact \mathcal{H}^s is a Hilbert space: for $v_j = \langle v, \varphi_j \rangle$ we may define the inner product

$$\langle u, v \rangle_{\mathcal{H}^s} = \sum_{j=1}^{\infty} j^{\frac{2s}{d}} u_j v_j.$$

For any $s > 0$, the Hilbert space $(\mathcal{H}^s, \langle \cdot, \cdot \rangle_{\mathcal{H}^s}, \|\cdot\|_{\mathcal{H}^s})$ is a subset of the original Hilbert space H ; for $s < 0$ the spaces are defined by duality and are supersets of H . Note also that we have Parseval-like identities showing that the \mathcal{H}^s norm on a function u is equivalent to the ℓ_w^2 norm on the sequence $\{u_j\}_{j=1}^{\infty}$ with the choice $w_j = j^{2s/d}$. The spaces \mathcal{H}^s are separable Hilbert spaces for any $s \in \mathbb{R}$.

A.1.4 Other Useful Function Spaces

As mentioned in passing, all of the preceding function spaces can be extended to functions taking values in $\mathbb{R}^n, \mathbb{R}^{n \times n}$; thus, we may then write $C(D; \mathbb{R}^n), L^p(D; \mathbb{R}^n)$, and $H^s(D; \mathbb{R}^n)$, for example. More generally we may wish to consider functions taking values in a separable Banach space E . For example, when we are interested in solutions of time-dependent PDEs, then these may be formulated as ordinary differential equations taking values in a separable Banach space E , with norm $\|\cdot\|_E$. It is then natural to consider Banach spaces such as $L^2((0, T); E)$ and $C([0, T]; E)$ with norms

$$\|u\|_{L^2((0, T); E)} = \sqrt{\left(\int_0^T \|u(\cdot, t)\|_E^2 dt \right)}, \quad \|u\|_{C([0, T]; E)} = \sup_{t \in [0, T]} \|u(\cdot, t)\|_E.$$

These norms can be generalized in a variety of ways, by generalizing the norm on the time variable.

The preceding idea of defining Banach space-valued L^p spaces defined on an interval $(0, T)$ can be taken further to define Banach space-valued L^p spaces defined on a measure space. Let (\mathcal{M}, ν) any countably generated measure space, like, for example, any Polish space (a separable completely metrizable topological space) equipped with a positive Radon measure ν . Again let E denote a separable Banach space. Then $L_v^p(\mathcal{M}; E)$ is the space of functions $u : \mathcal{M} \rightarrow E$ with norm (in this definition of norm we use Bochner integration, defined in the next subsection)

$$\|u\|_{L_v^p(\mathcal{M}; E)} = \left(\int_{\mathcal{M}} \|u(x)\|_E^p \nu(dx) \right)^{\frac{1}{p}}.$$

For $p \in (1, \infty)$ these spaces are separable. However, separability fails to hold for $p = \infty$. We will use these Banach spaces in the case where ν is a probability measure \mathbb{P} , with corresponding expectation \mathbb{E} , and we then have

$$\|u\|_{L_\nu^p(\mathcal{M}; E)} = \left(\mathbb{E}(\|u\|_E^p) \right)^{\frac{1}{p}}.$$

A.1.5 Interpolation Inequalities and Sobolev Embeddings

Here we state some useful interpolation inequalities and use them to prove a Sobolev embedding result, all in the context of fractional Sobolev spaces, in the generalized sense defined through a Hilbert scale of functions.

Let $p, q \in [1, \infty]$ be a pair of conjugate exponents so that $p^{-1} + q^{-1} = 1$. Then for any positive real a, b , we have the Young inequality

$$ab \leq \frac{a^p}{p} + \frac{b^q}{q}.$$

As a corollary of this elementary bound, we obtain the following Hölder inequality. Let (\mathcal{M}, μ) be a measure space and denote the norm $\|\cdot\|_{L_\nu^p(\mathcal{M}; \mathbb{R})}$ by $\|\cdot\|_p$. For $p, q \in [1, \infty]$ as above and $u, v: \mathcal{M} \rightarrow \mathbb{R}$ a pair of measurable functions, we have

$$\int_{\mathcal{M}} |u(x)v(x)| \mu(dx) \leq \|u\|_p \|v\|_q. \quad (10.105)$$

From this Hölder-like inequality, the following interpolation bound results: let $\alpha \in [0, 1]$ and let L denote a (possibly unbounded) self-adjoint operator on the Hilbert space $(H, \langle \cdot, \cdot \rangle, \|\cdot\|)$. Then, the bound

$$\|L^\alpha u\| \leq \|Lu\|^\alpha \|u\|^{1-\alpha} \quad (10.106)$$

holds for every $u \in \mathcal{D}(L) \subset H$.

Now assume that A is a self-adjoint unbounded operator on $L^2(D)$ with $D \subset \mathbb{R}^d$ a bounded open set with Lipschitz boundary. Assume further that A has eigenvalues $\alpha_j \asymp j^{\frac{2}{d}}$ and define the Hilbert scale of spaces $\mathcal{H}' = \mathcal{D}(A^{\frac{1}{2}})$. An immediate corollary of the bound (10.106), obtained by choosing $H = \mathcal{H}^s$, $L = A^{\frac{t-s}{2}}$, and $\alpha = (r-s)/(t-s)$, is:

Lemma 15. *Let Assumption 1 hold. Then for any $t > s$, any $r \in [s, t]$ and any $u \in \mathcal{H}'$, it follows that*

$$\|u\|_{\mathcal{H}'}^{t-s} \leq \|u\|_{\mathcal{H}'}^{r-s} \|u\|_{\mathcal{H}^s}^{t-r}.$$

It is of interest to bound the L^p norm of a function in terms of one of the fractional Sobolev norms, or more generally in terms of norms from a Hilbert scale. To do this we need to not only make assumptions on the eigenvalues of the operator

A which defines the Hilbert scale, but also on the behavior of the corresponding orthonormal basis of eigenfunctions in L^∞ . To this end we let Assumption 2 hold. It then turns out that bounding the L^∞ norm is rather straightforward and we start with this case.

Lemma 16. *Let Assumption 2 hold and define the resulting Hilbert scale of spaces \mathcal{H}^s by (10.104). Then for every $s > \frac{d}{2}$, the space \mathcal{H}^s is contained in the space $L^\infty(D)$ and there exists a constant K_1 such that $\|u\|_{L^\infty} \leq K_1 \|u\|_{\mathcal{H}^s}$.*

Proof. It follows from Cauchy-Schwarz that

$$\frac{1}{C} \|u\|_{L^\infty} \leq \sum_{k \in \mathbb{Z}^d} |u_k| \leq \left(\sum_{k \in \mathbb{Z}^d} (1 + |k|^2)^s |u_k|^2 \right)^{1/2} \left(\sum_{k \in \mathbb{Z}^d} (1 + |k|^2)^{-s} \right)^{1/2}.$$

Since the sum in the second factor converges if and only if $s > \frac{d}{2}$, the claim follows.

As a consequence of Lemma 16, we are able to obtain a more general Sobolev embedding for all L^p spaces:

Theorem 28 (Sobolev Embeddings). *Let Assumption 2 hold, define the resulting Hilbert scale of spaces \mathcal{H}^s by (10.104) and assume that $p \in [2, \infty]$. Then, for every $s > \frac{d}{2} - \frac{d}{p}$, the space \mathcal{H}^s is contained in the space $L^p(D)$, and there exists a constant K_2 such that $\|u\|_{L^p} \leq K_2 \|u\|_{\mathcal{H}^s}$.*

Proof. The case $p = 2$ is obvious and the case $p = \infty$ has already been shown, so it remains to show the claim for $p \in (2, \infty)$. The idea is to divide the space of eigenfunctions into ‘‘blocks’’ and to estimate separately the L^p norm of every block. More precisely, we define a sequence of functions $u^{(n)}$ by

$$u^{(-1)} = u_0 \varphi_0, \quad u^{(n)} = \sum_{2^n \leq j < 2^{n+1}} u_j \varphi_j,$$

where the φ_j are an orthonormal basis of eigenfunctions for A , so that $u = \sum_{n \geq -1} u^{(n)}$. For $n \geq 0$ the Hölder inequality gives

$$\|u^{(n)}\|_{L^p}^p \leq \|u^{(n)}\|_{L^2}^2 \|u^{(n)}\|_{L^\infty}^{p-2}. \quad (10.107)$$

Now set $s' = \frac{d}{2} + \epsilon$ for some $\epsilon > 0$ and note that the construction of $u^{(n)}$, together with Lemma 16, gives the bounds

$$\|u^{(n)}\|_{L^2} \leq K 2^{-ns/d} \|u^{(n)}\|_{\mathcal{H}^s}, \quad \|u^{(n)}\|_{L^\infty} \leq K_1 \|u^{(n)}\|_{\mathcal{H}^{s'}} \leq K 2^{n(s'-s)/d} \|u^{(n)}\|_{\mathcal{H}^s}. \quad (10.108)$$

Inserting this into (10.107), we obtain (possibly for an enlarged K)

$$\begin{aligned}\|u^{(n)}\|_{L^p} &\leq K \|u^{(n)}\|_{\mathcal{H}^s} 2^{n(\frac{(s'-s)\frac{p-2}{p}-\frac{2s}{p}}{d})/d} = K \|u^{(n)}\|_{\mathcal{H}^s} 2^{n(\epsilon \frac{p-2}{p} + \frac{d}{2} - \frac{d}{p} - s)/d} \\ &\leq K \|u\|_{\mathcal{H}^s} 2^{n(\epsilon + \frac{d}{2} - \frac{d}{p} - s)/d}.\end{aligned}$$

It follows that $\|u\|_{L^p} \leq |u_0| + \sum_{n \geq 0} \|u^{(n)}\|_{L^p} \leq K_2 \|u\|_{\mathcal{H}^s}$, provided that the exponent appearing in this expression is negative which, since ϵ can be chosen arbitrarily small, is precisely the case whenever $s > \frac{d}{2} - \frac{d}{p}$.

A.2 Probability and Integration In Infinite Dimensions

A.2.1 Product Measure for i.i.d. Sequences

Perhaps the most straightforward setting in which probability measures in infinite dimensions are encountered is when studying i.i.d. sequences of real-valued random variables. Furthermore, this is our basic building block for the construction of random functions – see Sect. 2.1 – so we briefly overview the subject. Let \mathbb{P}_0 be a probability measure on \mathbb{R} so that $(\mathbb{R}, \mathcal{B}(\mathbb{R}), \mathbb{P}_0)$ is a probability space and consider the i.i.d. sequence $\xi := \{\xi_j\}_{j=1}^\infty$ with $\xi_1 \sim \mathbb{P}_0$.

The construction of such a sequence can be formalised as follows. We consider ξ as a random variable taking values in the space \mathbb{R}^∞ endowed with the product topology, i.e. the smallest topology for which the projection maps $\ell_n : \xi \mapsto \xi_n$ are continuous for every n . This is a complete metric space; an example of a distance generating the product topology is given by

$$d(x, y) = \sum_{n=1}^{\infty} 2^{-n} \frac{|x_n - y_n|}{1 + |x_n - y_n|}.$$

Since we are considering a *countable* product, the resulting σ -algebra $\mathcal{B}(\mathbb{R}^\infty)$ coincides with the product σ -algebra, which is the smallest σ -algebra for which all ℓ_n 's are measurable.

In what follows we need the notion of the *pushforward* of a probability measure under a measurable map. If $f : B_1 \rightarrow B_2$ is a measurable map between two measurable spaces $(B_i, \mathcal{B}(B_i))$ $i = 1, 2$ and μ_1 is a probability measure on B_1 , then $\mu_2 = f^\# \mu_1$ denotes the pushforward probability measure on B_2 defined by $\mu_2(A) = \mu_1(f^{-1}(A))$ for all $A \in \mathcal{B}(B_2)$. (The notation $f^* \mu$ is sometimes used in place of $f^\# \mu$, but we reserve this notation for adjoints.) Recall that in Sect. 2, we construct random functions via the random series (10.11) whose coefficients are constructed from an i.i.d sequence. Our interest is in studying the pushforward measure $\mathcal{F}^\# \mathbb{P}_0$ where $\mathcal{F} : \mathbb{R}^\infty \rightarrow X'$ is defined by

$$\mathcal{F}\xi = m_0 + \sum_{j=1}^{\infty} \gamma_j \xi_j \phi_j. \quad (10.109)$$

In particular Sect. 2 is devoted to determining suitable separable Banach spaces X' on which to define the pushforward measure.

With the pushforward notation at hand, we may also describe Kolmogorov's extension theorem which can be stated as follows.

Theorem 29 (Kolmogorov Extension). *Let X be a Polish space and let I be an arbitrary set. Assume that, for any finite subset $A \subset I$, we are given a probability measure \mathbb{P}_A on the finite product space X^A . Assume furthermore that the family of measures $\{\mathbb{P}_A\}$ is consistent in the sense that if $B \subset A$ and $\Pi_{A,B}: X^A \rightarrow X^B$ denotes the natural projection map, then $\Pi_{A,B}^\sharp \mathbb{P}_A = \mathbb{P}_B$. Then, there exists a unique probability measure \mathbb{P} on X^I endowed with the product σ -algebra with the property that $\Pi_{I,A}^\sharp \mathbb{P} = \mathbb{P}_A$ for every finite subset $A \subset I$.*

Loosely speaking, one can interpret this theorem as stating that if one knows the law of any *finite* number of components of a random vector or function, then this determines the law of the *whole* random vector or function; in particular, in the case of the random function, this comprises *uncountably* many components. This statement is thus highly nontrivial as soon as the set I is infinite since we have a priori defined \mathbb{P}_A only for finite subsets $A \subset I$, and the theorem allows us to extend this uniquely also to infinite subsets.

As a simple application, we can use this theorem to define the infinite product measure $\mathbb{P} = \bigotimes_{k=1}^\infty \mathbb{P}_0$ as the measure given by Kolmogorov's Extension Theorem 29 if we take as our family of specifications $\mathbb{P}_A = \bigotimes_{k \in A} \mathbb{P}_0$. Our i.i.d. sequence ξ is then naturally defined as a random sample taken from the probability space $(\mathbb{R}^\infty, \mathcal{B}(\mathbb{R}^\infty), \mathbb{P})$. A more complicated example follows from making sense of the random field perspective on random functions as explained in Sect. 2.5.

A.2.2 Probability and Integration on Separable Banach Spaces

We now study probability and integration on separable Banach spaces B ; we let B^* denote the dual space of bounded linear functionals on B . The assumption of separability rules out some important function spaces like $L^\infty(D; \mathbb{R})$, but is required in order for the basic results of integration theory to hold. This is because, when considering a non-separable Banach space B , it is not clear what the “natural” σ -algebra on B is. One natural candidate is the Borel σ -algebra, denoted $\mathcal{B}(B)$, namely, the smallest σ -algebra containing all open sets; another is the cylindrical σ -algebra, namely, the smallest σ -algebra for which all bounded linear functionals on B are measurable. For i.i.d. sequences, the analogues of these two σ -algebras can be identified, whereas, in the general setting, the cylindrical σ -algebra can be strictly smaller than the Borel σ -algebra. In the case of separable Banach spaces, however, both σ -algebras agree:

Lemma 17. *Let B be a separable Banach space and let μ and ν be two Borel probability measures on B . If $\ell^\sharp \mu = \ell^\sharp \nu$ for every $\ell \in B^*$, then $\mu = \nu$.*

Thus, as for i.i.d. sequences, there is therefore a canonical notion of measurability. Whenever we refer to (probability) measures on a separable Banach space B in the sequel, we really mean (probability) measures on $(B, \mathcal{B}(B))$.

We now turn to the definition of integration with respect to probability measures on B . Given a (Borel) measurable function $f: \Omega \rightarrow B$ where $(\Omega, \mathcal{F}, \mathbb{P})$ is a standard probability space, we say that f is integrable with respect to \mathbb{P} if the map $\omega \mapsto \|f(\omega)\|$ belongs to $L^1_{\mathbb{P}}(\Omega; \mathbb{R})$. (Note that this map is certainly Borel measurable since the norm $\|\cdot\|: B \rightarrow \mathbb{R}$ is a continuous, and therefore also Borel measurable, function.) Given such an integrable function f , we *define* its Bochner integral by

$$\int f(\omega) \mathbb{P}(d\omega) = \lim_{n \rightarrow \infty} \int f_n(\omega) \mathbb{P}(d\omega),$$

where f_n is a sequence of simple functions, for which the integral on the right-hand side may be defined in the usual way, chosen such that

$$\lim_{n \rightarrow \infty} \int \|f_n(\omega) - f(\omega)\| \mathbb{P}(d\omega) = 0.$$

With this definition the value of the integral does not depend on the approximating sequence, it is linear in f , and

$$\int \ell(f(\omega)) \mathbb{P}(d\omega) = \ell\left(\int f(\omega) \mathbb{P}(d\omega)\right), \quad (10.110)$$

for every element ℓ in the dual space B^* .

Given a probability measure μ on a separable Banach space B , we now say that μ has *finite expectation* if the identity function $x \mapsto x$ is integrable with respect to μ . If this is the case, we define the expectation of μ as

$$\int_B x \mu(dx),$$

where the integral is interpreted as a Bochner integral.

Similarly, it is natural to say that μ has *finite variance* if the map $x \mapsto \|x\|^2$ is integrable with respect to μ . Regarding the covariance C_μ of μ itself, it is natural to define it as a bounded linear operator $C_\mu: B^* \rightarrow B$ with the property that

$$C_\mu \ell = \int_B x \ell(x) \mu(dx), \quad (10.111)$$

for every $\ell \in B^*$. At this stage, however, it is not clear whether such an operator C_μ always exists solely under the assumption that μ has finite variance. For any $x \in B$, we define the projection operator $P_x: B^* \rightarrow B$ by

$$P_x \ell = x \ell(x), \quad (10.112)$$

suggesting that we define

$$C_\mu := \int_B P_x \mu(dx). \quad (10.113)$$

The problem with this definition is that if we view the map $x \mapsto P_x$ as a map taking values in the space $\mathcal{L}(B^*, B)$ of bounded linear operators from $B^* \rightarrow B$, then, since this space is not separable in general, it is not clear a priori whether (10.113) makes sense as a Bochner integral. This suggests to define the subspace $B_*(B) \subset \mathcal{L}(B^*, B)$ given by the closure (in the usual operator norm) of the linear span of operators of the type P_x given in (10.112) for $x \in B$. We then have:

Lemma 18. *If B is separable, then $B_*(B)$ is also separable. Furthermore, $B_*(B)$ consists of compact operators.*

This leads to the following corollary:

Corollary 3. *Assume that μ has finite variance so that the map $x \mapsto \|x\|^2$ is integrable with respect to μ . Then the covariance operator C_μ defined by (10.113) exists as a Bochner integral in $B_*(B)$.*

Remark 3. Once the covariance is defined, the fact that (10.111) holds is then an immediate consequence of (10.110). In general, not every element $C \in B_*(B)$ can be realised as the covariance of some probability measure. This is the case even if we impose the positivity condition $\ell(C\ell) \geq 0$, which by (10.111) is a condition satisfied by every covariance operator. For further insight into this issue, see Lemma 23 which characterizes precisely the covariance operators of a Gaussian measure in separable Hilbert space. \square

Given any probability measure μ on B , we can define its *Fourier transform* $\hat{\mu}: B^* \rightarrow \mathbb{C}$ by

$$\hat{\mu}(\ell) := \int_B e^{i\ell(x)} \mu(dx). \quad (10.114)$$

For a Gaussian measure μ_0 on B with mean a and covariance operator C , it may be shown that, for any $\ell \in B^*$, the characteristic function is given by

$$\hat{\mu}_0(\ell) = e^{i\ell(a) - \frac{1}{2}\ell(C\ell)}. \quad (10.115)$$

As a consequence of Lemma 17, it is almost immediate that a measure is uniquely determined by its Fourier transform, and this is the content of the following result.

Lemma 19. *Let μ and ν be any two probability measures on a separable Banach space B . If $\hat{\mu}(\ell) = \hat{\nu}(\ell)$ for every $\ell \in B^*$, then $\mu = \nu$.*

A.2.3 Probability and Integration on Separable Hilbert Spaces

We will frequently be interested in the case where $B = \mathcal{H}$ for $(\mathcal{H}, \langle \cdot, \cdot \rangle, \|\cdot\|)$ some separable Hilbert space. Bochner integration can then, of course, be defined as a special case of the preceding development on separable Banach spaces. We make use of the Riesz representation theorem to identify \mathcal{H} with its dual and $\mathcal{H} \otimes \mathcal{H}$ with a subspace of the space of linear operators on \mathcal{H} . The covariance operator of a measure μ on \mathcal{H} may then be viewed as a bounded linear operator from \mathcal{H} into itself. The definition (10.111) of C_μ becomes

$$C_\mu \ell = \int_{\mathcal{H}} \langle \ell, x \rangle x \mu(dx), \quad (10.116)$$

for all $\ell \in \mathcal{H}$ and (10.113) becomes

$$C_\mu = \int_{\mathcal{H}} x \otimes x \mu(dx). \quad (10.117)$$

Corollary 3 shows that we can indeed make sense of the second formulation as a Bochner integral, provided that μ has finite variance in \mathcal{H} .

A.2.4 Metrics on Probability Measures

When discussing well posedness and approximation theory for the posterior distribution, it is of interest to estimate the distance between two probability measures, and thus we will be interested in metrics between probability measures. In this subsection we introduce two useful metrics on measures: the *total variation distance* and the *Hellinger distance*. We discuss the relationships between the metrics and indicate how they may be used to estimate differences between expectations of random variables under two different measures. We also discuss the *Kullback-Leibler divergence*, a useful distance measure which does not satisfy the axioms of a metric, but which may be used to bound both the Hellinger and total variation distances, and which is also useful in defining algorithms for finding the best approximation to a given measure from within some restricted class of measures, such as Gaussians.

Assume that we have two probability measures μ and μ' on a separable Banach space denoted by B (actually the considerations here apply on a Polish space but we do not need this level of generality). Assume that μ and μ' are both absolutely continuous with respect to a common reference measure ν , also defined on the same measure space. Such a measure always exists – take $\nu = \frac{1}{2}(\mu + \mu')$, for example. In the following, all integrals of real-valued functions over B are simply denoted by \int . The following define two concepts of distance between μ and μ' . The resulting metrics that we define are independent of the choice of this common reference measure.

Definition 3. The *total variation distance* between μ and μ' is

$$d_{\text{TV}}(\mu, \mu') = \frac{1}{2} \int \left| \frac{d\mu}{dv} - \frac{d\mu'}{dv} \right| dv. \quad \square$$

In particular, if μ' is absolutely continuous with respect to μ , then

$$d_{\text{TV}}(\mu, \mu') = \frac{1}{2} \int \left| 1 - \frac{d\mu'}{d\mu} \right| d\mu. \quad (10.118)$$

Definition 4. The *Hellinger distance* between μ and μ' is

$$d_{\text{Hell}}(\mu, \mu') = \sqrt{\frac{1}{2} \int \left(\sqrt{\frac{d\mu}{dv}} - \sqrt{\frac{d\mu'}{dv}} \right)^2 dv}. \quad \square$$

In particular, if μ' is absolutely continuous with respect to μ , then

$$d_{\text{Hell}}(\mu, \mu') = \sqrt{\frac{1}{2} \int \left(1 - \sqrt{\frac{d\mu'}{d\mu}} \right)^2 d\mu}. \quad (10.119)$$

Note that the numerical constant $\frac{1}{2}$ appearing in both definitions is chosen in such a way as to ensure the bounds

$$0 \leq d_{\text{TV}}(\mu, \mu') \leq 1, \quad 0 \leq d_{\text{Hell}}(\mu, \mu') \leq 1.$$

In the case of the total variation inequality, this is an immediate consequence of the triangle inequality, combined with the fact that both μ and μ' are probability measures, so that $\int \frac{d\mu}{dv} dv = 1$ and similarly for μ' . In the case of the Hellinger distance, it follows by expanding the square and applying similar considerations.

The Hellinger and total variation distances are related as follows, which shows in particular that they both generate the same topology:

Lemma 20. *The total variation and Hellinger metrics are related by the inequalities*

$$\frac{1}{\sqrt{2}} d_{\text{TV}}(\mu, \mu') \leq d_{\text{Hell}}(\mu, \mu') \leq d_{\text{TV}}(\mu, \mu')^{\frac{1}{2}}.$$

Proof. We have

$$\begin{aligned}
d_{\text{TV}}(\mu, \mu') &= \frac{1}{2} \int \left| \sqrt{\frac{d\mu}{dv}} - \sqrt{\frac{d\mu'}{dv}} \right| \left| \sqrt{\frac{d\mu}{dv}} + \sqrt{\frac{d\mu'}{dv}} \right| dv \\
&\leq \sqrt{\left(\frac{1}{2} \int \left(\sqrt{\frac{d\mu}{dv}} - \sqrt{\frac{d\mu'}{dv}} \right)^2 dv \right)} \sqrt{\left(\frac{1}{2} \int \left(\sqrt{\frac{d\mu}{dv}} + \sqrt{\frac{d\mu'}{dv}} \right)^2 dv \right)} \\
&\leq \sqrt{\left(\frac{1}{2} \int \left(\sqrt{\frac{d\mu}{dv}} - \sqrt{\frac{d\mu'}{dv}} \right)^2 dv \right)} \sqrt{\left(\int \left(\frac{d\mu}{dv} + \frac{d\mu'}{dv} \right) dv \right)} \\
&= \sqrt{2} d_{\text{Hell}}(\mu, \mu')
\end{aligned}$$

as required for the first bound.

For the second bound note that, for any positive a and b , one has the bound $|\sqrt{a} - \sqrt{b}| \leq \sqrt{a} + \sqrt{b}$. As a consequence, we have the bound

$$\begin{aligned}
d_{\text{Hell}}(\mu, \mu')^2 &\leq \frac{1}{2} \int \left| \sqrt{\frac{d\mu}{dv}} - \sqrt{\frac{d\mu'}{dv}} \right| \left| \sqrt{\frac{d\mu}{dv}} + \sqrt{\frac{d\mu'}{dv}} \right| dv \\
&= \frac{1}{2} \int \left| \frac{d\mu}{dv} - \frac{d\mu'}{dv} \right| dv \\
&= d_{\text{TV}}(\mu, \mu'),
\end{aligned}$$

as required.

Example 11. Consider two Gaussian densities on \mathbb{R} : $N(m_1, \sigma_1^2)$ and $N(m_2, \sigma_2^2)$. The Hellinger distance between them is given by

$$d_{\text{Hell}}(\mu, \mu')^2 = 1 - \sqrt{\exp\left(-\frac{(m_1 - m_2)^2}{2(\sigma_1^2 + \sigma_2^2)}\right) \frac{2\sigma_1\sigma_2}{(\sigma_1^2 + \sigma_2^2)}}.$$

To see this note that

$$d_{\text{Hell}}(\mu, \mu')^2 = 1 - \frac{1}{(2\pi\sigma_1\sigma_2)^{\frac{1}{2}}} \int_{\mathbb{R}} \exp(-Q) dx$$

where

$$Q = \frac{1}{4\sigma_1^2}(x - m_1)^2 + \frac{1}{4\sigma_2^2}(x - m_2)^2.$$

Define σ^2 by

$$\frac{1}{2\sigma^2} = \frac{1}{4\sigma_1^2} + \frac{1}{4\sigma_2^2}.$$

We change variable under the integral to y given by

$$y = x - \frac{m_1 + m_2}{2}$$

and note that then, by completing the square,

$$Q = \frac{1}{2\sigma^2}(y - m)^2 + \frac{1}{4(\sigma_1^2 + \sigma_2^2)}(m_2 - m_1)^2$$

where m does not appear in what follows and so we do not detail it. Noting that the integral is then a multiple of a standard Gaussian $N(m, \sigma^2)$ gives the desired result. In particular this calculation shows that the Hellinger distance between two Gaussians on \mathbb{R} tends to zero if and only if the means and variances of the two Gaussians approach one another. Furthermore, by the previous lemma, the same is true for the total variation distance. \square

The preceding example generalizes to higher dimension and shows that, for example, the total variation and Hellinger metrics cannot metrize weak convergence of probability measures (as one can also show that convergence in total variation metric implies strong convergence). They are nonetheless useful distance measures, for example, between families of measures which are mutually absolutely continuous. Furthermore, the Hellinger distance is particularly useful for estimating the difference between expectation values of functions of random variables under different measures. This is encapsulated in the following lemma:

Lemma 21. *Let μ and μ' be two probability measures on a separable Banach space X . Assume also that $f : X \rightarrow E$, where $(E, \|\cdot\|)$ is a separable Banach space, is measurable and has second moments with respect to both μ and μ' . Then*

$$\|\mathbb{E}^\mu f - \mathbb{E}^{\mu'} f\| \leq 2\left(\mathbb{E}^\mu \|f\|^2 + \mathbb{E}^{\mu'} \|f\|^2\right)^{\frac{1}{2}} d_{\text{Hell}}(\mu, \mu').$$

Furthermore, if E is a separable Hilbert space and $f : X \rightarrow E$ as before has fourth moments, then

$$\|\mathbb{E}^\mu(f \otimes f) - \mathbb{E}^{\mu'}(f \otimes f)\| \leq 2\left(\mathbb{E}^\mu \|f\|^4 + \mathbb{E}^{\mu'} \|f\|^4\right)^{\frac{1}{2}} d_{\text{Hell}}(\mu, \mu').$$

Proof. Let ν be a reference probability measure as above. We then have the bound

$$\begin{aligned} \|\mathbb{E}^\mu f - \mathbb{E}^{\mu'} f\| &\leq \int \|f\| \left| \frac{d\mu}{d\nu} - \frac{d\mu'}{d\nu} \right| d\nu \\ &= \int \left(\frac{1}{\sqrt{2}} \left| \sqrt{\frac{d\mu}{d\nu}} - \sqrt{\frac{d\mu'}{d\nu}} \right| \right) \left(\sqrt{2} \|f\| \left| \sqrt{\frac{d\mu}{d\nu}} + \sqrt{\frac{d\mu'}{d\nu}} \right| \right) d\nu \\ &\leq \sqrt{\left(\frac{1}{2} \int \left(\sqrt{\frac{d\mu}{d\nu}} - \sqrt{\frac{d\mu'}{d\nu}} \right)^2 d\nu \right)} \sqrt{\left(2 \int \|f\|^2 \left(\sqrt{\frac{d\mu}{d\nu}} + \sqrt{\frac{d\mu'}{d\nu}} \right)^2 d\nu \right)} \\ &\leq \sqrt{\left(\frac{1}{2} \int \left(\sqrt{\frac{d\mu}{d\nu}} - \sqrt{\frac{d\mu'}{d\nu}} \right)^2 d\nu \right)} \sqrt{\left(4 \int \|f\|^2 \left(\frac{d\mu}{d\nu} + \frac{d\mu'}{d\nu} \right) d\nu \right)} \\ &= 2 \left(\mathbb{E}^\mu \|f\|^2 + \mathbb{E}^{\mu'} \|f\|^2 \right)^{\frac{1}{2}} d_{\text{Hell}}(\mu, \mu') \end{aligned}$$

as required.

The proof for $f \otimes f$ follows from the bound

$$\begin{aligned} \|\mathbb{E}^\mu(f \otimes f) - \mathbb{E}^{\mu'}(f \otimes f)\| &= \sup_{\|h\|=1} \|\mathbb{E}^\mu \langle f, h \rangle f - \mathbb{E}^{\mu'} \langle f, h \rangle f\| \\ &\leq \int \|f\|^2 \left| \frac{d\mu}{d\nu} - \frac{d\mu'}{d\nu} \right| d\nu, \end{aligned}$$

and then arguing similarly to the first case but with $\|f\|$ replaced by $\|f\|^2$.

Remark 4. Note, in particular, that choosing $X = E$, and with f chosen to be the identity mapping, we deduce that the differences between the mean (respectively, covariance operator) of two measures are bounded above by their Hellinger distance, provided that one has some a priori control on the second (respectively, fourth) moments. \square

We now define a third widely used distance concept for comparing two probability measures. Note, however, that it does not give rise to a metric in the strict sense, because it violates both symmetry and the triangle inequality.

Definition 5. The Kullback-Leibler divergence between two measures μ' and μ , with μ' absolutely continuous with respect to μ , is

$$D_{\text{KL}}(\mu' \parallel \mu) = \int \frac{d\mu'}{d\mu} \log \left(\frac{d\mu'}{d\mu} \right) d\mu. \quad \square$$

If μ is also absolutely continuous with respect to μ' , so that the two measures are equivalent, then

$$D_{\text{KL}}(\mu' \parallel \mu) = - \int \log\left(\frac{d\mu}{d\mu'}\right) d\mu'$$

and the two definitions coincide.

Example 12. Consider two Gaussian densities on \mathbb{R} : $N(m_1, \sigma_1^2)$ and $N(m_2, \sigma_2^2)$. The Kullback-Leibler divergence between them is given by

$$D_{\text{KL}}(\mu_1 \parallel \mu_2) = \ln\left(\frac{\sigma_2}{\sigma_1}\right) + \frac{1}{2}\left(\frac{\sigma_1^2}{\sigma_2^2} - 1\right) + \frac{(m_2 - m_1)^2}{2\sigma_2^2}.$$

To see this note that

$$\begin{aligned} D_{\text{KL}}(\mu_1 \parallel \mu_2) &= \mathbb{E}^{\mu_1} \left(\ln \sqrt{\frac{\sigma_2^2}{\sigma_1^2}} + \frac{1}{2\sigma_2^2} |x - m_2|^2 - \frac{1}{2\sigma_1^2} |x - m_1|^2 \right) \\ &= \ln \frac{\sigma_2}{\sigma_1} + \mathbb{E}^{\mu_1} \left(\left(\frac{1}{2\sigma_2^2} - \frac{1}{2\sigma_1^2} \right) |x - m_1|^2 \right) \\ &\quad + \mathbb{E}^{\mu_1} \frac{1}{2\sigma_2^2} \left(|x - m_2|^2 - |x - m_1|^2 \right) \\ &= \ln \frac{\sigma_2}{\sigma_1} + \frac{1}{2} \left(\frac{\sigma_1^2}{\sigma_2^2} - 1 \right) + \frac{1}{2\sigma_2^2} \mathbb{E}^{\mu_1} \left(m_2^2 - m_1^2 + 2x(m_1 - m_2) \right) \\ &= \ln \frac{\sigma_2}{\sigma_1} + \frac{1}{2} \left(\frac{\sigma_1^2}{\sigma_2^2} - 1 \right) + \frac{1}{2\sigma_2^2} (m_2 - m_1)^2 \end{aligned}$$

as required. \square

As for Hellinger distance, this example shows that two Gaussians on \mathbb{R} approach one another in the Kullback-Leibler divergence if and only if their means and variances approach one another. This generalizes to higher dimensions. The Kullback-Leibler divergence provides an upper bound for the square of the Hellinger distance and for the square of the total variation distance.

Lemma 22. *Assume that two measures μ and μ' are equivalent. Then the bounds*

$$d_{\text{Hell}}(\mu, \mu')^2 \leq \frac{1}{2} D_{\text{KL}}(\mu \parallel \mu'), \quad d_{\text{TV}}(\mu, \mu')^2 \leq D_{\text{KL}}(\mu \parallel \mu'),$$

hold.

Proof. The second bound follows from the first by using Lemma 20, thus it suffices to proof the first. In the following we use the fact that

$$x - 1 \geq \log(x) \quad \forall x \geq 0,$$

so that

$$\sqrt{x} - 1 \geq \frac{1}{2} \log(x) \quad \forall x \geq 0.$$

This yields the bound

$$\begin{aligned} d_{\text{Hell}}(\mu, \mu')^2 &= \frac{1}{2} \int \left(\sqrt{\frac{d\mu'}{d\mu}} - 1 \right)^2 d\mu = \frac{1}{2} \int \left(\frac{d\mu'}{d\mu} + 1 - 2\sqrt{\frac{d\mu'}{d\mu}} \right) d\mu \\ &= \int \left(1 - \sqrt{\frac{d\mu'}{d\mu}} \right) d\mu \leq \frac{1}{2} \int \left(-\log \frac{d\mu'}{d\mu} \right) d\mu \\ &= \frac{1}{2} D_{\text{KL}}(\mu || \mu'), \end{aligned}$$

as required.

A.2.5 Kolmogorov Continuity Test

The setting of Kolmogorov's continuity test is the following. We assume that we are given a compact domain $D \subset \mathbb{R}^d$, a complete separable metric space X , as well as a collection of X -valued random variables $u : x \in D \mapsto X$. At this stage we assume no regularity whatsoever on the parameter x : the distribution of this collection of random variables is a measure μ_0 on the space X^D of all functions from D to X endowed with the product σ -algebra. Any consistent family of marginal distributions does yield such a measure by Kolmogorov's extension Theorem 29. With these notations at hand, Kolmogorov's continuity test can be formulated as follows and enables the extraction of regularity with respect to variation of $u(x)$ with respect to x .

Theorem 30 (Kolmogorov Continuity Test). *Let D and u be as above and assume that there exist $p > 1$, $\alpha > 0$ and $K > 0$ such that*

$$\mathbb{E} d(u(x), u(y))^p \leq K|x - y|^{p\alpha+d}, \quad \forall x, y \in D, \quad (10.120)$$

where d denotes the distance function on X and d the dimension of the compact domain D . Then, for every $\beta < \alpha$, there exists a unique measure μ on $C^{0,\beta}(D, X)$ such that the canonical process under μ has the same law as u .

We have here generalized the notion of Hölder spaces from Sect. A.1.2 to functions taking values in a Polish space; such generalizations are discussed in Sect. A.1.4. The notion of *canonical process* is defined in Sect. A.4.

We will frequently use Kolmogorov's continuity test in the following setting: we again assume that we are given a compact domain $D \subset \mathbb{R}^d$, and now a collection $u(x)$ of \mathbb{R}^n -valued random variables indexed by $x \in D$. We have the following:

Corollary 4. *Assume that there exist $p > 1$, $\alpha > 0$ and $K > 0$ such that*

$$\mathbb{E}|u(x) - u(y)|^p \leq K|x - y|^{p\alpha+d}, \quad \forall x, y \in D.$$

Then, for every $\beta < \alpha$, there exists a unique measure μ on $C^{0,\beta}(D)$ such that the canonical process under μ has the same law as u .

Remark 5. Recall that $C^{0,\gamma'}(D) \subset C_0^{0,\gamma}(D)$ for all $\gamma' > \gamma$ so that, since the interval $\beta < \alpha$ for this theorem is open, we may interpret the result as giving an equivalent measure defined on a separable Banach space.

A very useful consequence of Kolmogorov's continuity criterion is the following result. The setting is to consider a random function f given by the random series

$$u = \sum_{k \geq 0} \xi_k \psi_k \tag{10.121}$$

where $\{\xi_k\}_{k \geq 0}$ is an i.i.d. sequence and the ψ_k are real- or complex-valued Hölder functions on bounded open $D \subset \mathbb{R}^d$ satisfying, for some $\alpha \in (0, 1]$,

$$|\psi_k(x) - \psi_k(y)| \leq h(\alpha, \psi_k)|x - y|^\alpha \quad x, y \in D; \tag{10.122}$$

of course if $\alpha = 1$ the functions are Lipschitz.

Corollary 5. *Let $\{\xi_k\}_{k \geq 0}$ be countably many centred i.i.d. random variables (real or complex) with bounded moments of all orders. Moreover let $\{\psi_k\}_{k \geq 0}$ satisfy (10.122). Suppose there is some $\delta \in (0, 2)$ such that*

$$S_1 := \sum_{k \geq 0} \|\psi_k\|_{L^\infty}^2 < \infty \quad \text{and} \quad S_2 := \sum_{k \geq 0} \|\psi_k\|_{L^\infty}^{2-\delta} h(\alpha, \psi_k)^\delta < \infty. \tag{10.123}$$

Then u defined by (10.121) is almost surely finite for every $x \in D$, and u is Hölder continuous for every Hölder exponent smaller than $\alpha\delta/2$.

Proof. Let us denote by $\kappa_n(X)$ the n th cumulant of a random variable X . The odd cumulants of centred random variables are zero. Furthermore, using the fact that the

cumulants of independent random variables simply add up and that the cumulants of ξ_k are all finite by assumption, we obtain for $p \geq 1$ the bound

$$\begin{aligned} |\kappa_{2p}(u(x) - u(y))| &= \left| \sum_{k \geq 0} \kappa_{2p}(\xi_k) (\psi_k(x) - \psi_k(y))^{2p} \right| \\ &\lesssim C_p \sum_{k \geq 0} \min\{2^{2p} \|\psi_k\|_{L^\infty}^{2p}, h(\alpha, \psi_k)^{2p} |x - y|^{2p\alpha}\} \\ &\lesssim C_p \sum_{k \geq 0} \|\psi_k\|_{L^\infty}^{(1-\frac{\delta}{2})2p} h(\alpha, \psi_k)^{2p \cdot \frac{\delta}{2}} |x - y|^{2p\alpha \cdot \frac{\delta}{2}} \\ &\lesssim C_p |x - y|^{p\alpha\delta}, \end{aligned}$$

with C_p denoting positive constants depending on p which can change from occurrence to occurrence and where we used that $\min\{a, bx^2\} \leq a^{1-\delta/2} b^{\delta/2} |x|^\delta$ for any $a, b \geq 0$ and the finiteness of S_2 . In a similar way, we obtain $|\kappa_{2p}u(x)| < \infty$ for every $p \geq 1$. Since the random variables $u(x)$ are centred, all moments of even order $2p$, $p \geq 1$, can be expressed in terms of homogeneous polynomials of the even cumulants of order upto $2p$, so that

$$\mathbb{E}|u(x) - u(y)|^{2p} \lesssim C_p |x - y|^{p\alpha\delta}, \quad \mathbb{E}|u(x)|^{2p} < \infty,$$

uniformly over $x, y \in D$. The almost sure boundedness on L^∞ follows from the second bound. The Hölder continuity claim follows from Kolmogorov's continuity test in the form of Corollary 4, after noting that $p\alpha\delta = 2p\left(\frac{1}{2}\alpha\delta - \frac{d}{2p}\right) + d$ and choosing p arbitrarily large.

Remark 6. Note that (10.121) is simply a rewrite of (10.11), with $\psi_0 = m_0$, $\xi_0 = 1$ and $\psi_k = \gamma_k \phi_k$. In the case where the ξ_k are standard normal, then the ψ_k 's in Corollary 5 form an orthonormal basis of the Cameron-Martin space (see Definition 7) of a Gaussian measure. The criterion (10.123) then provides an effective way of showing that the measure in question can be realised on a space of Hölder continuous functions. \square

A.3 Gaussian Measures

A.3.1 Separable Banach Space Setting

We start with the definition of a Gaussian measure on a separable Banach space B . There is no equivalent to Lebesgue measure in infinite dimensions (as it could not be σ -additive), and so we cannot define a Gaussian measure by prescribing the form of its density. However, note that Gaussian measures on \mathbb{R}^n can be characterised by prescribing that the projections of the measure onto any one-dimensional subspace

of \mathbb{R}^n are all Gaussian. This is a property that can readily be generalised to infinite-dimensional spaces:

Definition 6. A *Gaussian probability measure* μ on a separable Banach space B is a Borel measure such that $\ell^\sharp\mu$ is a Gaussian probability measure on \mathbb{R} for every continuous linear functional $\ell: B \rightarrow \mathbb{R}$. (Here, Dirac measures are considered to be Gaussian measures with zero variance.) The measure is said to be *centred* if $\ell^\sharp\mu$ has mean zero for every ℓ . \square

This is a reasonable definition since, provided that B is separable, the one-dimensional projections of any probability measure carry sufficient information to characterise it – see Lemma 17. We now state an important result which controls the tails of Gaussian distributions:

Theorem 31 (Fernique). Let μ be a Gaussian probability measure on a separable Banach space B . Then, there exists $\alpha > 0$ such that $\int_B \exp(\alpha \|x\|^2) \mu(dx) < \infty$.

As a consequence of the Fernique theorem and the Corollary 3, every Gaussian measure μ admits a compact covariance operator C_μ given by (10.113), because the second moment is bounded. In fact the techniques used to prove the Fernique theorem show that, if $M = \int_B \|x\| \mu(dx)$, then there is a global constant $K > 0$ such that

$$\int_B \|x\|^{2n} \mu(dx) \leq n! K \alpha^{-n} M^{2n}. \quad (10.124)$$

Since the covariance operator, and hence the mean, exist for a Gaussian measure, and since they may be shown to characterize the measure completely, we write $N(m, C_\mu)$ for a Gaussian with mean m and covariance operator C_μ .

Measures in infinite-dimensional spaces are typically mutually singular. Furthermore, two Gaussian measures are either mutually singular or equivalent (mutually absolutely continuous). The Cameron-Martin space plays a key role in characterizing whether or not two Gaussians are equivalent.

Definition 7. The *Cameron-Martin space* \mathcal{H}_μ of measure μ on a separable Banach space B is the completion of the linear subspace $\mathring{\mathcal{H}}_\mu \subset B$ defined by

$$\mathring{\mathcal{H}}_\mu = \{h \in B : \exists h^* \in B^* \text{ with } h = C_\mu h^*\}, \quad (10.125)$$

under the norm $\|h\|_\mu^2 = \langle h, h \rangle_\mu = h^*(C_\mu h^*)$. It is a Hilbert space when endowed with the scalar product $\langle h, k \rangle_\mu = h^*(C_\mu k^*) = h^*(k) = k^*(h)$.

The Cameron-Martin space is actually independent of the space B in the sense that, although we may view the measure as living on a range of separable Hilbert or Banach spaces, the Cameron-Martin space will be the same in all cases. The space

characterizes exactly the directions in which a centred Gaussian measure may be shifted to obtain an equivalent Gaussian measure:

Theorem 32 (Cameron-Martin). *For $h \in B$, define the map $T_h: B \rightarrow B$ by $T_h(x) = x + h$. Then, the measure $T_h^\sharp\mu$ is absolutely continuous with respect to μ if and only if $h \in \mathcal{H}_\mu$. Furthermore, in the latter case, its Radon-Nikodym derivative is given by*

$$\frac{dT_h^\sharp\mu}{d\mu}(u) = \exp(h^*(u) - \frac{1}{2}\|h\|_\mu^2)$$

where $h = C_\mu h^*$.

Thus, this theorem characterizes the Radon-Nikodym derivative of the measure $N(h, C_\mu)$ with respect to the measure $N(0, C_\mu)$. Below, in the Hilbert space setting, we also consider changes in the covariance operator which lead to equivalent Gaussian measures. However, before moving to the Hilbert space setting, we conclude this subsection with several useful observations concerning Gaussians on separable Banach spaces. The *topological support* of measure μ on the separable Banach space B is the set of all $u \in B$ such that any neighborhood of u has a positive measure.

Theorem 33. *The topological support of a centred Gaussian measure μ on B is the closure of the Cameron-Martin space in B . Furthermore the Cameron-Martin space is dense in X . Therefore all balls in B have positive μ -measure.*

Since the Cameron-Martin space of Gaussian measure μ is independent of the space on which we view the measure as living, this following useful theorem shows that the unit ball in the Cameron-Martin space is compact in any separable Banach space X for which $\mu(X) = 1$:

Theorem 34. *The closed unit ball in the Cameron-Martin space \mathcal{H}_μ is compactly embedded into the separable Banach space B .*

In the setting of Gaussian measures on a separable Banach space, all balls have positive probability. The Cameron-Martin norm is useful in the characterization of small-ball properties of Gaussians. Let $B^\delta(z)$ denote a ball of radius δ in B centred at a point $z \in \mathcal{H}_\mu$.

Theorem 35. *The ratio of small ball probabilities under Gaussian measure μ satisfy*

$$\lim_{\delta \rightarrow 0} \frac{\mu(B^\delta(z_1))}{\mu(B^\delta(z_2))} = \exp\left(\frac{1}{2}\|z_2\|_\mu^2 - \frac{1}{2}\|z_1\|_\mu^2\right).$$

Example 13. Let μ denote the Gaussian measure $N(0, K)$ on \mathbb{R}^n with K positive definite. Then Theorem 35 is the statement that

$$\lim_{\delta \rightarrow 0} \frac{\mu(B^\delta(z_1))}{\mu(B^\delta(z_2))} = \exp\left(\frac{1}{2}|K^{-\frac{1}{2}}z_2|^2 - \frac{1}{2}|K^{-\frac{1}{2}}z_1|^2\right)$$

which follows directly from the fact that the Gaussian measure at point $z \in \mathbb{R}^n$ has Lebesgue density proportional to $\exp\left(-\frac{1}{2}|K^{-\frac{1}{2}}z|^2\right)$ and the fact that the Lebesgue density is a continuous function. \square

A.3.2 Separable Hilbert Space Setting

In these notes our approach is primarily based on defining Gaussian measures on Hilbert space; the Banach spaces which are of full measure under the Gaussian are then determined via the Kolmogorov continuity theorem. In this subsection we develop the theory of Gaussian measures in greater detail within the Hilbert space setting. Throughout $(\mathcal{H}, \langle \cdot, \cdot \rangle, \|\cdot\|)$ denotes the separable Hilbert space on which the Gaussian is constructed. Actually, in this Hilbert space setting, the covariance operator C_μ has considerably more structure than just the boundedness implied by (10.124): it is trace class and hence necessarily compact on \mathcal{H} :

Lemma 23. *A Gaussian measure μ on a separable Hilbert space \mathcal{H} has covariance operator $C_\mu: \mathcal{H} \rightarrow \mathcal{H}$ which is trace class and satisfies*

$$\int_{\mathcal{H}} \|x\|^2 \mu(dx) = \text{Tr } C_\mu. \quad (10.126)$$

Conversely, for every positive trace class symmetric operator $K: \mathcal{H} \rightarrow \mathcal{H}$, there exists a Gaussian measure μ on \mathcal{H} such that $C_\mu = K$.

Since the covariance operator $C_\mu: \mathcal{H} \rightarrow \mathcal{H}$ of a Gaussian on \mathcal{H} is a compact operator, it follows that if operator $C_\mu: \mathcal{H} \rightarrow \mathcal{H}$ has an inverse, then it will be a densely defined unbounded operator on \mathcal{H} ; we call this the *precision operator*. Both the covariance and the precision operators are self-adjoint on appropriate domains, and fractional powers of them may be defined via the spectral theorem.

Theorem 36 (Cameron-Martin Space on Hilbert Space). *Let μ be a Gaussian measure on a Hilbert space \mathcal{H} with strictly positive covariance operator K . Then the Cameron-Martin space \mathcal{H}_μ consists of the image of \mathcal{H} under $K^{1/2}$ and the Cameron-Martin norm is given by $\|h\|_\mu^2 = \|K^{-\frac{1}{2}}h\|^2$.*

Example 14. Consider two Gaussian measures μ_i on $\mathcal{H} = L^2(J)$, $J = (0, 1)$ both with precision operator $L = -\frac{d^2}{dx^2}$ where $\mathcal{D}(L) = H_0^1(J) \cap H^2(J)$. (Informally $-L$ is the Laplacian on J with homogeneous Dirichlet boundary conditions.) Let

\mathcal{C} denote the inverse of L on \mathcal{H} . Assume that $\mu_1 \sim N(m, \mathcal{C})$ and $\mu_2 \sim N(0, \mathcal{C})$. Then \mathcal{H}_{μ_i} is the image of \mathcal{H} under $\mathcal{C}^{\frac{1}{2}}$ which is the space $= H_0^1(J)$. It follows that the measures are equivalent if and only if $m \in H_0^1(J)$. If this condition is satisfied then, from Theorem 36, the Radon-Nikodym derivative between the two measures is given by

$$\frac{d\mu_1}{d\mu_2}(x) = \exp\left(\langle m, x \rangle_{H_0^1} - \frac{1}{2}\|m\|_{H_0^1}^2\right). \quad \square$$

We now turn to the Feldman-Hájek theorem in the Hilbert Space setting. Let $\{\varphi_j\}_{j=1}^\infty$ denote an orthonormal basis for \mathcal{H} . Then the *Hilbert-Schmidt norm* of a linear operator $L : \mathcal{H} \rightarrow \mathcal{H}$ is defined by

$$\|L\|_{\text{HS}}^2 := \sum_{j=1}^{\infty} \|L\varphi_j\|^2.$$

The value of the norm is, in fact, independent of the choice of orthonormal basis. In the finite-dimensional setting, the norm is known as the *Frobenius norm*.

Theorem 37 (Feldman-Hájek on Hilbert Space). *Let μ_i with $i = 1, 2$ be two centred Gaussian measures on some fixed Hilbert space \mathcal{H} with means m_i and strictly positive covariance operators \mathcal{C}_i . Then the following hold:*

1. μ_1 and μ_2 are either singular or equivalent.
2. The measures μ_1 and μ_2 are equivalent Gaussian measures if and only if:
 - a) The images of \mathcal{H} under $\mathcal{C}_i^{\frac{1}{2}}$ coincide for $i = 1, 2$, and we denote this common image space by E ;
 - b) $m_1 - m_2 \in E$;
 - c) $\|(\mathcal{C}_1^{-1/2}\mathcal{C}_2^{1/2})(\mathcal{C}_1^{-1/2}\mathcal{C}_2^{1/2})^* - I\|_{\text{HS}} < \infty$.

Remark 7. The final condition may be replaced by the condition that

$$\|(\mathcal{C}_1^{1/2}\mathcal{C}_2^{-1/2})(\mathcal{C}_1^{1/2}\mathcal{C}_2^{-1/2})^* - I\|_{\text{HS}} < \infty$$

and the theorem remains true; this formulation is sometimes useful. \square

Example 15. Consider two mean-zero Gaussian measures μ_i on $\mathcal{H} = L^2(J)$, $J = (0, 1)$ with precision operators $L_1 = -\frac{d^2}{dx^2} + I$ and $L_2 = -\frac{d^2}{ds^2}$, respectively, both with domain $H_0^1(J) \cap H^2(J)$. The operators L_1, L_2 share the same eigenfunctions

$$\phi_k(x) = \sqrt{2} \sin(k\pi x)$$

and have eigenvalues

$$\lambda_k(1) = \lambda_k(2) + 1, \quad \lambda_k(2) = k^2\pi^2,$$

respectively. Thus $\mu_1 \sim N(0, \mathcal{C}_1)$ and $\mu_2 \sim N(0, \mathcal{C}_2)$ where, in the basis of eigenfunctions, \mathcal{C}_1 and \mathcal{C}_2 are diagonal with eigenvalues

$$\frac{1}{k^2\pi^2 + 1}, \quad \frac{1}{k^2\pi^2}$$

respectively. We have, for $h_k = \langle h, \phi_k \rangle$,

$$\frac{\pi^2}{\pi^2 + 1} \leq \frac{\langle h, \mathcal{C}_1 h \rangle}{\langle h, \mathcal{C}_2 h \rangle} = \frac{\sum_{k \in \mathbb{Z}^+} (1 + k^2\pi^2)^{-1} h_k^2}{\sum_{k \in \mathbb{Z}^+} (k\pi)^{-2} h_k^2} \leq 1.$$

From this it follows that the Cameron-Martin spaces of the two measures coincide and are equal to $H_0^1(J)$. Notice that

$$T = \mathcal{C}_1^{-\frac{1}{2}} \mathcal{C}_2 \mathcal{C}_1^{-\frac{1}{2}} - I$$

is diagonalized in the same basis as the \mathcal{C}_i and has eigenvalues

$$\frac{1}{k^2\pi^2}.$$

These are square summable and so by Theorem 37 the two measures are absolutely continuous with respect to one another. \square

A.4 Wiener Processes in Infinite-Dimensional Spaces

Central to the theory of stochastic PDEs is the notion of a *cylindrical Wiener process*, which can be thought of as an infinite-dimensional generalization of a standard n -dimensional Wiener process. This leads to the notion of the A -Wiener process (A -) for certain classes of operators A . Before we proceed to the definition and construction of such Wiener processes in separable Hilbert spaces, let us recall a few basic facts about stochastic processes in general.

In general, a stochastic process u over a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ and taking values in a separable Hilbert space \mathcal{H} is nothing but a collection $\{u(t)\}$ of \mathcal{H} -valued random variables indexed by time $t \in \mathbb{R}$ (or taking values in some subset of \mathbb{R}). By Kolmogorov's Extension Theorem 29, we can also view this as a map $u: \Omega \rightarrow \mathcal{H}^\mathbb{R}$, where $\mathcal{H}^\mathbb{R}$ is endowed with the product sigma-algebra. A notable special case which will be of interest here is the case where the probability space is taken to be $\Omega = C([0, T], \mathcal{H})$ (or some other space of \mathcal{H} -valued continuous functions) endowed with some Gaussian measure \mathbb{P} and where the process X is given by

$$u(t)(\omega) = \omega(t), \quad \omega \in \Omega.$$

In this case, u is called the canonical process on Ω .

The usual (one-dimensional) Wiener process is a real-valued centred Gaussian process $B(t)$ such that $B(0) = 0$ and $\mathbb{E}|B(t) - B(s)|^2 = |t - s|$ for any pair of times s, t . From our point of view, the Wiener process on any finite time interval I can always be realised as the canonical process for the Gaussian measure on $C(I, \mathbb{R})$ with covariance function $c(s, t) = s \wedge t = \min\{s, t\}$. Note that such a measure exists by the Kolmogorov continuity test, and Corollary 4 in particular.

The standard n -dimensional Wiener process $B(t)$ is simply given by n independent copies of a standard one-dimensional Wiener process $\{\beta_j\}_{j=1}^n$, so that its covariance is given by

$$\mathbb{E}\beta_i(s)\beta_j(t) = (s \wedge t)\delta_{i,j}.$$

In other words, if u and v are any two elements in \mathbb{R}^n , we have

$$\mathbb{E}\langle u, B(s) \rangle \langle B(t), v \rangle = (s \wedge t)\langle u, v \rangle.$$

This is the characterization that we will now extend to an arbitrary separable Hilbert space \mathcal{H} . One natural way of constructing such an extension is to fix an orthonormal basis $\{e_n\}_{n \geq 1}$ of \mathcal{H} and a countable collection $\{\beta_j\}_{j=1}^\infty$ of independent one-dimensional Wiener processes, and to set

$$B(t) := \sum_{n=1}^{\infty} \beta_n(t) e_n. \quad (10.127)$$

If we define

$$B^N(t) := \sum_{n=1}^N \beta_n(t) e_n$$

then clearly $\mathbb{E}\|B^N(t)\|_{\mathcal{H}}^2 = tN$ and so the series will not converge in \mathcal{H} for fixed $t > 0$. However the expression (10.127) is nonetheless the right way to think of a cylindrical Wiener process on \mathcal{H} ; indeed for fixed $t > 0$ the truncated series for B^N will converge in a larger space containing \mathcal{H} . We define the following scale of Hilbert subspaces, for $r > 0$, by

$$\mathcal{X}^r = \{u \in \mathcal{H} \mid \sum_{j=1}^{\infty} j^{2r} |\langle u, \phi_j \rangle|^2 < \infty\}$$

and then extend to superspaces $r < 0$ by duality. We use $\|\cdot\|_r$ to denote the norm induced by the inner-product

$$\langle u, v \rangle_r = \sum_{j=1}^{\infty} j^{2r} u_j v_j$$

for $u_j = \langle u, \phi_j \rangle$ and $v_j = \langle v, \phi_j \rangle$. A simple argument, similar to that used to prove Theorem 8, shows that $\{B^N(t)\}$ is, for fixed $t > 0$, Cauchy in \mathcal{X}^r for any $r < -\frac{1}{2}$. In fact it is possible to construct a stochastic process as the limit of the truncated series, living on the space $C([0, \infty), \mathcal{X}^r)$ for any $r < -\frac{1}{2}$, by the Kolmogorov Continuity Theorem 30 in the setting where $D = [0, T]$ and $X = \mathcal{X}^r$. We give details in the more general setting that follows.

Building on the preceding we now discuss construction of a \mathcal{C} -Wiener process W , using the finite-dimensional case described in Remark 2 to guide us. Here $\mathcal{C} : \mathcal{H} \rightarrow \mathcal{H}$ is assumed to be trace-class with eigenvalues γ_j^2 . Consider the cylindrical Wiener process given by

$$B(t) = \sum_{j=1}^{\infty} \beta_j e_j,$$

where $\{\beta_j\}_{j=1}^{\infty}$ is an i.i.d. family of unit Brownian motions on \mathbb{R} with $\beta_j \in C([0, \infty); \mathbb{R})$. We note that

$$\mathbb{E}|\beta_j(t) - \beta_j(s)|^2 = |t - s|. \quad (10.128)$$

Since $\sqrt{\mathcal{C}}e_j = \gamma_j e_j$, the \mathcal{C} -Wiener process $W = \sqrt{\mathcal{C}}B$ is then

$$W(t) = \sum_{j=1}^{\infty} \gamma_j \beta_j(t) e_j. \quad (10.129)$$

The following formal calculation gives insight into the properties of W :

$$\begin{aligned} \mathbb{E} W(t) \otimes W(s) &= \mathbb{E} \left(\sum_{j=1}^{\infty} \sum_{k=1}^{\infty} \gamma_j \gamma_k \beta_j(t) \beta_k(s) e_j \otimes e_k \right) \\ &= \left(\sum_{j=1}^{\infty} \sum_{k=1}^{\infty} \gamma_j \gamma_k \mathbb{E}(\beta_j(t) \beta_k(s)) e_j \otimes e_k \right) \\ &= \left(\sum_{j=1}^{\infty} \sum_{k=1}^{\infty} \gamma_j \gamma_k \delta_{jk}(t \wedge s) e_j \otimes e_k \right) \\ &= \sum_{j=1}^{\infty} (\gamma_j^2 \phi_j \otimes \phi_j) t \wedge s \\ &= \mathcal{C}(t \wedge s). \end{aligned}$$

Thus the process has the covariance structure of Brownian motion in time, and covariance operator \mathcal{C} in space. Hence the name \mathcal{C} -Wiener process.

Assume now that the sequence $\gamma = \{\gamma_j\}_{j=1}^\infty$ is such that $\sum_{j=1}^\infty j^{2r} \gamma_j^2 = M < \infty$ for some $r \in \mathbb{R}$. For fixed t it is then possible to construct a stochastic process as the limit of the truncated series

$$W^N(t) = \sum_{j=1}^N \gamma_j \beta_j(t) e_j,$$

by means of a Cauchy sequence argument in $L^2_{\mathbb{P}}(\Omega; \mathcal{X}^r)$. Similarly $W(t) - W(s)$ may be defined for any t, s . We may then also discuss the regularity of this process in time. Together equations (10.128), (10.129) give $\mathbb{E}\|W(t) - W(s)\|_r^2 = M^2|t - s|$. It follows that $\mathbb{E}\|W(t) - W(s)\|_r \leq M|t - s|^{\frac{1}{2}}$. Furthermore, since $W(t) - W(s)$ is Gaussian, we have by (10.124) that $\mathbb{E}\|W(t) - W(s)\|_r^{2q} \leq K_q|t - s|^q$. Applying the Kolmogorov continuity test of Theorem 30 then demonstrates that the process given by (10.129) may be viewed as an element of the space $C^{0,\alpha}([0, T]; \mathcal{X}^r)$ for any $\alpha < \frac{1}{2}$. Similar arguments may be used to study the cylindrical Wiener process, showing that it lives in $C^{0,\alpha}([0, T]; \mathcal{X}^r)$ for $\alpha < \frac{1}{2}$ and $r < -\frac{1}{2}$.

A.5 Bibliographical Notes

- Section A.1 introduces various Banach and Hilbert spaces, as well as the notion of separability; see [100]. In the context of PDEs, see [33] and [87], for all of the function spaces defined in Sects. A.1.1–A.1.3; Sobolev spaces are developed in detail in [2]. The nonseparability of the Hölder spaces $C^{0,\beta}$ and the separability of $C_0^{0,\beta}$ is discussed in [40]. For asymptotics of the eigenvalues of the Laplacian operator see [91, Chapter 11]. For discussion of the more general spaces of E -valued functions over a measure space (\mathcal{M}, ν) we refer the reader to [100]. Section A.1.5 concerns Sobolev embedding theorems, building rather explicitly on the case of periodic functions. The corresponding embedding results in domains with more general boundary conditions or even on more general manifolds or unbounded domains, we refer to the comprehensive series of monographs [95–97]. The interpolation inequality of (10.106) and Lemma 15 may be found in [87]; see also Proposition 6.10 and Corollary 6.11 of [40]. The proof of Theorem 28 closely follows that given in [40, Theorem 6.16], and is a slight generalization to the Hilbert scale setting used here.
- Section A.2 briefly introduces the theory of probability measures on infinite-dimensional spaces. We refer to the extensive treatise by Bogachev [15], and to the much shorter but more readily accessible book by Billingsley [12], for more details. The subject of independent sequences of random variables, as overviewed in Sect. A.2.1 in the i.i.d. case, is discussed in detail in [27, section 1.5.1]. The Kolmogorov Extension Theorem 29 is proved in numerous texts in the setting where $X = \mathbb{R}$ [79]; since any Polish space is isomorphic to \mathbb{R} it may be stated as it is here. Proofs of Lemmas 17 and 19 may be found in

[40], where they appear as Proposition 3.6 and Proposition 3.9 respectively. For (10.115) see [28, Chapter 2]. In Sect. A.2.2 we introduce the Bochner integral; see [13, 48] for further details. Lemma 18 and the resulting Corollary 3 are stated and proved in [14]. The topic of metrics on probability measures, introduced in Sect. A.2.4 is overviewed in [38], where detailed references to the literature on the subject may also be found; the second inequality in Lemma 22 is often termed the *Pinsker inequality* and can be found in [22]. Note that the choice of normalization constants in the definitions of the total variation and Hellinger metrics differs in the literature. For a more detailed account of material on weak convergence of probability measures we refer, for example, to [12, 15, 98]. A proof of the Kolmogorov continuity test as stated in Theorem 30 can be found in [85, p. 26] for simple case of D an interval and X a separable Banach space; the generalization given here may be found in a forthcoming up-to-date version of [40].

- The subject of Gaussian measures, as introduced in Sect. A.3, is comprehensively studied in [14] in the setting of locally convex topological spaces, including separable Banach spaces as a special case. See also [67] which is concerned with Gaussian random functions. The Fernique theorem 31 is proved in [35] and the reader is directed to [40] for a very clear exposition. In Theorem 31 it is possible to take for α any value smaller than $1/(2\|C_\mu\|)$ and this value is sharp: see [66, Thm 4.1]. See [14, 67] for more details on the Cameron-Martin space, and proof of Theorem 32. Theorem 33 follows from Theorem 3.6.1 and Corollary 3.5.8 of [14]: Theorem 3.6.1 shows that the topological support is the closure of the Cameron-Martin space in B and Corollary 3.5.8 shows that the Cameron-Martin space is dense in B . The *reproducing kernel Hilbert space* for μ (or just *reproducing kernel* for short) appears widely in the literature and is isomorphic to the Cameron-Martin space in a natural way. There is considerable confusion between the two as a result. We retain in these notes the terminology from [14], but the reader should keep in mind that there are authors who use a slightly different terminology. Theorem 35 as stated is a consequence of Proposition 3 in section 18 in [67]. Turning now to the Hilbert space setting we note that Lemma 23 is proved as Proposition 3.15, and Theorem 36 appears as Exercise 3.34, in [40]. See [14, 28, 52] for alternative developments of the Cameron-Martin and Feldman-Hájek theorems. The original statement of the Feldman-Hájek Theorem 37 can be found in [34, 45]. Our statement of Theorem 37 mirrors Theorem 2.23 of [28] and Remark 7 is Lemma 6.3.1(ii) of [14]. Note that we have not stated a result analogous to Theorem 32 in the case where of two equivalent Gaussian measures with differing covariances. Such a result can be stated, but is technically complicated in general because the ratio of normalization constants of approximating finite-dimensional measures can blow up as the limiting infinite-dimensional Radon-Nikodym derivative is attained; see Corollary 6.4.11 in [14].
- Section A.4 contains a discussion of cylindrical and \mathcal{C} -Wiener processes. The development is given in more detail in section 3.4 of [40], and in section 4.3 of [28].

Acknowledgements The authors are indebted to Martin Hairer for help in the development of these notes, and in particular for considerable help in structuring the Appendix, for the proof of Theorem 28 (which is a slight generalization to Hilbert scales of Theorem 6.16 in [40]) and for the proof of Corollary 5 (which is a generalization of Corollary 3.22 in [40] to the non-Gaussian setting and to Hölder, rather than Lipschitz, functions $\{\psi_k\}$). They are also grateful to Joris Bierkens, Patrick Conrad, Matthew Dunlop, Shiwei Lan, Yulong Lu, Daniel Sanz-Alonso, Claudia Schillings and Aretha Teckentrup for careful proof-reading of the notes and related comments. AMS is grateful for various hosts who gave him the opportunity to teach this material in short course form at TIFR-Bangalore (Amit Apté), Göttingen (Axel Munk), PKU-Beijing (Teijun Li), ETH-Zurich (Christoph Schwab) and Cambridge CCA (Arieh Iserles), a process which led to refinements of the material; the authors are also grateful to the students on those courses, who provided useful feedback. The authors would also like to thank Sergios Agapiou and Yuan-Xiang Zhang for help in the preparation of these lecture notes, including type-setting, proof-reading, providing the proof of Lemma 3 and delivering problems classes related to the short courses. AMS is also pleased to acknowledge the financial support of EPSRC, ERC and ONR over the last decade, while the research that underpins this work has been developed.

Abstract

This chapter discusses a Bayesian methodology to integrate model verification, validation, and calibration activities for the purpose of overall uncertainty quantification in model-based prediction. The methodology is first developed for single-level models and then extended to systems that are studied using multilevel models that interact with each other. Two types of interactions among multilevel models are considered: (1) Type-I, where the output of a lower-level model (component and/or subsystem) becomes an input to a higher-level system model, and (2) Type-II, where parameters of the system model are inferred using lower-level models and tests (that describe simplified components and/or isolated physics). The various models; their inputs, parameters, and outputs; experimental data; and various sources of model error are connected through a Bayesian network. The results of calibration, verification, and validation with respect to each individual model are integrated using the principles of conditional probability and total probability and propagated through the Bayesian network in order to quantify the overall system-level prediction uncertainty. For Type-II model, the relevance of each lower-level output to the system-level quantity of interest is quantified by comparing Sobol indices, thus measuring the extent to which a lower-level test represents the characteristics of the system so that the calibration results can be reliably used in the system level. The proposed methodology is illustrated with numerical examples that deal with heat conduction and structural dynamics.

1 Introduction

1.1 Motivation

Individual activities such as calibration, verification, and validation address different aspects of model uncertainty (i.e., model parameters, solution approximations, and model form), and corresponding methods have been discussed in previous chapters. A pertinent question is how to integrate the results of these activities for the purpose of overall uncertainty quantification in the model prediction. This is not trivial because of several reasons. First, the solution approximation errors calculated as a result of the verification process should be considered during calibration, validation, and prediction. Second, the result of validation may lead to a binary result, i.e., the model is accepted or rejected; however, even when the model is accepted, it is not completely correct. Hence, it is necessary to account for the degree of correctness

of the model during prediction uncertainty quantification. Third, if calibration and validation are performed using independent data sets, it is not straightforward to compute their combined effect on the overall uncertainty in the response.

The issue gets further complicated when the behavior of complex engineering systems is studied using multiple component-level and subsystem-level models that integrate to form an overall multilevel system model. In each level, there is a computational model with inputs, parameters, and outputs, experimental data (hopefully available for calibration and validation separately), and several sources of uncertainty physical variability, data uncertainty (sparse or imprecise data, measurement errors), and model uncertainty (parameter uncertainty, solution approximation errors, and model form error). In such a multilevel system, the first task would be to connect all the available models and associated sources of uncertainty.

Recent studies [1, 2] have demonstrated that the Bayesian network methodology provides an efficient and powerful tool to integrate multiple levels of models, associated sources of uncertainty and error, and available data at multiple levels. While the Bayesian approach can be used to perform calibration and validation individually for each model in the multilevel system, it is not straightforward to integrate the information from these activities in order to compute the overall uncertainty in the system-level prediction. This chapter extends the Bayesian approach to integrate and propagate information from verification, calibration, and validation activities in order to quantify the margins and uncertainties in the overall system-level prediction. In Bayesian calibration, the goal is to estimate the probability distributions of the underlying model parameters, using the data available for calibration. Once the model is calibrated, it is validated using an independent set of input-output data. There are two advantages in using a Bayesian methodology for both calibration and validation:

1. Both calibration and validation involve comparing model prediction against experimental data; the Bayesian approach not only allows the comparison of entire distributions of model prediction and experimental data, but also provides a systematic approach to include various types of uncertainty – physical variability, data uncertainty, and model uncertainty/errors – through a Bayesian network.
2. The Bayesian approach can systematically handle epistemic uncertainty due to sparse, imprecise, and unpaired input-output data, as demonstrated by the authors for calibration [3] as well as validation [4–6].

While the Bayesian approach offers several advantages, there are some practical challenges in implementing Bayesian methods. The need to assume prior probability distributions might be challenging in some situations, whereas it might be attractive in other situations to incorporate prior knowledge (if available) and use non-informative prior probability distributions [7] when no prior knowledge is available. Bayesian techniques involve the computation of high-dimensional integrals that are often solved through Markov chain Monte Carlo (MCMC) sampling techniques that require extensive computational effort. With the advent of the high-performance

computing techniques, it has become easier to implement such computationally intensive methods for practical applications, and therefore, Bayesian methods are being increasingly studied in engineering disciplines in recent years.

Methods for calibration and validation have been demonstrated only for individual models with calibration and validation data. What happens when there is flow of information across multiple levels of models that are used to study a multilevel system? Since the Bayesian approach represents the various types of uncertainty at multiple levels through probability distributions, the problem reduces to propagating these probability distributions through component and subsystems, in order to compute the uncertainty in the system-level prediction. Both solution approximation errors and model form errors can be included in a Bayesian network representation as additional nodes [2, 8, 9]. The Bayesian network can be used for both the forward problem of uncertainty propagation [8] and inverse problem of calibration [9, 10]. The results of calibration and validation activities are expressed in terms of probability distributions for the model parameters and the probability that each model is valid, respectively. The Bayesian approach is thus able to provide a unified framework for integrating information from verification, calibration, and validation at multiple levels to calculate the overall system-level prediction uncertainty. Using the principles of conditional probability and total probability, this chapter introduces a computational approach for such integration. This approach is first developed for single-level models and then extended to multilevel system models.

1.2 Multilevel System Models

Typically, a multilevel system is studied using different types of models; each model may represent a particular component, a particular subsystem, or an isolated set of features/physics of the original system. The interaction between any two models depends on what features of the original system they represent, and it is necessary to translate the dependency between the features into mathematical relationship between the models. In order to facilitate such translation, and hence, the objectives of this chapter, two types of interactions (designated as Type-I and Type-II in this chapter) are considered in detail. In both of these types, the quantity of interest is an overall system-level response, but there is a significant difference in how this quantity is calculated using information from lower-level models, verification, validation, and calibration.

The interaction between two models (denoted by G and H in Fig. 11.1a) is considered to be “Type-I,” when the lower-level model G represents the behavior of a particular component/subsystem whose output (Y) becomes an input to a higher-level subsystem/component whose behavior is represented by the higher-level model H . Each model has its own set of model parameters (not indicated in Fig. 11.1a); there may or may not be any model parameter common between two models. For example, the rise in the temperature (Y , computed using G) of a conducting wire leads to a change in its resistance and, hence, in its current carrying capacity (Z , which is computed using H).

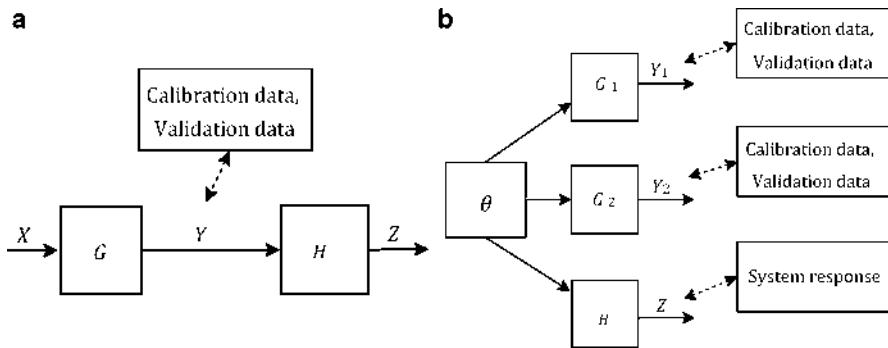

Fig. 11.1 Two types of interactions between models. (a) Type-I interaction. (b) Type-II interaction

The interaction between two models is said to be “Type-II,” when the lower-level model represents a simplification of the overall system. Typically, it may not be possible to study certain features of the system (i.e., the system parameters) since extensive testing of the overall system may be prohibitory. Therefore, a simplified configuration that consists of an isolated set of features and/or an isolated set of physics of the multilevel system is often considered for testing. The response of the simplified subsystem is not directly related to the response of the overall system; however, there are some parameters (θ) of the system model (H) that can be inferred using lower-level models and experiments. Further, multiple test options may be available (two in Fig. 11.1b), where the Level 2 model G_2 may describe more features than the Level 1 model G_1 , in terms of complexity. The model of the highest complexity (H) represents the system of interest and the system-level response (Z) needs to be calculated. The model parameters (θ) are calibrated using models and experiments of reduced complexity (e.g., isolated components or physics) and then propagated through the system model to compute the desired response.

For example, consider a coupon subjected to axial testing (say, the axial deflection is modeled using G_1), a cantilever beam subjected to point loading (say, the deflection is modeled using G_2), and a plate subjected to bending (say, the bending stress is modeled using H), where the coupon, the beam, and the plate are made of the same material. While both the axial deflection of the coupon (Y_1) and the deflection of the beam (Y_2) are not directly related to the bending stress in the plate (Z), some material properties (like the elastic modulus, denoted by θ) of the plate can be studied using tests performed on the coupon and the beam. Note that there is no interaction between models G_1 and G_2 ; there is “Type-II” interaction between models G_1 and H and between models G_2 and H . Urbina et al. [1], Sankararaman et al. [11], Mullins et al. [12], and Li et al. [13] discuss practical multilevel systems with Type-II interaction; these studies consider lower-level models of increasing complexity and physics, i.e., only a few aspects of physics are captured at the lowest level model and more aspects are increasingly captured in subsequent higher levels.

In some cases, an extrapolation problem can be described using two models with “Type-II” interaction. When the application conditions are physically different from validation conditions (e.g., validating using a beam but extrapolating to a plate), model G_2 may correspond to the validation conditions and model H may correspond to the extrapolation conditions.

For Type-II interaction, a reasonable route is to quantify the model parameters using lower-level data and propagate the results through the computational model at the system level. However, model calibration can be conducted using the data from a single level or multiple levels. For the problem in Fig. 11.1b with two lower levels, three calibration options are possible: (1) calibration using the data and model from Level 1 alone, (2) calibration using the data and model from Level 2 alone, and (3) calibration using the data and models from both Level 1 and Level 2. Generally, if data are available at n_m different levels, $2^{n_m} - 1$ model calibration options are possible to quantify the uncertainty of model parameters [14].

This chapter uses Bayesian inference for model calibration, thus the result of model calibration is a joint posterior distribution of model parameters. As Kennedy and O’Hagan [15] pointed out, the posterior distribution is the “best-fitting” results in the sense of representing the calibration data faithfully, not necessarily representing the true physical values. One possibility is to use all the lower-level data in model calibration and propagate the resultant posterior distribution to predict the system-level output. However, this result is conditioned on the event that both the models at Level 1 and Level 2 are valid, which may or may not be true [16]. This chapter answers this question by assigning a “confidence” measure to each posterior distribution. Note that this chapter is not using the term “confidence” in the same sense as is used in statistics (as in confidence interval). This “confidence” measure constitutes of two components: (1) the model validity at the corresponding lower level (one can think of this as local confidence regarding each lower level) and (2) the relationship between the lower level and the system level, i.e., the relevance of the posterior distribution obtained at the lower level to the system-level prediction problem (one can think of this as inter-level confidence).

The reason to use model validation to quantify the local confidence is explained here. In model validation, the assessed model validity of the prediction model $G(\mathbf{x}; \boldsymbol{\theta})$ at a lower level is a combined effect of (1) $G(\mathbf{x}; \boldsymbol{\theta})$ and (2) the posterior distribution of $\boldsymbol{\theta}$. The second aspect corresponds to the “local confidence” (not to be confused with confidence intervals used in statistics); thus this chapter takes the model validity as one factor affecting our confidence in extrapolating the posterior distribution of the model parameter from the lower level to the system level. This is reasonable since the model parameter has been calibrated with a model corresponding to the lower-level experiment, and it is important to know whether the model was calibrated accurately; the calibration result is obviously affected by how accurately the lower-level model represents the physics in the lower-level experiment.

The inter-level confidence to extrapolate a lower-level posterior distribution to the system level is about the relationship between the lower level and the system level. In this chapter, the relationship between the lower level and the system level

is quantified by a relevance analysis [17, 18]. The necessity of relevance analysis is explained here. An inherent assumption in the relevance analysis is that if the physical configuration of a lower-level experiment (say Level 2 in Fig. 11.1b) is more similar to the system level than another lower-level experiment (say Level 1 in Fig. 11.1b), it is reasonable to assign higher confidence to the calibration result at this level (i.e., Level 2). Thus the relevance of the lower level to the system level is the degree to which the experimental configuration at a lower level reflects the physical characteristics of the system so that the calibration results can be reliably used in the system-level prediction. The relevance decides the inter-level confidence on the calibration at lower levels and influences the uncertainty integration. This chapter discusses a method to quantify the relevance using Sobol indices and the cosine similarity of sensitivity vectors.

Note that there is a third type of interaction between two models that is commonly observed in multidisciplinary systems. The two models represent different physics, but the output of each model is the input to the other. This is feedback coupling, and it is necessary to perform iterative analysis between these two models in order to compute the system-level response. The authors developed a likelihood-based method [19] to mathematically transform two-way coupling to one-way coupling; as a result, the method in this chapter for Type-I interaction can also be applied to models with feedback coupling. Further, there may be other types of interactions in multilevel models, but this chapter studies only the two types of interactions (Type-I and Type-II) in detail. The primary goal of this chapter is to develop a framework for the integration of verification, validation, and calibration activities in order to facilitate system-level uncertainty quantification, by considering multilevel models that exhibit Type-I or Type-II interaction. This is accomplished by computing the probability density function (PDF) or the cumulative distribution function (CDF) of the system-level response quantity of interest, and this PDF or CDF needs to incorporate the results of verification, validation, and calibration.

The integration methodology is different for system models with Type-I and Type-II interactions. In the former case, the linking variables between two models are the outputs of the lower-level models that become inputs to the higher-level models, whereas in the latter case, the linking variables are the common model parameters. With the focus on the linking variables and using the principles of conditional probability and total probability, this chapter develops a Bayesian network-based methodology to integrate the results of verification, validation, and calibration activities and to compute the uncertainty in the overall system-level prediction.

1.3 Organization of the Chapter

The rest of the chapter is organized as follows. Section 2 develops the methodology for the integration of calibration, verification, and validation in a single-level model, followed by a numerical example in Sect. 3. Section 4 develops the integration

methodology for multilevel models with Type-I interaction, followed by a numerical example in Sect. 5. Section 6 develops the integration methodology for multilevel models with Type-II interaction, followed by a numerical example in Sect. 7. Though the methodology is individually developed for each type of interaction, it is straightforward to extend it to multilevel models that may contain both types of interactions.

2 Integration of Verification, Validation, and Calibration (Single Level)

Consider a single-level model as shown in Fig. 11.2. The inputs are x , the model parameters are θ , the true solution of the mathematical equation is y , and the code output is y_c . Both y_c and y are deterministic functions of inputs (x) and model parameters (θ).

This section discusses methods to integrate the results of calibration, verification, and validation of the model. Since the process of verification is not related to experimental data, it needs to be performed first; both calibration and validation must include the results of verification analysis (i.e., solution error quantification). Then, the results of verification, calibration, and validation are integrated to compute the overall uncertainty in the response quantity.

2.1 Verification

The process of verification checks how close the code output is to the true solution of the mathematical equation. Verification includes both code verification (identification of programming errors and debugging) and solution verification (convergence studies, identifying and computing solution approximation errors) [20,21]. Methods for code verification [22–27] and estimation of solution approximation error [25, 27–34] have been investigated by several researchers. It is desirable to perform verification before calibration and validation so that the solution approximation errors are accounted for during calibration and validation. Solution approximation errors in finite element analysis have been estimated using a variety

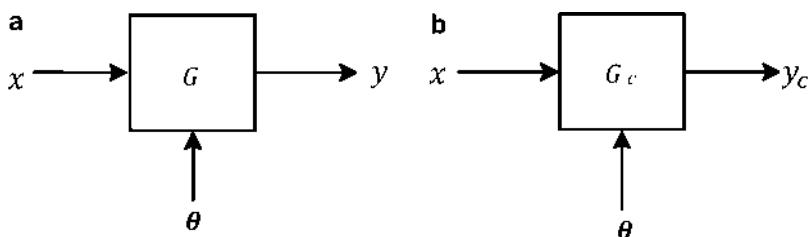

Fig. 11.2 A single-level model. (a) Mathematical equation. (b) Computer code

of techniques, such as convergence analysis [35] a posteriori error estimation [36] Richardson extrapolation [34, 37, 38] etc. Another type of solution approximation error arises when the underlying model is replaced with a surrogate model for fast uncertainty propagation and/or model calibration. Many surrogate modeling techniques have been developed, such as regression models [38] polynomial chaos expansions [39], radial basis functions [40] or Gaussian processes [41]. The quantification of this surrogate model error is different for different types of surrogate models, and the methods are well established in the literature. Once the solution approximation error is computed, the true solution of mathematical equation can be computed as a function of the model inputs and parameters as $y(\mathbf{x}; \boldsymbol{\theta}) = y_c(\mathbf{x}; \boldsymbol{\theta}) + G_{se}(\mathbf{x}; \boldsymbol{\theta})$, where $G_{se}(\mathbf{x}; \boldsymbol{\theta})$ denotes the solution approximation error. Two types of solution approximation errors – discretization error and surrogate modeling error – are considered in this chapter. However, the integration methodology is general enough to accommodate other types of solution approximation errors, once such errors can be quantified.

In general, solution approximation errors ($G_{se}(\mathbf{x}; \boldsymbol{\theta})$) are deterministic quantities; however, sometimes, when probabilistic approaches are used to quantify them, it becomes necessary to represent solution approximation errors using probability distributions. For example, the discretization error in finite element analysis is a deterministic quantity. When Richardson extrapolation [42] is used to quantify this error, then $G_{se}(\mathbf{x}; \boldsymbol{\theta})$ can be calculated deterministically. When a probabilistic method, such as Gaussian process modeling [34, 43], is used, both the mean and variance of $G_{se}(\mathbf{x}; \boldsymbol{\theta})$ are predicted; this variance is simply dependent on the training points used to train the Gaussian process model and on how far it is necessary to extrapolate, and it does not imply that $G_{se}(\mathbf{x}; \boldsymbol{\theta})$ is a physically random quantity. Similarly, when a high fidelity simulation (such as a computationally intensive finite element analysis) is replaced by an inexpensive surrogate model, the surrogate model error (i.e., the difference between the prediction of the original high fidelity simulation and the surrogate model) is a deterministic quantity. However, the solution of the underlying high fidelity simulation is only available at a few input settings. The surrogate model prediction and the error (at untrained input locations) are therefore expressed using a probability distribution; this probability distribution only indicates the analyst's uncertainty regarding the surrogate model error and does not imply that the surrogate model error is random. This uncertainty is epistemic and reduces as the number of training points increases. The Bayesian framework represents such epistemic uncertainty through probability distributions.

In this chapter, Richardson extrapolation is used to compute discretization error, and Gaussian process surrogate models are used to replace high fidelity simulations. While the former leads to deterministic error estimates ($G_{se}(\mathbf{x}; \boldsymbol{\theta})$ is point-valued), the latter leads to stochastic error representation ($G_{se}(\mathbf{x}; \boldsymbol{\theta})$) is a probability distribution). In practical engineering problems, both discretization and surrogate modeling may be necessary, and therefore, the overall solution approximation error is composed of both deterministic and stochastic terms. In the context of uncertainty propagation, deterministic errors are addressed by correcting the bias, whenever they occur, and the corrected solutions are used to train the surrogate model; the

stochastic errors of the surrogate model are accounted for through sampling based on their estimated distributions. As a result, the overall solution approximation error $G_{se}(\mathbf{x}; \boldsymbol{\theta})$ is also stochastic, i.e., y is stochastic even for given values of \mathbf{x} and $\boldsymbol{\theta}$, and this stochasticity, without physical randomness, also needs to be interpreted subjectively. The remainder of this subsection briefly reviews the estimation of discretization error and surrogate model uncertainty.

Recall that verification is performed before calibration and validation in the approach of this chapter. Once the solution approximation errors are quantified, the model predictions are corrected as explained above; the corrected solution (y) and not the code output (y_c) is used for calibration and validation. Such an approach integrates the result of verification into calibration, validation, and all subsequent uncertainty quantification.

2.1.1 Discretization Error

Several methods are available in the literature [36, 44, 45] to estimate discretization error in finite element analysis, but many of them only quantify a surrogate measure of error to facilitate adaptive mesh refinement. The Richardson extrapolation (RE) method has been found to come closest to quantifying the actual discretization error [32, 42]. This technique has been commonly applied to quantifying discretization error in finite element analysis by several researchers [2, 24, 25, 28].

Consider a polynomial model $y = y_c + Ah^p$, where y_c is the solution corresponding to mesh size h , and y corresponds to the “true” solution of the mathematical equation which is obtained as h tends to zero. Three different mesh sizes ($h_1 < h_2 < h_3$) are considered, and the corresponding finite element solutions ($y_c(h_1) = \Psi_1$, $y_c(h_2) = \Psi_2$, $y_c(h_3) = \Psi_3$) are calculated. Using the aforementioned polynomial model, y can be estimated by solving three simultaneous equations in three variables. Closed-form solutions are available in some special cases; for example, if $r = \frac{h_3}{h_2} = \frac{h_2}{h_1}$, then the discretization error (ϵ_h) and the true solution can be calculated as:

$$\begin{aligned} y &= \Psi_1 - \epsilon_h \\ \Psi_2 - \Psi_1 &= \epsilon(r^p - 1) \\ p \log(r) &= \log\left(\frac{\Psi_3 - \Psi_2}{\Psi_2 - \Psi_1}\right) \end{aligned} \tag{11.1}$$

The solutions Ψ_1 , Ψ_2 , and Ψ_3 are dependent on both \mathbf{x} and $\boldsymbol{\theta}$, and hence the error estimate ϵ_h and the true solution y are also functions of both \mathbf{x} and $\boldsymbol{\theta}$. Since the discretization error is a deterministic quantity, it needs to be corrected for, in the context of uncertainty propagation.

Recently, Rangavajhala et al. [34] extended the Richardson extrapolation methodology from a polynomial relation to a more flexible Gaussian process extrapolation. This approach expresses the discretization error as a probability distribution, and therefore, the training points (in particular, the output values)

for the surrogate model are themselves stochastic. Rasmussen [46–48] discusses constructing GP models when the training point values are themselves stochastic.

2.1.2 Surrogate Model Uncertainty

This section considers the case where the original computer code is replaced with a Gaussian process surrogate model. The basic idea of the GP model is that the response values Y evaluated at different values of the input variables \mathbf{x} , are modeled as a Gaussian random field, with a mean and covariance function. Suppose that there are m training points, $x_1, x_2, x_3, \dots, x_m$ of a d -dimensional input variable vector, yielding the output values $Y(x_1), Y(x_2), Y(x_3), \dots, Y(x_m)$. The training points can be compactly written as x_T vs. y_T where the former is a $m \times d$ matrix and the latter is a $m \times 1$ vector. Suppose that it is desired to predict the response (output values y_P) corresponding to the input x_P , where x_P is $p \times d$ matrix; in other words, it is desired to predict the output at p input combinations simultaneously. Then, the joint density of the output values y_P can be calculated as

$$p(y_P | x_P, x_T, y_T; \Theta) \sim N(m, s) \quad (11.2)$$

where Θ refers to the hyper-parameters of the Gaussian process, which need to be estimated based on the training data. The prediction mean and covariance matrix (m and S respectively) can be calculated as

$$\begin{aligned} m &= K_{PT}(K_{TT} + \sigma_n^2 I)^{-1}y_T \\ S &= K_{PP} - K_{PT}(K_{TT} + \sigma_n^2 I)^{-1}K_{TP} \end{aligned} \quad (11.3)$$

In Eq. (11.3), K_{TT} is the covariance function matrix (size $m \times m$) among the input training points (x_T), and K_{PT} is the covariance function matrix (size $p \times m$) between the input prediction point (x_P) and the input training points (x_T). These covariance matrices are constructed using the chosen covariance function (squared exponential is chosen, in this chapter), which are functions of the training points terms and the hyper-parameters (Θ): a multiplicative term (θ), the length scale in all dimensions (l_q , $q = 1$ to d), and the noise standard deviation (σ_n). These hyper-parameters are estimated based on the training data by maximizing the following log-likelihood function:

$$\log p(y_T | x_T; \Theta) = -\frac{y_T^T}{2}(K_{TT} + \sigma_n^2 I)^{-1}y_T - \frac{1}{2} \log |(K_{TT} + \sigma_n^2 I)| + \frac{d}{2} \log(2\pi) \quad (11.4)$$

Once the hyper-parameters are estimated, then the Gaussian process model can be used for predictions using Eq. (11.3). For details of this method, refer to [46, 48–54].

Note that the variance in Eq. (11.3) is representative of the uncertainty due to the use of the GP surrogate model, and this uncertainty needs to be accounted for, while computing the overall prediction uncertainty.

2.2 Calibration

The purpose of model calibration is to adjust a set of parameters associated with a computational model so that the agreement between model prediction and experimental observation is maximized [55]. Least squares [56], likelihood-based [57, 58], and Bayesian [11, 15, 59–63] methods are available for model parameter estimation. In classical statistics, the fundamental assumption is that the parameter is a deterministic unknown quantity, and it is not meaningful to discuss the probability distribution of the parameter; therefore, the uncertainty about the value of the parameter is expressed in terms of confidence intervals. On the other hand, the Bayesian approach attributes a probability distribution (prior and posterior) to the model parameters, and this distribution represents the analyst’s uncertainty about the model parameter.

The model parameters ($\boldsymbol{\theta}$) may be calibrated with input-output (x versus y) data collected for calibration (D^C), using Bayes’ theorem as

$$f_{\Theta}(\boldsymbol{\theta}|G, D^c) = \frac{L(\boldsymbol{\theta})f_{\Theta}(\boldsymbol{\theta})}{\int L(\boldsymbol{\theta})f_{\Theta}(\boldsymbol{\theta})d\boldsymbol{\theta}} \quad (11.5)$$

In Eq. (11.5), $f_{\Theta}(\boldsymbol{\theta})$ is the prior PDF and $f_{\Theta}(\boldsymbol{\theta})$ is the prior PDF and $f_{\Theta}(\boldsymbol{\theta}|G, D^c)$ is the posterior PDF; the calibration procedure uses the model form G and hence the posterior is conditioned on G . The function $L(\boldsymbol{\theta})$ is the likelihood of $\boldsymbol{\theta}$ defined as being proportional to the probability of observing the data D^C (given as x_i vs. y_i ; $i = 1$ to n) conditioned on the parameters $\boldsymbol{\theta}$. This likelihood function is evaluated as

$$L(\boldsymbol{\theta}) \propto \prod_{i=1}^n \frac{1}{\sigma \sqrt{2\pi}} \exp\left(-\frac{(y_i - G(\mathbf{x}_i, \boldsymbol{\theta}))^2}{2\sigma^2}\right) \quad (11.6)$$

where σ is the standard deviation of $\epsilon_{obs} = y - G(\mathbf{x}, \boldsymbol{\theta})$. Note that the likelihood is constructed using the actual solution of the mathematical equation (y), i.e., after correcting the raw code prediction (y_c) with solution approximation errors (ϵ_{soln}). Sometimes, σ is also inferred along with $\boldsymbol{\theta}$, by constructing the joint likelihood $L(\boldsymbol{\theta}, \sigma)$. Note that Eq. (11.6) assumes that the experimental observations are unbiased. If the predictions are biased due to modeling errors, then the output can be modeled as $y = G(\mathbf{x}, \boldsymbol{\theta}) + \delta + \epsilon_{obs}$, where δ represents the modeling error and is inferred along with $\boldsymbol{\theta}$. This approach was further extended by Kennedy and O’Hagan [30] by modeling the output as $= G(\mathbf{x}, \boldsymbol{\theta}) + \delta(\mathbf{x}) + \epsilon_{obs}$, where $\delta(\mathbf{x})$ (sometimes, referred to as the model inadequacy function) is represented using a Gaussian process (GP) whose “hyper-parameters” are also inferred along with $\boldsymbol{\theta}$. A challenge with the Kennedy O’Hagan (KOH) framework is that it is necessary to (1) simultaneously calibrate both the model parameters and the GP hyper-parameters and (2) possess good prior knowledge regarding both the model parameters and the GP hyper-parameters. This is a challenging issue and still being addressed by several researchers [64, 65]. Using the KOH framework, all the parameters to

calibrate include (1) model parameters θ , (2) hyper-parameters in the surrogate model for $G(\theta; \mathbf{x})$ if it is replaced by a surrogate model, (3) hyper-parameters θ_δ of the model discrepancy $\delta(\mathbf{x})$, and (4) standard deviation σ of ϵ_{obs} . The presence of so many calibration parameters is challenging if calibration data are sparse. All the available data have been used in [15] to simultaneously estimate both the model parameters and the model discrepancy in the calibration step. An alternative approach is to consider separate sets of data for calibration and validation; first, the model parameters are estimated (with or without including the model discrepancy term) in the calibration step, and then, the effect of model form error is inferred in the validation step by calculating a validation metric. The latter route is pursued in this chapter, in an effort to distinctly separate the two steps of calibration and validation and use different sets of data for these two activities. In addition, this chapter ignores the hyper-parameter uncertainty in the GP model of $G(\theta; \mathbf{x})$ for three reasons: (1) enough training points are used to build an accurate GP model with small variance in the GP prediction, thus the hyper-parameter uncertainty is expected to be small; (2) considering this hyper-parameter uncertainty will bring enormous computational effort [64] in model calibration and validation, whereas this hyper-parameter uncertainty is not the focus of this chapter; and (3) the uncertainty in the hyper-parameters is typically negligible compared to actual model parameters [66]. Thus we first estimate the hyper-parameters of the GP model and then fix them as deterministic values in the subsequent calibration of model parameters θ .

Note that the model “ G ” is used for calibration in Eq. (11.5); recall that “ G ” refers to the model corrected for solution approximation errors. Hence, the results of verification are included in the calibration procedure. Deterministic discretization errors are corrected for before training the surrogate model, and the surrogate model uncertainty is included in the likelihood function as demonstrated by Kennedy and O’Hagan [15] and McFarland [51]. In addition, the construction of the likelihood function can also include additional uncertainty in inputs and parameters and account for imprecise and unpaired data. Refer to [2, 9, 57, 67] for further details on the construction of the likelihood function in different types of situations.

The posterior PDFs of the model parameters can be calculated using direct integration of the denominator in Eq. (11.5), if the number of calibration parameters is small. Alternatively, Markov chain Monte Carlo sampling [68] methods such as Metropolis algorithm [69], Gibbs algorithm [70], or slice sampling [71] can be used to generate samples of the posterior distributions of the parameters.

2.3 Validation

Model validation refers to the process of determining the degree to which a model is an accurate representation of the real world from the perspective of the intended use of the model [22, 72]. Generally model validation is realized by comparing the model prediction against experimental data. Different types of validation metrics have been studied in the literature to express the accuracy of a computational model through comparison of its prediction against observed data and to determine whether the

model is adequate for its intended use (sometimes referred to as qualification [25]). Coleman and Stern [73] and Oberkampf and Trucano [25] discussed conceptual and practical aspects of model validation and provided guidelines for conducting validation experiments and developing validation metrics. Available approaches for quantitative model validation are based on statistical confidence intervals [74], computing distance between the model prediction and experimental data by computing the area metric [9, 75], normalizing residuals [76], classical statistics-based hypothesis testing [77], Bayesian hypothesis testing [4, 78–81], and reliability analysis-based techniques [82–84]. Liu et al. [85] and Ling and Mahadevan [5] investigated several of these validation approaches in detail and discussed their practical implications in engineering.

The term “validation” has been used to imply different approaches in different studies. While some studies compute validation metrics, some other approaches focus on estimating the model discrepancy [15, 32] as the difference between the model prediction and the underlying physical phenomenon the model seeks to represent. Comprehensive reviews on model validation can be found in [25, 74, 86, 87]. The present chapter only focuses on computing validation metrics with validation data and does not estimate the model form error with validation data. The model discrepancy is computed through the use of a discrepancy function in the Kennedy O’Hagan framework during model calibration, a previous task. Separate sets of data are considered for calibration and validation.

In this chapter, model calibration and model validation are distinct activities. Model validation can be conducted exclusive of any model calibration [74] if the model parameters are assumed to be known. However, the model parameters θ are often unknown. Therefore, prior to model validation, model calibration can be conducted to quantify the values of θ or reduce the uncertainty about their values. Thus validation is a subsequent and distinct activity after validation. Both model calibration and model validation are conducted in this chapter, but they use different sets of experimental data (no calibration data is used in model validation), as suggested by [88]. The model parameters θ do not change as a result of model validation.

Among the validation methods mentioned above, this chapter uses Bayesian hypothesis testing and the model reliability metric for the purpose of uncertainty integration, since both methods give the validation result as a probability value. The Bayes factor metric in Bayesian hypothesis testing is the ratio of the likelihoods that the model is valid and that the model is invalid. The Bayes factor can be used to directly calculate the posterior probability that the model is valid. Further, the threshold Bayes factor for model acceptance can be derived based on a risk vs. cost trade-off, thereby aiding in robust, meaningful decision-making, as shown by Jiang and Mahadevan [89]. Alternatively, the model reliability metric [83] can also compute the probability that the model is valid.

2.3.1 Validation by Bayesian Hypothesis Testing

Assume that an independent set of validation data (D^V) is available. The prediction of the verified and calibrated model prediction is compared against the validation data. The model prediction can be computed as a function of input as

$$f_Y(y|\mathbf{x}, G, D^C) = \int f_Y(y|\mathbf{x}, \boldsymbol{\theta}) f_{\Theta}(\boldsymbol{\theta}|G, D^C) d\boldsymbol{\theta} \quad (11.7)$$

In the case of partially characterized validation data (e.g., field data), the input \mathbf{x} may not be measured, in which case the model prediction must include the uncertainty in the input as

$$f_Y(y|G, D^C) = \int f_Y(y|\mathbf{x}, \boldsymbol{\theta}) f_X(\mathbf{x}) f_{\Theta}(\boldsymbol{\theta}|G, D^C) d\boldsymbol{\theta} d\mathbf{x} \quad (11.8)$$

The above equations simply refer to uncertainty propagation through the model, and hence the model prediction is conditioned on the event that the mathematical model is correct and written as $f_y(y|G, D^c)$. The results of verification are included while computing y , and the results of calibration are included by using the posterior PDF of the model parameter ($f_{\Theta}(\boldsymbol{\theta}|G, D^c)$) in the prediction.

The model prediction is then compared with the validation data using Bayesian hypothesis testing in this section. Let $P(G)$ and $P(G')$ denote the probabilities that the model is valid (null hypothesis) and that the model is invalid (alternate hypothesis), respectively. Prior to validation, if no information is available, $P(G) = P(G') = 0.5$. Using Bayesian hypothesis testing, these probabilities can be updated using the validation data (D^V), and the likelihood ratio, referred to as Bayes factor, is defined as

$$B = \frac{P(D^V|G)}{P(D^V|G')} \quad (11.9)$$

The likelihoods $P(D^V|G)$ and $P(D^V|G')$ are denoted as $L(G)$ and $L(G')$, respectively. The numerator $P(D^V|G)$ can be calculated using $f_y(y|G, D^c)$ as

$$L(G) \propto P(D^V|G) \propto \int f(D^V|y) f_Y(y|G, D^C) dy \quad (11.10)$$

In Eq. (11.10), the term $f(D^V|y)$ is calculated based on the measurement error $\epsilon_{obs} \sim N(0, \sigma^2)$, as

$$f(D^V|y) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(D^V - y)^2}{2\sigma^2}\right) \quad (11.11)$$

In order to compute $P(D^V|G')$, it is necessary to assume the alternate PDF $f_Y(y|G')$, i.e., the PDF of Y when the model is wrong. Expert opinion may be used to construct this PDF, or a uniform PDF may be used if no additional information is available. (This issue is a limitation of this method.) Then $L(G')$ is calculated similar to Eq. (11.10) by replacing $f_Y(y|G, D^C)$ with $f_Y(y|G')$. Using Bayes' theorem and assuming that G and G' are equally likely before collecting

data, the probability that the model is correct, i.e., $P(G|D^V)$, can be calculated as $B/B + 1$ [32].

2.3.2 Model Validation by Model Reliability Metric

Model Reliability Metric

The Bayes factor gives a probabilistic measure of model validity. While the Bayesian hypothesis testing is one approach to calculate the probability that the model is correct, the model reliability metric [82, 83] provides an alternative methodology.

In the model reliability metric, the model is defined to be valid if the difference between the model prediction y and the corresponding validation measurement is less than a predefined tolerance λ . The value of λ is chosen by the user based on the accuracy requirement for the specific application. Due to the measurement error ($\epsilon_{obs} \sim N(0, \sigma^2)$), the measurement is actually a random variable. For a single observed value D , this random variable is denoted by d with mean value D and standard deviation σ , i.e., $d \sim N(D, \sigma^2)$. Let G denote the event that the model is valid and y denotes the prediction, then the model reliability is defined as the probability of event G :

$$P(G|D) = P(|y - d| < \lambda) \quad (11.12)$$

The probability in Eq. (11.12) is used as a metric to measure model validity; thus this metric is named as “model reliability metric.” If y and σ are deterministic, Eq. (11.13) computes the model reliability where ε is a dummy variable for integration:

$$P(G|D) = \int_{-\lambda}^{\lambda} \frac{1}{\sigma_m \sqrt{2\pi}} \exp \left[-\frac{(\varepsilon - (y - D))^2}{2\sigma_m^2} \right] d\varepsilon \quad (11.13)$$

Note here that the model prediction y refers to the computational model output $y = G(\mathbf{x}; \boldsymbol{\theta})$; this prediction may either include a model discrepancy term explicitly or not, depending on the situation. The discussion below is valid in both cases, and the numerical examples in this chapter illustrate both types of situations. Although model input \mathbf{x} is known, the model prediction y is still stochastic due to the uncertainty of $\boldsymbol{\theta}$. In this case, the model reliability is

$$P(G|D) = \int P(G|\boldsymbol{\theta}, D) f''(\boldsymbol{\theta}) d\boldsymbol{\theta} \quad (11.14)$$

where $P(G|\boldsymbol{\theta}, D)$ is given by the right side of Eq. (11.13) and $f''(\boldsymbol{\theta})$ is the joint posterior distribution of $\boldsymbol{\theta}$.

Equations (11.13) and (11.14) are only suitable for a single observed value D for a scalar output quantity. The concept of the model reliability metric can be extended to deal with multiple data points and multivariate output, as follows.

Stochastic Model Reliability Metric

The first extension is the stochastic model reliability metric. As shown in Eqs. (11.13) and (11.14), the value of model reliability $P(G)$ is deterministic at a single data point D , but changes over different data points. If model inputs \mathbf{x} of these data points are known, a mathematical function $P(G|\mathbf{x}) = s(\mathbf{x})$ can be established where $P(G|\mathbf{x})$ is the model reliability at model input \mathbf{x} . However, this function may be not accurate when the validation data is sparse. Thus constructing a mathematical function for model reliability (as a function of \mathbf{x}) is not considered in this chapter. Instead, this chapter uses a probability distribution to represent the variability in $P(G)$, and this distribution is constructed using the model reliability values computed at different validation data points (the first option could be considered if a large number of validation experiments are conducted).

In this chapter, model reliability $P(G)$ is assumed to have a beta distribution since $P(G) \in [0,1]$ and the sample space of beta distribution is also the interval $[0,1]$. Another option is the t -distribution [14]. If a data set $\mathbf{D} = \{D_1, D_2, \dots, D_n\}$ of one output quantity is observed for model validation from n experiments with different inputs, the corresponding model reliability values computed by Eq. (11.14) at each experiment are $\mathbf{D}_R = \{D_{R_1}, D_{R_2}, \dots, D_{R_n}\}$. Using \mathbf{D}_R , several methods can be used to construct the PDF of model reliability, such as the method of maximum likelihood, method of moments, or Bayesian inference. This chapter uses the method of moments to construct the PDF of $P(G)$. In summary, this approach gives a stochastic representation of model reliability, i.e., $P(G)$ is not a single value but represented by a probabilistic distribution.

Multivariate Output

In the case of multivariate output, if K output quantities are observed in a validation experiment, we have a set of K models sharing the same model input and model parameters:

$$\mathbf{y} = \mathbf{G}(\mathbf{x}; \boldsymbol{\theta}) \Leftrightarrow \begin{cases} y_1 = G_1(\mathbf{x}; \boldsymbol{\theta}) \\ y_2 = G_2(\mathbf{x}; \boldsymbol{\theta}) \\ \dots \\ y_K = G_K(\mathbf{x}; \boldsymbol{\theta}) \end{cases} \quad (11.15)$$

where $G_j(\mathbf{x}; \boldsymbol{\theta})$ ($j = 1$ to K) is the computational model of the j th quantity (as mentioned earlier in Sect. 2.3, the prediction may explicitly or implicitly include the effect of model discrepancy). Each quantity also has a measurement error $\epsilon_{obs_j} \sim N(0, \sigma_j^2)$ and the corresponding variable $Z_j = y_j + N(0, \sigma_j^2)$ representing the measurement. We denote $\mathbf{Z} = \{Z_1, \dots, Z_j, \dots, Z_k\}^T$. Assume that n experiments are conducted. In the i th experiment ($i = 1$ to n), data points for k quantities form

a data set $\mathbf{D}_i = \{D_{i1}, \dots, D_{ij}, \dots, D_{ik}\}^T$. In addition, the predefined tolerance for each quantity is included in a vector $\boldsymbol{\lambda} = \{\lambda_1, \dots, \lambda_j, \dots, \lambda_k\}^T$.

The distance between \mathbf{Z} and \mathbf{D}_i can be measured by multiple distance functions such as the Euclidean distance, Chebyshev distance, Manhattan distance, and Minkowski distance [90]. This chapter uses the Mahalanobis distance [91]. The Mahalanobis distance between \mathbf{Z} and \mathbf{D}_i is defined as $M = \sqrt{(\mathbf{Z} - \mathbf{D}_i)^T \boldsymbol{\Sigma}_Z^{-1} (\mathbf{Z} - \mathbf{D}_i)}$ where $\boldsymbol{\Sigma}_Z$ is the covariance matrix of \mathbf{Z} . The Mahalanobis distance transfers \mathbf{Z} and \mathbf{D}_i into the normalized principal component (PC) space [91] by using $\boldsymbol{\Sigma}_Z^{-1}$. Compared to other distance functions, the Mahalanobis distance brings two advantages: (1) the correlations between output quantities are considered, and (2) the output quantities are normalized to the same scale to prevent any quantity from dominating the metric simply due to large numerical values. Using the Mahalanobis distance, the model reliability for multivariate output is defined as

$$P(G|\mathbf{D}_i) = P(M < \lambda_M) = P\left(\sqrt{(\mathbf{Z} - \mathbf{D}_i)^T \boldsymbol{\Sigma}_Z^{-1} (\mathbf{Z} - \mathbf{D}_i)} < \sqrt{\lambda^T \boldsymbol{\Sigma}_Z^{-1} \lambda}\right) \quad (11.16)$$

where $\lambda_M = \sqrt{\lambda^T \boldsymbol{\Sigma}_Z^{-1} \lambda}$ is the normalized tolerance.

Generally the posterior distributions obtained in model calibration are numerical samples generated by MCMC, so the subsequent model reliability in Eqs. (11.13) and (11.14) is also computed numerically. Numerical computation also facilitates the realization of the extended model reliability in Eq. (11.16). Here the model reliability is expressed as

$$\begin{aligned} P(G|\mathbf{D}_i) &= P(M < \lambda_M|\mathbf{D}_i) = \int_0^{\lambda_M} f(M|\mathbf{D}_i) dM \\ &= \int_0^{\lambda_M} (f(M|\mathbf{D}_i, \theta) f''(\theta) d\theta) dm \end{aligned} \quad (11.17)$$

Eq. (11.17) indicates a numerical algorithm to compute the model reliability:

1. Generate a random sample of $\boldsymbol{\theta}$ from its posterior distribution $f''(\boldsymbol{\theta})$;
2. Generate a sample of M conditioned on $\boldsymbol{\theta}$ by generating a sample of and computing its Mahalanobis distance from \mathbf{D}_i ;
3. Repeat steps 1 and 2 to obtain N samples of M ; these samples can be used to construct the distribution $f(M|\mathbf{D}_i)$, which is not conditioned on $\boldsymbol{\theta}$;
4. If N' out of N samples in step 3 satisfy $M < \lambda_M$, the model reliability is $P(G|\mathbf{D}_i) = N'/N$

The model reliability $P(G|\mathbf{D}_i)$ by Eq. (11.17) is regarding a single experiment and $P(G|\mathbf{D}_i)$ is a deterministic value. Thus n experiments will give n different

model reliability values $P(G|D_1), \dots, P(G|D_n)$. Using the stochastic model reliability metric, these values can be used to build a probability distribution for the model reliability $P(G)$, by treating $P(G)$ as a random variable instead of a deterministic value.

2.4 Integration for Overall Uncertainty Quantification

The calibration procedure in Sect. 2.2 assumed that the model form G is valid and estimated the model parameters θ . In contrast, the validation procedure in Sect. 2.3.1 calculated the probability that the model G is valid by assuming the uncertainty in the model parameters θ . The two results can be combined to calculate the overall uncertainty in the model prediction, using the theorem of total probability as

$$f_Y(y|D^C, D^V) = P(G|D^V) f_Y(y|G, D^C) + P(G') f_Y(y|G') \quad (11.18)$$

In Eq. (11.18), $P(G|D^V)$ can also be calculated using the model reliability metric instead of Bayesian hypothesis testing. Note that the result of verification, i.e., solution approximation error, was already included in both calibration and validation. Thus, the PDF $f_Y(y|D^C, D^V)$ includes the results of verification, calibration, and validation activities.

3 Numerical Example: Single-Level Model

This section discusses a numerical example, where a single-level model is subject to verification, validation, and calibration. The results of these activities are integrated to calculate the overall uncertainty in the response quantity.

3.1 Description of the Problem

Consider steady state heat transfer in a thin wire of length L , with thermal conductivity k and convective heat coefficient β . Assume that the heat source is $Q(x) = 25(2x - L)^2$, where x is measured along the length of the wire. For the sake of illustration, it is assumed that this problem is essentially one dimensional and that the solution can be obtained from the following boundary value problem [32]:

$$\begin{aligned} -k \frac{\partial^2 T}{\partial x^2} + \beta T &= Q(x) \\ T(0) &= T_0 \\ T(L) &= T_L \end{aligned} \quad (11.19)$$

The length of the wire is assumed to be deterministic ($L = 4\text{ m}$). The boundary conditions, i.e., the temperatures at the ends of the wire ($T(0)$ and $T(L)$), are assumed to be normally distributed with statistics $N(0, 1)$. The thermal conductivity of the wire (k) is assumed to be normally distributed $N(5, 0.2)$ with units $\text{Wm}^{-1}/^\circ\text{C}$. The convective heat coefficient (β) is an unknown parameter which needs to be estimated using calibration data (D^C); this quantity is assumed to have a normally distributed prior as $N(0.5, 0.05)$. The goal of the model is to predict the temperature (Y) at the midpoint of the wire.

3.2 Verification, Validation, and Calibration

First, the differential equation in Eq. (11.19) is solved using a finite difference code. Three different discretization sizes are considered, and Richardson extrapolation [42] is used to calculate the solution approximation error which is used to correct the model prediction every time this differential equation is solved. Since there are four uncertain quantities (T_0 , T_L , k , and the model parameter being updated, i.e., β), it is necessary to quantify the solution approximation error as a function of these four quantities. Every time the model prediction Y needs to be computed as a function of these four quantities, a mesh refinement study is conducted, i.e., three different mesh sizes are considered (with sizes 0.01, 0.005, and 0.0025), and Eq. 11.1 is used to compute the solution approximation error and, hence, the corrected prediction.

It may be noted that, for this particular numerical example, linear diffusion dominates and therefore, the solution approximation error is not very sensitive to k . However, this behavior is not explicitly considered during verification. This is because of two reasons. First, it may be recalled that, in order to integrate the results of verification into calibration and validation, the solution approximation errors are computed and corrected whenever needed while performing calibration (update β using data $D^C = \{22; 23; 25; 261; 254\}$, in $^\circ\text{C}$) and validation. In other words, during calibration, samples of the aforementioned four uncertain quantities are generated through slice sampling; for each generated sample, the solution approximation error is quantified through mesh refinement. Since it is necessary to repeat this procedure for every generated sample, it does not matter whether the nominal value of k or the actually sampled value of k is used, from a computational point of view. The second reason is that the underlying physics behavior and the choice of numerical values are not exploited during the implementation of the methodology. The code used to solve the differential equation in Eq. (11.19) is treated as if it were a black box model, in an effort to keep the illustration as general as possible. In specific problems, special features may be exploited to reduce computational effort.

The prior ($f_\Theta(\theta)$) and posterior ($f_\Theta(\theta|G, D^C)$) PDFs of β are shown in Fig. 11.3. Additional validation data ($D^V = \{24; 245; 246; 238\}$, in $^\circ\text{C}$) is used to compute the probability that the temperature prediction model is correct, i.e., $P(G) = 0.84$.

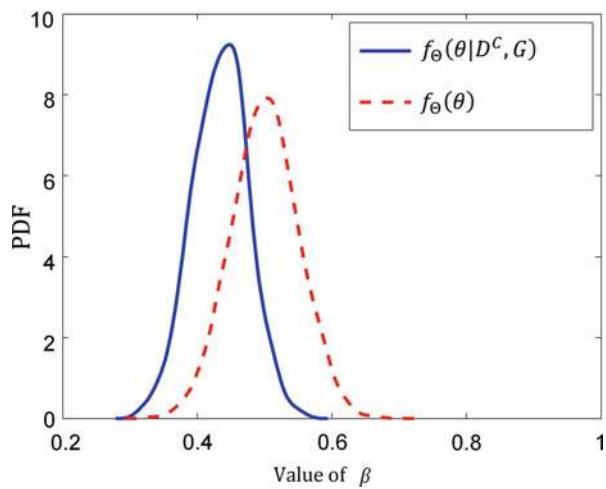

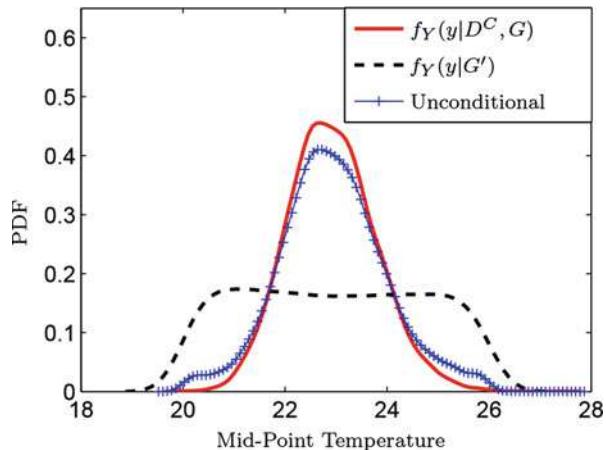

Fig. 11.4 PDF of midpoint temperature

3.3 Integration and Overall Uncertainty Quantification

The method developed in Sect. 2.4 is used to calculate the unconditional PDF of temperature using the principle of total probability, as shown in Fig. 11.4. This PDF integrates the results of verification, validation, and calibration to compute the overall uncertainty in the temperature at the midpoint of the wire.

Figure 11.4 indicates three PDFs: (i) $f_Y(y|G, D^C)$ denotes the model prediction, (ii) $f_Y(y|G')$ denotes the prediction under the alternate hypothesis (assumed uniform; due to sampling errors and use of kernel density estimation for plotting, the PDF is not perfectly horizontal in Fig. 11.4), and (iii) $f_Y(y|G, D^C, D^V)$ which represents the PDF that integrates the validation result with the previous calibration and verification activities. The third PDF is referred to as the unconditional PDF of the temperature response, since it is not conditioned on the model form.

Conventionally, the model prediction is used for performance prediction, failure analysis, and reliability analysis. Since failures are, generally, events with low probabilities of occurrence, it is important to be able to accurately capture tail probabilities in order to predict failures. For example, if the component is assumed to fail when the temperature is greater than 25 °C, then the model prediction PDF gives the failure probability as 0.0135, whereas the unconditional PDF gives the failure probability as 0.0390. Thus, it is clear that, using the raw model prediction (i.e., by simply considering the calibrated model, without accounting for the result of validation) underestimates the failure probability, whereas the approach outlined in Sect. 2 and followed in this example systematically includes the effect of model uncertainty in reliability analysis by integrating verification, validation, and calibration during system-level uncertainty quantification.

4 Multilevel Models with Type-I Interaction

Consider a system that is studied using multiple levels of models with Type-I interaction, i.e., the output of a lower-level model becomes an input to the higher-level model and hence is the linking variable between the two models. While the methods of verification, validation, and calibration can be applied to each of the individual models, the challenge is to integrate the results from these activities performed at multiple levels. This section discusses a methodology for the integration of verification, validation, and calibration across multiple levels of modeling with Type-I interaction. The methodology in this section is illustrated for two levels of models, as shown in Fig. 11.5 and Eq. (11.20), but can be extended to any number of levels of modeling without loss of generality.

$$\begin{aligned} Y &= G(X; \theta) \\ Z &= H(Y, W; \alpha) \end{aligned} \quad (11.20)$$

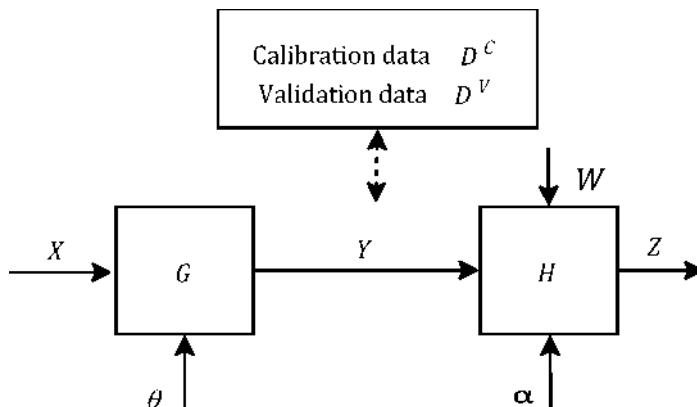

Fig. 11.5 Type-I interaction: two levels of models

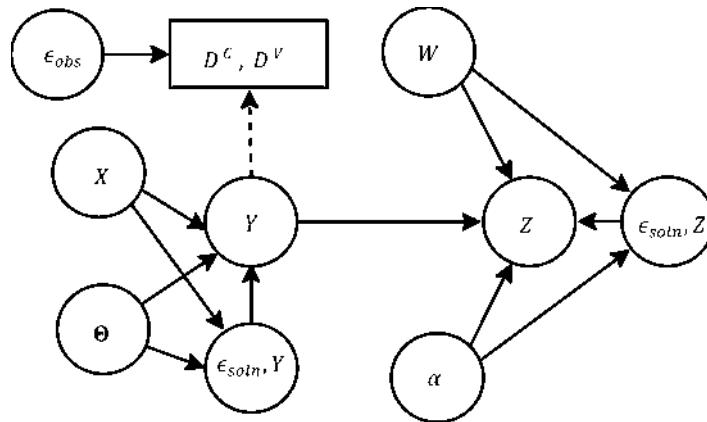

Fig. 11.6 Bayesian network: Type-I interaction between two models

Assume that data are not available at the system level, i.e., it is not possible to validate/calibrate model H . Let D^C and D^V denote the data available on Y for calibration (of θ) and validation (of G), respectively. Let $\epsilon_{obs} \sim N(0, \sigma_{obs}^2)$ denote the measurement errors in the data.

The first step is to connect the various sources of uncertainty using a Bayesian network, as shown in Fig. 11.6.

This Bayesian network indicates that two sets of data are available for calibration and validation; the Bayesian methods for calibration and validation can be applied to these sets. (If the KOH framework is pursued for calibration, then both the parameters and the model inadequacy function can be included in the Bayesian network.) While Bayesian updating is used for model calibration, either Bayesian hypothesis testing or the model reliability metric can be pursued for model validation.

The task is to compute the overall uncertainty in Z by using lower-level data; this uncertainty must include the effect of verification, calibration, and validation activities.

4.1 Verification, Calibration, and Validation

Both the models G and H can be verified since experimental data are not required for verification. During the process of verification, the solution approximation error (ϵ_{soln}) is quantified for both the models G and H . Note that the solution approximation error is a function of the inputs and the model parameters. Note that these solution approximation errors (ϵ_{soln} for both G and H) account for the combined effect of both deterministic and stochastic errors, as discussed in Sect. 2.1.

Now the Bayesian network includes quantification of solution approximation error, and it can now be used for calibration, validation, and system-level prediction.

The next step is to calibrate the model parameters. Suppose that the PDFs of the parameters $\boldsymbol{\theta}$ and $\boldsymbol{\alpha}$ are assumed to be $f_{\Theta}(\boldsymbol{\theta})$ and $f_{\alpha}(\boldsymbol{\alpha})$ before any testing; these are the prior PDFs. Since no data are available on Z , it is not possible to update the PDF of $\boldsymbol{\alpha}$. The data on Y , i.e., D^C , is used to calibrate the parameters $\boldsymbol{\theta}$, using Bayesian inference, as in Sect. 2.2. The calibration procedure uses the data and assumes that the model is correct, and hence the posterior PDF of $\boldsymbol{\theta}$ is denoted by $f_{\Theta}(\boldsymbol{\theta}|G, D^C)$. During the calibration procedure, for every realization of $(\boldsymbol{\theta})$, the corresponding solution approximation error is estimated, and therefore, calibration is based on comparing y against experimental data, rather than y_c , thereby accounting for the results of verification during calibration.

Additional independent data (D^V) is assumed to be available for the purpose of validating the model G . The alternate hypothesis PDF $f_Y(y|G')$ is assumed, and the posterior probability of model being correct, i.e., $P(G|D^V)$, is calculated as explained in Sect. 2.3.1; alternatively, the model reliability metric $P(M)$ can also be used instead of $P(G|D^V)$.

4.2 Integration for Overall Uncertainty Quantification

The Bayesian network can be used for forward propagation of uncertainty using the principles of conditional probability and total probability. Prior to the collection of any data, the uncertainty in x , $\boldsymbol{\theta}$, and $\boldsymbol{\alpha}$ can be propagated through the models as

$$\begin{aligned} f_Z(Z|H) &= \int f_Z(Z|\mathbf{w}, \boldsymbol{\alpha}, y, H) f_W(\mathbf{w}) f_{\alpha}(\boldsymbol{\alpha}) f_Y(y|G) d\mathbf{w} d\boldsymbol{\alpha} dy \\ f_Y(y|G) &= \int f_Y(y|x, \boldsymbol{\theta}, G) f_X(x) f_{\Theta}(\boldsymbol{\theta}) dx d\boldsymbol{\theta} \end{aligned} \quad (11.21)$$

However, this procedure assumes that (1) the PDFs of the parameters $\boldsymbol{\theta}$ and $\boldsymbol{\alpha}$ are $f_{\Theta}(\boldsymbol{\theta})$ and $f_{\alpha}(\boldsymbol{\alpha})$ and (2) the models G and H are correct. These two issues were addressed in calibration and validation, respectively. While the PDF of $\boldsymbol{\alpha}$ did not change, the PDF of $f_{\Theta}(\boldsymbol{\theta})$ was updated to $f_{\Theta}(\boldsymbol{\theta}|G, D^C)$. Further, the probability that G is correct, i.e., $P(G|D^V)$, was evaluated. These two quantities can now be used to calculate the overall uncertainty in Z . First, if the calibration data alone was used, then the PDFs of Y and Z are given by

$$\begin{aligned} f_Z(Z|G, H, D^C) &= \int f_Z(Z|\mathbf{w}, \boldsymbol{\alpha}, y, H) f_W(\mathbf{w}) f_{\alpha}(\boldsymbol{\alpha}) f_Y(y|G, D^C) d\mathbf{w} d\boldsymbol{\alpha} dy \\ f_Y(y|G, D^C) &= \int f_Y(y|x, \boldsymbol{\theta}, G) f_X(x) f_{\Theta}(\boldsymbol{\theta}|G, D^C) dx d\boldsymbol{\theta} \end{aligned} \quad (11.22)$$

The theorem of total probability can then be used to include the result of validation. The PDF of Y is modified as

$$f_Y(y|D^C, D^V) = P(G|D^V) f_Y(y|G, D^C) + P(G'|D^V) f_Y(y|G') \quad (11.23)$$

The overall uncertainty in Z , which includes the results of verification, calibration, and validation, can be calculated as

$$\begin{aligned} f_Z(Z|H, D^C, D^V) &= P(G|D^v) f_Z(Z|G, H, D^C) + P(G'|D^V) f_Z(Z|G', H) \\ f_Z(Z|G', H) &= \int f_Z(Z|\boldsymbol{w}, \boldsymbol{\alpha}, y, H) f_{\boldsymbol{w}}(\boldsymbol{w}) f_{\boldsymbol{\alpha}}(\boldsymbol{\alpha}) f_Y(y|G') d\boldsymbol{w} d\boldsymbol{\alpha} dy \end{aligned} \quad (11.24)$$

The PDF of Z is still conditioned on H because it is assumed that the model H is correct and it is not possible to calibrate/validate this model. In fact, Eq. (11.24) is equivalent to simply propagating the PDF $f_Y(y|D^C, D^V)$ (in Eq. (11.23)) through the model H . Note that the model H has been verified; therefore, during uncertainty propagation, it is necessary to estimate and account for the solution approximation error, thereby including the result of verification of H during calibration, validation, and response computation. Thus, the PDF of the linking variable can be used to compute the uncertainty in the system-level response, thereby integrating the results of verification, validation, and calibration activities at a lower level.

The principles of conditional probability and total probability can also be extended to multiple models that exhibit Type-I interaction, as explained below.

4.3 Extension to Multiple Models

Until now, only the first model G was considered for verification, validation, and calibration. However, the methodology is general and can be extended to multiple models. For example, consider the case where there are two models whose individual outputs become inputs for the system model. For example, consider the equations:

$$\begin{aligned} Y_1 &= G_1(X_1, \theta_1) \\ Y_2 &= G_2(X_2, \theta_2) \\ Z &= H(Y_1, Y_2) \end{aligned} \quad (11.25)$$

The inputs to the models G_1 and G_2 are X_1 and X_2 , respectively; the corresponding parameters are θ_1 and θ_2 , respectively. The Bayesian network for this multilevel system is shown in Fig. 11.7.

Assume that there is no data at the system level Z , but data are available for calibration and validation of lower-level models G_1 and G_2 , as shown in the Bayesian network in Fig. 11.7. Using the calibration data, the PDFs $f(\theta_1|G_1, D_1^c)$, $f(\theta_2|G_2, D_2^c)$, $f(y_1|G_1, D_1^c)$, and $f(y_2|G_2, D_2^c)$ are calculated. Using the validation data, the probability $P(G_1|D_1^v)$ and $P(G_2|D_2^v)$ are calculated; further $P(G'_1|D_1^v) = 1 - P(G_1|D_1^v)$ and $P(G'_2|D_2^v) = 1 - P(G_2|D_2^v)$. As explained earlier, the probabilities that G_1 and G_2 are correct can also be calculated using the reliability-based metric.

The unconditional PDF of Z needs to be calculated by considering four quantities:

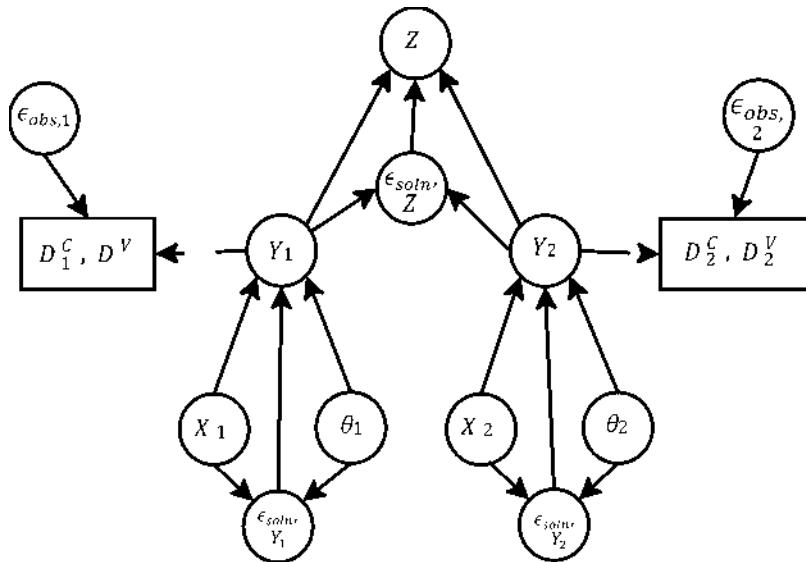

Fig. 11.7 Bayesian network: Type-I interaction between multiple models

1. $P(G_1 \cap G_2 | D_1^V, D_2^V) = P(G_1 | D_1^V) P(G_2 | D_2^V)$
2. $P(G_1 \cap G'_2 | D_1^V, D_2^V) = P(G_1 | D_1^V) P(G'_2 | D_2^V)$
3. $P(G'_1 \cap G_2 | D_1^V, D_2^V) = P(G'_1 | D_1^V) P(G_2 | D_2^V)$
4. $P(G'_1 \cap G'_2 | D_1^V, D_2^V) = P(G'_1 | D_1^V) P(G'_2 | D_2^V)$

Note the assumption that the two models G_1 and G_2 are independent. If the dependence is known, then it can be included in the calculation of the joint probabilities. Then, the unconditional PDF of Z is written as

$$\begin{aligned}
 f_Z(Z | D_1^C, D_1^V, D_2^C, D_2^V, H) \\
 &= P(G_1 | D_1^V) P(G_2 | D_2^V) f_Z(Z | G_1, G_2, H) \\
 &\quad + P(G'_1 | D_1^V) P(G_2 | D_2^V) f_Z(Z | G'_1, G_2, H) \\
 &\quad + P(G_1 | D_1^V) P(G'_2 | D_2^V) f_Z(Z | G_1, G'_2, H) \\
 &\quad + P(G'_1 | D_1^V) P(G'_2 | D_2^V) f_Z(Z | G'_1, G'_2, H)
 \end{aligned} \tag{11.26}$$

In Eq. (11.26), $f_Z(Z | G_1, G_2, H)$ is calculated by propagating the posteriors of Y_1 and Y_2 through H , since both the models are correct; $f_Z(Z | G'_1, G_2, H)$ is calculated by propagating the alternate PDF of Y_1 and the posterior of Y_2 through H , since only G_2 is correct; similarly, $f_Z(Z | G_1, G'_2, H)$ is calculated by propagating the posterior of Y_1 and alternate PDF of Y_2 , and $f_Z(Z | G'_1, G'_2, H)$ is calculated by propagating the alternate PDFs of Y_1 and Y_2 . If there are more than two lower-

level models (G_1 , G_2 , G_3 and so on), the number of terms on the right hand side of Eq. (11.26) increases exponentially, since the number of terms will be equal to 2^{n_m} where n_m is the number of models. Each of these terms indicates which subset of the models is correct. For example, in the case of three models, the event “ $G_1 \cap G'_2 \cap G'_3$ ” indicates that the model G_1 is correct, whereas the models G_2 and G_3 are not. Similarly, the event “ $G_1 \cap G_2 \cap G'_3$ ” indicates that the model G_2 is correct, whereas the models G_1 and G_3 are not. Though Eq. (11.26) clearly distinguishes between all such possibilities, the computation of the right hand side of this equation may be cumbersome due to the exponential number of terms. Such computational complexity can be easily avoided by first computing the unconditional PDFs of the lower-level outputs ($f(y_1|D_1^c, D_1^v)$ and $f(y_2|D_2^c, D_2^v)$ in this case) similar to Eq. (11.23) and then propagating these PDFs through the model H . Both the approaches will yield the same resultant PDF of Z , which accounts for the results of verification, validation, and calibration activities in both the models G_1 and G_2 .

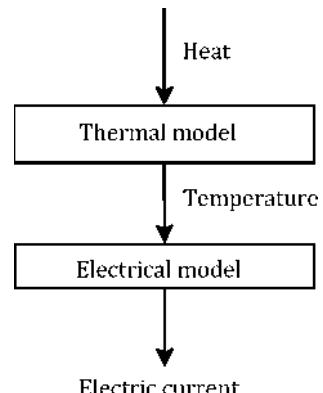

5 Numerical Example: Two Models with Type-I Interaction

This section illustrates two models that represent thermal and electrical analyses, with Type-I interaction. This example is an extension of the heat conduction problem in Sect. 3; the temperature rise in the wire causes change in the electrical resistance. The goal is to predict the system response, which is the electric current in the wire. Hence, the output of the lower-level model (temperature predictor in Eq. (11.19)), i.e., temperature, becomes an input to a higher-level model (current predictor), as shown in Fig. 11.8.

Consider the same wire as in Sect. 3. Before application of the heat, the resistance of the wire is given in terms of the resistivity (ρ), the cross-section area (A), and length (L) as

$$R_{old} = \rho \frac{L}{A} \quad (11.27)$$

Fig. 11.8 Thermal electrical analysis

After steady state is reached, the midpoint temperature (Y) computed in Eq. (11.19) causes an increase in the resistance of the wire; this increase is evaluated using the coefficient of resistivity (α). The current through the wire when a 10V voltage is applied is calculated as

$$I = \frac{10}{R_{old} (1 + \alpha Y)} \quad (11.28)$$

Assume that there is no electrical performance test data for the wire, and it is required to predict the uncertainty in the electrical current, by including the results of verification (using Richardson extrapolation), validation, and calibration in the lower-level model. The two models and the associated sources of uncertainty are connected through a Bayesian network as shown in Fig. 11.9. The four uncertain quantities (T_0 , T_L , k , β) are used to predict the midpoint temperature (Y) which is then used to compute the resistance (R) as a function of higher-level model parameters (A , α , I , ρ). Notice that the lower-level solution approximation error is actually a function of the aforementioned four uncertain quantities (T_0 , T_L , k , β). Data (D^C , D^V) is available for comparison against Y , and ϵ_m is the measurement error associated with such data.

Since the thermal model used for temperature prediction has already been verified, calibrated, and validated, the unconditional PDF of the temperature is simply propagated through the current-predictor model to calculate the current in the wire. For the purpose of illustration and to see the effect of uncertainty in Y on the uncertainty in electrical current (I), the other parameters of the current-predictor model (α , A , ρ) are chosen to be deterministic. The PDF of the current of the wire is shown in Fig. 11.10, for three cases.

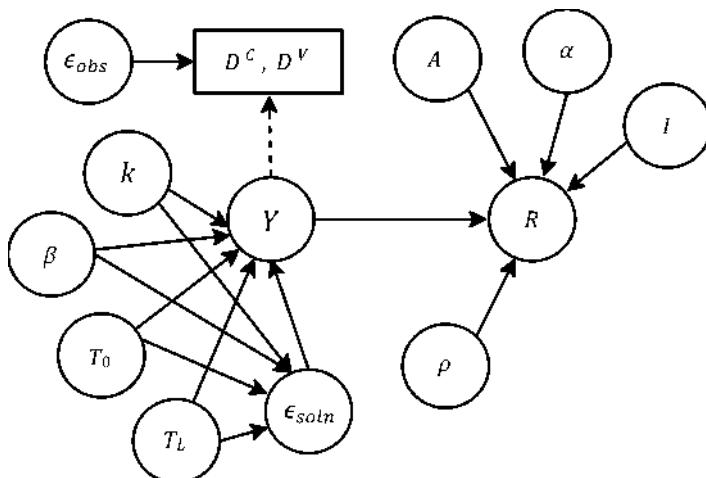

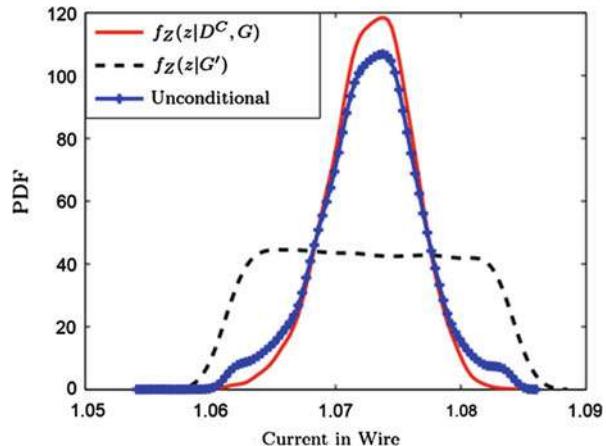

Fig. 11.9 Bayesian network: thermal electrical analysis

Fig. 11.10 PDF of electric current: system response

The PDF $f_Z(Z|G, D^C)$ is obtained by propagating the model prediction of thermal model through the electrical model, and the PDF $f_Z(Z|G')$ is obtained by propagating the alternate PDF of temperature ($f_Y(y|G')$) through the electrical model. The unconditional PDF ($f_Z(Z|D^C, D^V)$) represents the current response by integrating verification, validation, and calibration activities for the lower-level heat conduction model. Similar to the previous example, the difference between $f_Z(Z|G, D^C)$ and the unconditional $f_Z(Z|D^C, D^V)$ can be quantified; for example, $1 - F_Z(Z = 1.08|G) = 0.0086$, whereas $1 - F_Z(Z = 1.08) = 0.0400$.

6 Multilevel Models with Type-II Interaction

Sometimes, a system model is developed using progressively complex models and corresponding experiments (isolated features, isolated physics, simplified geometry, scaled models, etc.). The experiments of lowest complexity (simplest geometry or single physics) have been referred to as unit-level experiments [76]. A higher-level experiment could include an assembly of units or combined physics.

A typical example of such a system is discussed in [1], where material-level tests (lowermost level), performance of a single joint, and performance of three joints are used to calibrate underlying material and model parameters that are used in the overall system-level model. Usually, in such a system, the complexity increases going from the lower level to the higher level (more physics, features, components, etc.). The response of a lower-level experiment may not be directly related to the system-level response. However, there are some system-level parameters that can be inferred using lower-level experiments.

Assume that a generic system-level model is given by

$$Z = H(\theta, X, \Psi) \quad (11.29)$$

In Eq. (11.29), Z is the system-level prediction, θ is the set of model parameters which are calibrated based on lower-level models and tests, Ψ is the set of additional model parameters at the system level, and X are the inputs. Consider two lower-level models G_1 and G_2 . Both these models have common model parameters θ , but they have their own inputs (X_1 and X_2) and outputs (Y_1 and Y_2); in addition, they may have additional lower-level model parameters (Ψ_1 and Ψ_2).

$$\begin{aligned} Y_1 &= G_1(\theta, X_1, \Psi_1) \\ Y_2 &= G_2(\theta, X_2, \Psi_2) \end{aligned} \quad (11.30)$$

Assume that separate sets of data are available for calibration (D_1^c and D_2^c for levels 1 and 2, respectively) and validation (D_1^v and D_2^v for levels 1 and 2, respectively). Full system testing is not possible, i.e., no test data are available at the system level (Z), and it is required to quantify the uncertainty in the system-level prediction using the data at the lower levels (Y_1 and Y_2). The inputs, model parameters, outputs, and data at all levels are connected through a Bayesian network, as shown in Fig. 11.11.

6.1 Verification, Calibration, and Validation

The steps of verification, calibration, and validation in each model are similar to the previous sections; however the procedure for integration of these activities is different.

If θ is estimated using each individual model (G_1 or G_2) and the corresponding calibration data (D_1^c or D_2^c), then the corresponding PDFs of the model parameter θ are $f(\theta|D_1^c, G_1)$ or $(\theta|D_2^c, G_2)$, respectively.

The Bayesian network facilitates the simultaneous use of both models and the corresponding data to calibrate θ and obtain the PDF $f(\theta|D_1^c, D_2^c, G_1, G_2)$. This step of simultaneous calibration using multiple data sets from experiments of differing complexity is different from the calibration considered in Sects. 2 and 4, where only one model and the corresponding calibration data were used to estimate θ . In order to integrate the results of verification, validation, and calibration in Sect. 6.3 below, all the PDFs, i.e., those calibrated using individual data sets ($f(\theta|D_1^c, G_1)$ and $f(\theta|D_2^c, G_2)$) as well as those calibrated using multiple data sets ($f(\theta|D_1^c, D_2^c, G_1, G_2)$), are necessary.

The use of validation data is identical to the procedure in Sects. 2 and 4. The quantities $P(G_1|D_1^c)$ and $P(G_2|D_2^v)$ are calculated using the Bayes factor metric; further $P(G'_1|D_1^v) = 1 - P(G_1|D_1^v)$ and $P(G'_2|D_2^v) = 1 - P(G_2|D_2^v)$. Alternatively, the reliability-based method can also be used to calculate this probability. Since the two models are assumed independent, $P(G_1 \cap G_2|D_1^v, D_2^v) = P(G_1|D_1^v)P(G_2|D_2^v)$.

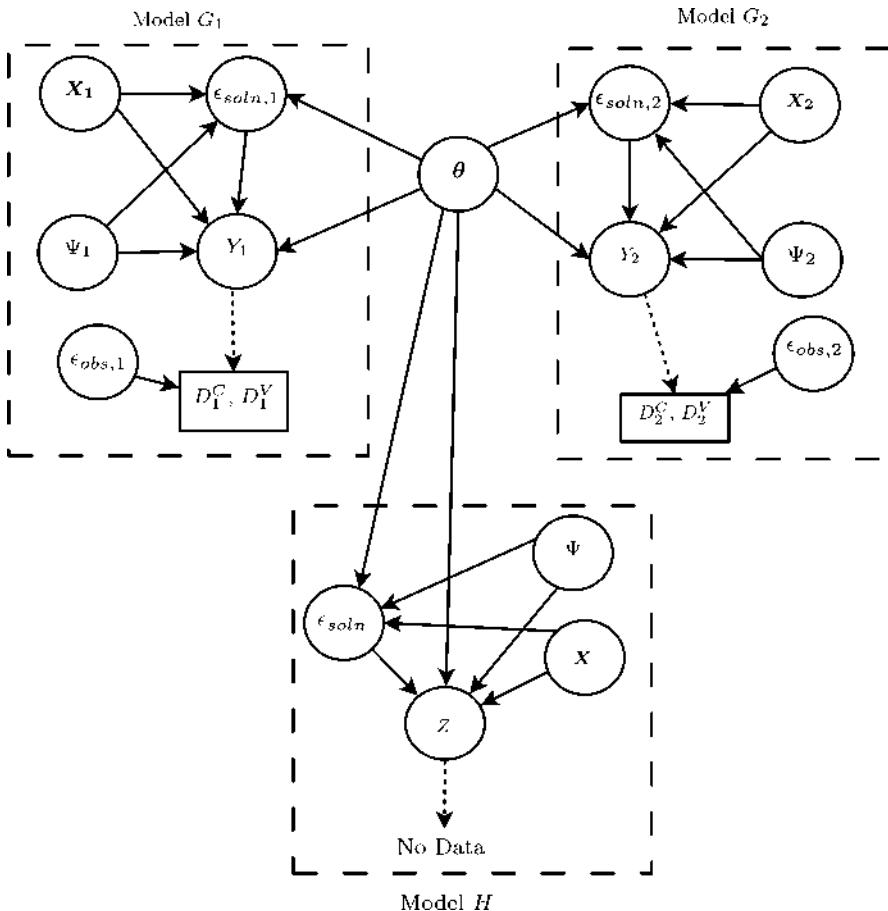

Fig. 11.11 Bayesian network: Type-II interaction between models

6.2 Relevance Analysis

Section 1.2 mentioned the necessity to assign larger weight to the level physically “closer” or more relevant to the system level than the other in the case of Type-II interaction. Hence this section develops a method for relevance analysis, which measures the degree to which the experimental configuration at a lower level has similar physical characteristics as the system of interest. Currently such measure is only intuitive and qualitative; an objective quantitative measure of relevance is needed for uncertainty integration.

The methodology to measure relevance should have two desired features. First, the defined methodology needs no mathematical details of the model in each level, since the model in each level could be a black box. Second, the resultant relevance

measure can be used conveniently as a weighting term in uncertainty integration. To fulfill these two criteria, a relevance analysis using Sobol indices is discussed in this section.

Consider a model $Y = F(X)$ where $X = \{X^1, \dots, X^N\}$ is a vector containing all the inputs. Sensitivity analysis measures the contribution of each input to the uncertainty of Y [92]. Compared to local sensitivity analysis, global sensitivity analysis (GSA) considers the entire probability distribution of the input, not just the contribution at a local point. The Sobol indices for GSA have been developed in the literature based on the variance decomposition theorem [93], including first-order index and total effects index. For a particular input X^i , its first-order index is $S_1^i = V(E(Y|X^i))/V(Y)$, and its total effects index is $S_T^i = 1 - V(E(Y|X^{-i}))/V(Y)$ where X^{-i} means all the inputs other than X^i . The first-order index S_1^i measures the contribution of X^i by itself, and the sum of first-order indices of all inputs is always less than or equal to unity. The difference between this sum and unity is the contribution of the interaction among inputs. In contrast, the total effects index S_T^i contains not only the contribution of X^i , but also the interaction effect of X^i with other inputs. The interaction between variables will be ignored if the first-order index is used, thus this chapter uses the total effects index to develop a method to quantify the relevance. In the following discussion, the term sensitivity index indicates the total effects index.

Without loss of generality, this chapter takes the multilevel problem in Fig. 11.1b for the illustration of relevance analysis. To predict the system output y_s , the same quantity is also measured at lower levels (in the numerical example, the maximum acceleration at the top mass is also measured at Level 1 and Level 2). The three prediction models for this quantity at different levels are $y_{L_1} = G_{L_1}(\mathbf{x}_{L_1}; \boldsymbol{\theta})$, $Y_{L_2} = G_{L_2}(\mathbf{x}_{L_2}; \boldsymbol{\theta})$, and $y_{L_1} = G_s(\mathbf{x}_s; \boldsymbol{\theta})$ where $\boldsymbol{\theta}$ are model parameters and \mathbf{x}_{L_1} , \mathbf{x}_{L_2} , and \mathbf{x}_s are the model inputs at each level. Note that (1) the computational models are replaced by the GP models to improve computational efficiency, (2) model errors are considered in Level 1 and Level 2, and (3) model error at the system level is not considered since no information on it is available. These prediction models are stochastic, i.e., the output is stochastic even at fixed values of model inputs and model parameters. However, the Sobol indices computation requires a deterministic model, i.e., deterministic output at given values of model inputs and model parameters. This chapter applies the auxiliary variable methodology based on the probability integral transform, as developed in Ref. [94, 95], to obtain a deterministic value of the output for a given realization of inputs and model parameters; thus the Sobol indices can be computed.

Assume model parameters, model inputs, and auxiliary variables constitute N_{L_1} elements in total at Level 1; since each element has a corresponding sensitivity index, a N_{L_1} -dimensional vector V_{L_1} of sensitivity indices will be obtained at Level 1. Similarly, a N_{L_2} -dimensional sensitivity vector N_{L_2} will be obtained at Level 2, and a N_s -dimensional sensitivity vector V_s will be obtained at the system level.

Rigorously, measuring the relevance requires comparing the mathematical model of the lower level and the mathematical model of the system level. However, this

comparison is not easy if the models at different levels have distinct formats and are addressing different physical configurations. Further, the model sometimes may be a black box; thus we cannot access its mathematical details and a direct comparison would be difficult. The obtained sensitivity vectors quantify the contribution of each model input/parameter toward the uncertainty in the model output. In other words, the sensitivity vector indicates which model input/parameter is more important in affecting the model output uncertainty. Whether a model input/parameter is important is determined by the physics of the model, thus the sensitivity vector represents the physics to the extent that the model represents the physics accurately. Therefore, this chapter considers the sensitivity vector as an indicator of the physics captured in the model. (Of course, how well the physics is captured in the model is already indicated by the model reliability metric.) Thus the comparison of the vectors from two different levels is used to quantify the relevance between these two levels.

One issue in the comparison of V_{L_i} ($i = 1, 2$) and V_s is that they may have different sizes (N_{L_1}, N_{L_2}, N_s may not be equal to each other) and some elements in one vector may not be present in the other vector. The shared dimensions of V_{L_i} and V_s are model parameters θ , and the unshared dimensions are the different model inputs and auxiliary variables at each level. To solve this problem, we add the unshared dimension in V_{L_i} or V_s to the other vectors but set the corresponding sensitivity indices as zero since the added dimensions have no effect in the computation of the original sensitivity vector. Thus all the vectors V_{L_i} or V_s are brought to the same size.

Several methods are available to compare two vectors, such as Euclidean distance [90], Manhattan distance [90], Chebyshev distance [90], and cosine similarity [90, 96]. To include the relevance in the subsequent uncertainty integration conveniently, we define the relevance index R as the square of cosine similarity of the sensitivity vectors, where the cosine similarity is the standardized dot product of two vectors:

$$R = \left(\frac{V_{L_i} \cdot V_s}{\|V_{L_i}\| \|V_s\|} \right)^2 \quad (11.31)$$

In other words, the above relevance index is the square of the cosine value of the angle between two sensitivity vectors, the elements in which are all positive. If the angle is zero, the relevance among the two levels is 1; if the two vectors are perpendicular, the relevance is 0.

In addition, this definition of relevance generates a value on the interval $[0, 1]$, and its complement, the square of the sine value, indicates physical non-relevance; hence the sum of “relevance” and “non-relevance” is the unity. Here the relevance index is a plausibility model for the proposition “The lower level model reflects the physical characteristics of the system Level,” and the plausibility of this proposition is the relevance index. Based on Cox’s theorem [97], this plausibility model is isomorphic to probability since (1) the relevance index is a real value depending on the information of sensitivity vectors we obtained and (2) the relevance index changes sensibly as the sensitivity vectors change. Thus the relevance index can

be converted to probability by scaling, which has been done since the relevance index defined in Eq. (11.31) is already on the interval [0, 1]. Therefore in the roll-up methodology Sect. 6.3, we treat the relevance index as a probability and conveniently include it as a weighting term in the uncertainty integration.

A further question arises in the computation of relevance index. Sobol indices consider the entire distribution of the influencing variable, but the posterior distribution of θ_m (to be used in system-level prediction) is unknown before the uncertainty integration. In order to solve this problem, a straightforward iterative algorithm to compute the relevance index R is as below:

1. Set an initial value of R
2. Obtain the integrated distribution of each model parameter using the current relevance and the roll-up method in Sect. 6.3 below.
3. Use the integrated distributions from step 2 to compute the sensitivity indices, and recompute the updated relevance index R .
4. Repeat steps 2 and 3 until the relevance index R converges.

Thus, the results of calibration and validation at each lower level and relevance indices between the lower levels and the system level have been obtained. The next task is to construct the integrated distribution of the system-level model parameters and predict the system output.

6.3 Integration for Overall Uncertainty Quantification

The method for the integration of the verification, calibration, validation, and relevance analysis results for Type-II interaction is different from Sect. 4 because the linking variables in this case are the model parameters, whereas the linking variables in Type-I interaction were the outputs of lower-level models. While the unconditional PDF of the lower-level output was calculated in Sect. 4, it is now necessary to calculate the integrated distribution of the model parameters that also accounts for validation and relevance results.

For a multilevel problem of Type-II interaction, the purpose of uncertainty integration is to combine all the available information (from calibration, validation, and relevance analysis) from the lower levels and predict the response at the system level. In this chapter the information from the lower level includes (1) the posterior distributions from model calibration by considering data at each individual lower level, as well as data from multiple lower levels, (2) the model reliability distributions from model validation at each lower level, and (3) the relevance indices between each lower level and the system level. A roll-up methodology has been proposed in [16, 98] for uncertainty integration. This methodology computes the unconditional PDF of the model parameters as a weighted average of each posterior distributions, where the weight term of each posterior is purely decided by model validation, and the model validity is a fixed value. This section extends this method to include two additional concepts:

1. *Stochastic model reliability*: The model reliability $P(G_i)$ is a random variable with PDF $f(P(G_i))$ as explained in Sect. 2.3.2;
2. *Relevance index*: This has been defined in Sect. 6.2 as the square of the cosine value of the angle between the sensitivity vectors at lower level and system level. We treat the relevance index similar to probability in the roll-up methodology, based on Cox's theorem. If S_i denotes the event that Level i is relevant to the system level, then the probability $P(S_i|G_i)$ is equal to the value of the relevance index R ; this probability is conditioned on G_i since the computation of the relevance index uses the model at Level i ; in contrast $p(S'_i|G_i)$ denotes the probability of non-relevance and is equal to $1 - R$.

Take the multilevel problem in Fig. 11.1b as an example. The integrated distribution of model parameters θ conditioned on the calibration and validation data and model reliability $P(G_i)(i = 1, 2)$ is [99]:

$$\begin{aligned} f_{\Theta}(\theta | D_1^C, D_1^V, D_2^C, D_2^V, P(G_1), P(G_2)) \\ = P(G_1 G_2 S_1 S_2) f(\theta | D_1^C, D_2^C) + P(G_1 S_1 \cap (G_2' \cup S_2')) f(\theta | D_1^C) \\ + P(G_2 S_2 \cap (G_1' \cup S_1')) f(\theta | D_2^C) + P((G_1' \cup S_1') \cap (G_2' \cup S_2')) f(\theta) \end{aligned} \quad (11.32)$$

From the view of generating samples, Eq. (11.32) indicates two criteria: (1) whether a level is relevant to the system level and (2) whether a level has a valid model. A sample of θ is generated from $f_{\Theta}(\theta | D_1^c, D_2^c)$ only when both levels satisfy both criteria, a sample of θ is generated from $f_{\Theta}(\theta | D_i^c)$ if level i satisfies both criteria but the other level does not, and a sample of θ is generated from the prior distribution $f_{\Theta}(\theta)$ if neither level satisfies both criteria. By assuming independence of model validity and relevance between different lower levels, the weight terms in Eq. (11.32) are computed by using the values of $P(G_i)$, $P(S_i|G_i)$ and two fundamental probability relationships: $P(G_i S_i) = P(G_i)P(S_i|G_i)$, $P(G'_i \cup S'_i) = 1 - P(G_i S_i)$. Eq. (11.11) also implies the option of “using only data from one level.” If both the model validity and relevance are 1 for Level 1 and either model validity or relevance is 0 for Level 2, Eq. (11.11) reduces to $f_{\Theta}(\theta | D_1^{c,v}, D_2^{c,v}) = f_{\Theta}(\theta | D_1^c)$, i.e., only Level 1 data is used.

The integrated distribution of θ , which is conditioned on both calibration and validation data, can now be computed as

$$\begin{aligned} f_{\Theta}(\theta | D_1^C, D_1^V, D_2^C, D_2^V) \\ = \iint f_{\Theta}(\theta | D_1^C, D_1^V, D_2^C, D_2^V, P(G_1), P(G_2)) f(P(G_1)) \\ f(P(G_2)) dP(G_1) dP(G_2) \end{aligned} \quad (11.33)$$

Eqs. (11.32) and (11.33) express the approach to integrate calibration, validation, and relevance results at lower levels. Note that Eq. (11.33) accounts for stochastic

model reliability. The analytical expression of $f_{\Theta}(\boldsymbol{\theta}|D_1^C, D_1^V, D_2^C, D_2^V)$ is difficult to derive since the results we collect in model calibration and validation are all numerical. A single loop sampling approach is given here to construct $f_{\Theta}(\boldsymbol{\theta}|D_1^C, D_1^V, D_2^C, D_2^V)$ numerically, as follows:

1. Generate a sample of $P(G_1)$ and $P(G_2)$ from their distributions.
2. Compute the weight terms in Eq. (11.32). Divide the interval $[0, 1]$ into four ranges; the length of the k th range is equal to the value of the k th weight in Eq. (11.32)
3. Generate a random number from the uniform distribution $U(0, 1)$
4. Generate a sample of $\boldsymbol{\theta}$ using stratified sampling, i.e., from $f_{\Theta}(\boldsymbol{\theta}|D_1^C, D_2^C)$ if the random number in step 3 is located in the first range, from $f_{\Theta}(\boldsymbol{\theta}|D_1^V)$ if located in the second range, from $f_{\Theta}(\boldsymbol{\theta}|D_2^V)$ if located in the third domain, and from $f_{\Theta}(\boldsymbol{\theta})$ if located in the fourth domain.
5. Repeat steps 1 to 4 to obtain multiple samples of $\boldsymbol{\theta}$; then construct the PDF $f_{\Theta}(\boldsymbol{\theta}|D_1^C, D_1^V, D_2^C, D_2^V)$ by any method such as kernel density estimation [100]

(In general, if there are n_m models, then the right hand side of Eq. (11.32) has 2^{n_m} terms. Each of these terms, except the one corresponding to the case where all the models are not correct, needs to be computed through a Bayesian inference procedure. Hence, this may be a computational challenge in larger applications. In such scenarios, the use of an inexpensive surrogate model is recommended for such repeated Bayesian inference calculations, as performed in this chapter.)

The PDF $f_{\Theta}(\boldsymbol{\theta}|D_1^C, D_1^V, D_2^C, D_2^V)$ calculated in Eq. (11.33) accounts for the verification, calibration, validation, and relevance analysis activities with respect to each of the lower-level models. This unconditional PDF is propagated through the system model $H(\boldsymbol{\theta}, \mathbf{X}, \Psi)$, in order to quantify the uncertainty in the system-level response Z . This can be done by Monte Carlo sampling or other preferred stochastic analysis methods. Thus, similar to Sect. 4, it can be seen that the tools of conditional probability and total probability are directly useful for integrating verification, validation, and calibration and, thereby, aid in the quantification of the system-level prediction uncertainty.

7 Numerical Example: Models with Type-II Interaction

7.1 Problem Description

A multilevel structural dynamics challenge problem provided by Sandia National Laboratories [101] is used to illustrate the methodology developed in Sect. 6. As shown in Fig. 11.12, Level 1 contains three mass-spring-damper dynamic components in series, and a sinusoidal force input $p = 300 \sin(500t)$ is applied to m_1 . At Level 2, the dynamic system is mounted on a beam supported by a hinge at one end and a spring at the other end; a sinusoidal force input $p = 300 \sin(350t)$ is applied on the beam. The configuration of the system level is the same as Level 2, but the

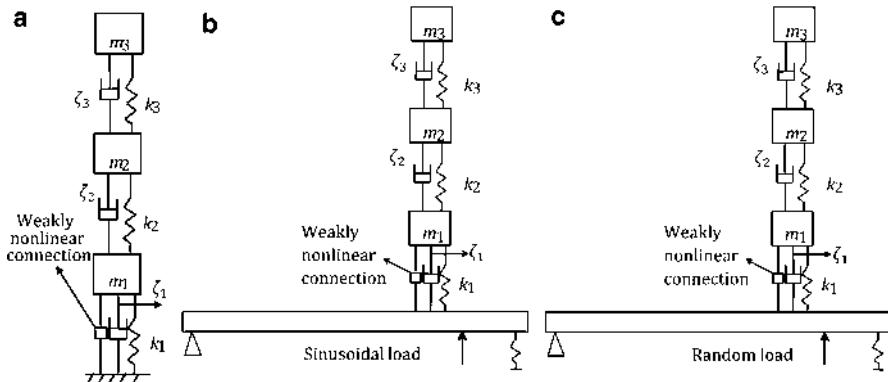

Fig. 11.12 Structural dynamics challenge problem. (a) Level 1. (b) Level 2. (c) System level

input is a random process loading (indicating difference in usage condition). Here Level 1 and Level 2 are defined as lower levels, and experimental data are assumed to be available only at the lower levels. All levels share six model parameters: three spring stiffnesses $k_i (i = 1, 2, 3)$ and three damping ratios $\zeta_i (i = 1, 2, 3)$, and they are assumed to be deterministic but unknown parameters, which are to be calibrated. The units of all quantities are nondimensional.

Suppose ten experiments are conducted at each of Level 1 and Level 2, and the displacement, velocity, and acceleration history at each degree of freedom are recorded. Six quantities at each lower level are extracted from these records as the synthetic experimental data in model calibration and validation:

- (1) $A_i (i = 1, 2, 3)$: the maximum acceleration in the i th mass;
- (2) $D_i (i = 1, 2, 3)$: the energy dissipated by the i th damper in 1000 time units

The data points for each quantity from the first five tests are selected as calibration data and the rest five as validation data.

Computational models for the three levels have been established. The method to solve the dynamic problem at Level 1 can be found in structural dynamics textbooks [102], and the computational models using the finite element method for Level 2 and the system level are provided by Sandia National Laboratories [101].

Since the model input at each level is fixed, the input-dependent model error is an unknown deterministic value. Thus the parameters to be calibrated in this example are the spring stiffnesses $k_i (i = 1, 2, 3)$, the damping ratios $\zeta_i (i = 1, 2, 3)$, model error δ , and the output measurement error standard deviation σ_m if the data of the corresponding quantity are used in model calibration. Based on expert opinion, suppose the prior distribution of each k_i and ζ_i is assumed to be lognormal with a coefficient of variation of 10% and mean values of $\mu_{k_1} = 5000$, $\mu_{k_2} = 9000$, $\mu_{k_3} = 8000$, $\mu_{\zeta_i} = 0.025 (i = 1, 2, 3)$. The prior distribution of model error is assumed to be uniform, i.e., $\delta \sim U(a, b)$ and the prior of σ_m is Jeffrey's prior $f'(\sigma) \propto 1/\sigma$.

The objective in this numerical example is to quantify the uncertainty in the prediction of maximum acceleration at m_3 in the system level, by using available models and experimental data.

Since as many as six quantities are measured, we can choose any combination of these six quantities in the analysis. Measurement data on more output quantities reduce the uncertainty in the system output prediction, but the computational effort will also increase and each quantity will bring two more related terms (δ and σ) for calibration. For the sake of brevity, only the calibration and validation results using the test data for all six quantities are provided below. But a plot showing the reduction in the uncertainty of system output prediction with the increase of output quantity measurements is also provided at the end.

7.2 Results and Analysis

In order to reduce the computational effort, Gaussian process (GP) surrogate models are established to replace the computational models for all the output quantities. The surrogate model uncertainty introduced by the GP models is incorporated in model calibration and validation, as explained in Sects. 2 and 3.1. The calibration results of k_i and ζ_i using the calibration data of the six output quantities at different levels are shown in Fig. 11.13, including all the PDFs needed in Eq. (11.32). As more data are used in the calibration, the uncertainty of the model parameters will decline. Thus Fig. 11.13 shows that the posterior distributions using the data at both levels always have less uncertainty than those using data at a single level. The difference between the posterior distributions within each sub-figure also indicates that the posterior distribution is a best-fitting result in the sense of representing that particular data set, but we do not yet know how to combine these alternatives in the subsequent prediction. This is answered by model validation and relevance analysis.

Next model validation is performed using the stochastic model reliability metric with multivariate output. The tolerance for each quantity is chosen to be 15% of the validation data. Level 2 is expected to have lower model reliability value for two main factors:

1. The discretization error at Level 2 due to a limited number of finite elements for the beam (41 in this example). But this factor is not effective here since the data at Level 2 are synthetic data generated using the computational model, meaning that the difference between the computational model and the physics model is ignored. This factor will come into play if experimental data instead of synthetic data are used.
2. The coupling between the beam and the damped mass-spring system brings stronger nonlinearity at Level 2. Under the same number of training points, the GP surrogate model at Level 2 has more surrogate uncertainty (larger GP model prediction variance) than the GP surrogate model at Level 1. This factor is included in the numerical example.

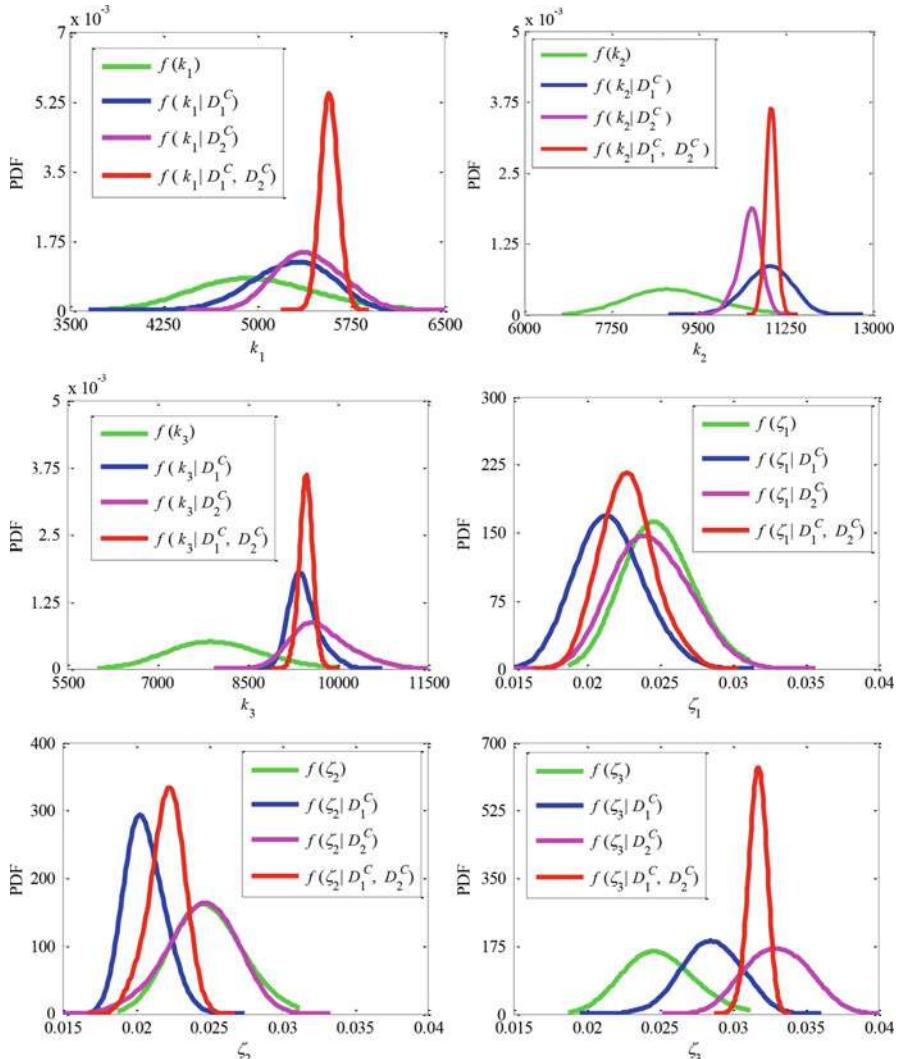

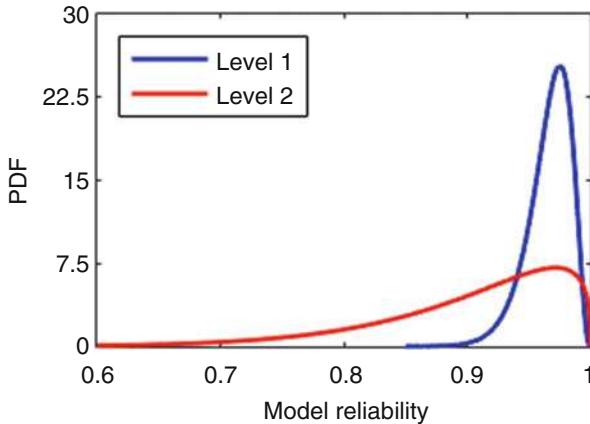

Fig. 11.13 Posterior distributions of model parameters

The model reliability values given by the validation data from each validation test are listed in Table 11.1, which indicate lower model reliability at Level 2. In Fig. 11.14, these values are used to construct the distributions of model reliability at Level 1 and Level 2 using the method of moments. However, even though the model at Level 1 has higher model reliability than the model at Level 2, the configuration at Level 2 is closer to the system level of interest. Therefore relevance analysis also needs to be considered.

Table 11.1 Model reliability values

Validation test	1	2	3	4	5
Model reliability at Level 1	0.9702	0.958	0.9398	0.9828	0.9800
Model reliability at Level 2	0.9616	0.8564	0.9208	0.9796	0.7904

**Fig. 11.14** Distribution of model reliability

The relevance index of each lower level to the system level is computed using the iterative algorithm in Sect. 6.2. The initial values of relevance indices for both lower levels are set as 1. The algorithm converges after three iterations for Level 1 and after five iterations for Level 2. The results are $P(S_1) = 0.5785$ and $P(S_2) = 0.8971$. This result means that Level 2 is more relevant to the system level, which is consistent with our intuition since Level 2 has the same structural configuration as the system and differs only in the load input (sinusoidal vs. random process). Compared with the result of model validation, Level 2 has a lower value of model reliability but higher relevance index.

Based on all the information from calibration, validation, and relevance analyses, the integrated distributions of all six model parameters are constructed in Fig. 11.15 using Eqs. (11.32) and (11.33). Figure 11.15 also shows the result by considering validation only (no relevance) using the previous roll-up method in Ref. [98], but stochastic model reliability metric is still used. It is shown that the new roll-up method is more conservative than the previous one, since we add one more criterion of relevance during the generation of samples from the posterior distribution.

The system output is predicted by propagating the integrated distribution of model parameters through the computational model at the system level. Figure 11.16 gives not only the prediction using the data of all six quantities but also the prediction by other combinations of quantities whose names are shown in the legend. The mean values and variances of the predictions are shown in Table 11.2.

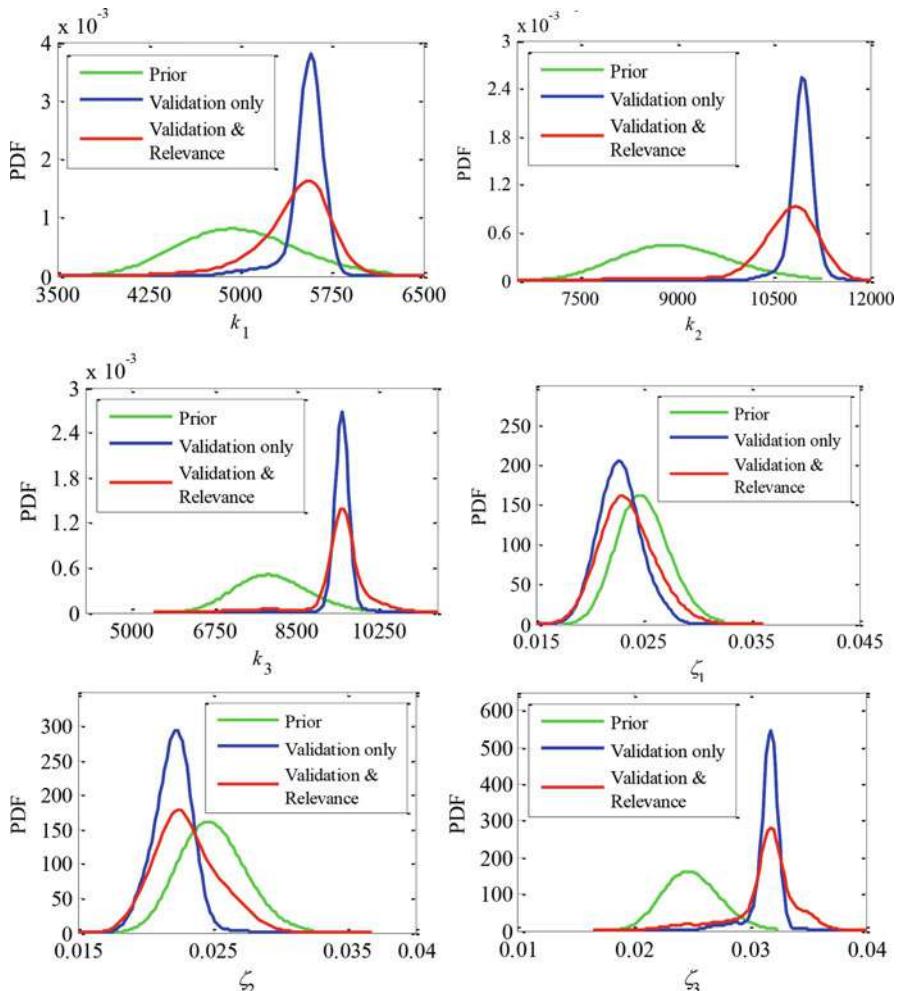

Fig. 11.15 Integrated distributions of model parameters

Table 11.2 Mean values and variances of predictions

Number of quantities	1	2	3	4	5	6
Mean values	710	713	690	632	655	656
Variance	12,202	10,499	10,959	4868	5432	2301

As more quantities are employed, the mean value of prediction decreases from 712 to 656, and the variance shows an overall decreasing tendency, but not monotonic (the variance increases slightly when the number of outputs considered rises from 2 to 3 and from 4 to 5).

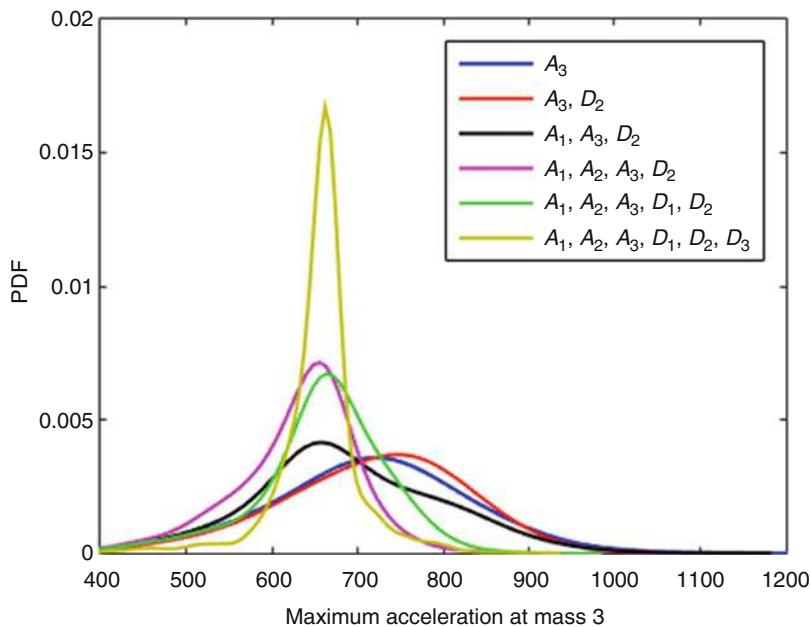

Fig. 11.16 System output prediction

8 Conclusion

Verification, validation, and calibration are significant activities in the process of model development. While methods for individual activities have been addressed in the past, the quantification of the combined effect of these activities on the overall system-level prediction uncertainty is addressed in this chapter, for single-level and multilevel models.

This topic is of specific importance in systems which are studied using multiple models where data may be available only at lower levels, and it may be desired to quantify the uncertainty in the system-level prediction using lower-level data. This chapter discussed a Bayesian network-based methodology to integrate the various uncertainty quantification activities, including verification, validation, and calibration, performed at lower levels, and rigorously account for their effects on the system-level prediction uncertainty. The Bayesian network is first used to connect the multiple models, the corresponding inputs, parameters, outputs, error estimates, and all available data. During the verification procedure, the solution approximation errors are quantified and accounted for. Both deterministic and stochastic errors are properly included, and the model is corrected before calibration and validation. Two independent sets of test data are considered: the first set is used to calibrate the model parameters and the second set is used to validate the calibrated model. The principles of conditional probability and total probability are then used to integrate

the results of calibration and validation in order to compute the overall uncertainty in the model-based prediction.

The integration methodology is first developed for single-level models and then extended to multilevel systems that consist of interacting models. Two types of interactions are discussed in detail: (1) Type-I interaction, where the output of a lower-level model becomes an input to the higher-level model, and (2) Type-II interaction, where models and experiments at various levels of reduced complexity are used to infer system model parameters. While verification is performed before calibration and validation in both the cases, in order to account for the results of verification during calibration and validation, the procedure for the integration of calibration and validation results at lower levels is different for Type-I and Type-II interactions; in the former case, the key idea is to compute the unconditional PDF of the *output* of the lower-level model, whereas in the latter case, the key idea is to compute the unconditional PDF of the system *model parameters*. If a system-level prediction is based on models with both types of interactions (both Type-I and Type-II), then the unconditional PDFs of the intermediate output and the parameters can both be used to compute the uncertainty in the overall system-level prediction uncertainty.

The multilevel roll-up methodology described in this chapter offers considerable promise toward the quantification of margins and uncertainties in multilevel system prediction. While calibration and validation have previously been performed independently at individual levels, this methodology systematically integrates all such activities in order to compute the system-level prediction uncertainty, thereby aiding in risk-informed decision-making with all available information. Only two types of interactions between multiple models were considered in this chapter.

An important related issue is the extrapolation of the model to application conditions under which experiments may not have been performed. Often, there are two types of extrapolation. The first type is where the model is validated at certain input values, but prediction needs to be performed at other input values that are not contained in the validation domain. The second type of extrapolation is where validation is performed using a simplified system (with restricted features, physics, etc.) and the desired prediction is of the original system. While regression-based techniques have been developed for the first type of extrapolation [27], the second type of extrapolation could be represented through a Type-II configuration discussed in Sects. 6 and 7. The methods discussed in this chapter can only be used for the propagation of uncertainty to the extrapolation domain *as long as there is no change in the physics of the system between validation and extrapolation domains*.

Abstract

Cubic splines are commonly used in numerical analysis. It has also become popular in the analysis of computer experiments, thanks to its adoption by the software JMP 8.0.2 2010. In this chapter, a Bayesian version of the cubic spline method is proposed, in which the random function that represents prior uncertainty about y is taken to be a specific stationary Gaussian process and y is the output of the computer experiment. A Markov chain Monte Carlo (MCMC) procedure is developed for updating the prior given the observed y values. Simulation examples and a real data application are given to show that the proposed Bayesian method performs better than the frequentist cubic spline method and the standard method based on the Gaussian correlation function.

1 Introduction

Because of the advances in complex mathematical models and fast computation, computer experiments have become popular in engineering and scientific investigations. Computer simulations can be much faster or less costly than running physical experiments. Furthermore, physical experiments can be hard to conduct or even infeasible when only rare events, like landslides or hurricanes, are observed. There are many successful applications of computer experiments as reported in the literature. The Gaussian process (GP) has been used as the main tool for modeling computer experiments. See the books by Santner, Williams, and Notz [31]; Fang, Li, and Sudjianto [8]; as well as the November 2009 issue of *Technometrics*, which was devoted to computer experiments.

First, the GP model is introduced. Suppose an experiment involves k factors $\mathbf{x} = (x_1, \dots, x_k)^t$ and n computer runs are performed at $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$. The input can be written as the $n \times k$ matrix $D = (\mathbf{x}_1, \dots, \mathbf{x}_n)^t$. The corresponding response values are the vector $\mathbf{Y}_D = (y_1, \dots, y_n)^t$. The GP model assumes that

$$y(\mathbf{x}) = \mathbf{b}' \mathbf{f}(\mathbf{x}) + Z(\mathbf{x}), \quad (12.1)$$

where $\mathbf{f}(\mathbf{x}) = (f_1(\mathbf{x}), \dots, f_s(\mathbf{x}))^t$ is a vector of s known regression functions, $\mathbf{b} = (b_1, \dots, b_s)^t$ is a vector of unknown coefficients, and $Z(\mathbf{x})$ is a stationary GP with mean zero, variance σ^2 , and isotropic correlation function $\text{corr}(y(\mathbf{x}_1), y(\mathbf{x}_2)) = R(\mathbf{x}_1, \mathbf{x}_2) = R(\|\mathbf{x}_1 - \mathbf{x}_2\|)$. For the GP model in (12.1), the best linear unbiased predictor (BLUP) of $y(\mathbf{x})$ is an interpolator, which will be shown in (12.5).

One popular choice of the correlation function is the Gaussian correlation function, which is the product exponential correlation function with power two. For the one-dimension case, it can be written as

$$R(d) = \exp(-\theta d^2), \quad (12.2)$$

where $d = \|\mathbf{x}_1 - \mathbf{x}_2\|$ is the distance between two input values \mathbf{x}_1 and \mathbf{x}_2 and θ is the scale parameter. It has been used in many applications [1, 24, 28, 29] and software including JMP 8.0.2 2010. However, a process $y(\mathbf{x})$ with (12.2) as the correlation function has the property that its realization on an arbitrarily small, continuous interval determines the realization on the whole real line. This global influence of local data is considered unrealistic and possibly misleading in some applications [6, p. 54]. This property will be referred to hereafter as *global prediction*. Another

well-known correlation function is the Matérn family (Matérn, 1960). For the one-dimension case, it is a two-parameter family:

$$R(d) = \{2^{v-1} \Gamma(v)\}^{-1} (d/\phi)^v K_v(d/\phi),$$

where $K_v(\cdot)$ denotes a modified Bessel function of order $v > 0$ and $\phi > 0$ is a scale parameter for the distance d . As $v \rightarrow \infty$, the Matérn correlation function converges to (12.2).

Another commonly used interpolation method is the spline. An order- s spline with knots ξ_i , $i = 1, \dots, l$ is a piecewise polynomial of order s and has continuous derivatives up to order $s - 2$. A cubic spline has $s = 4$. The GP may also be viewed as a spline in a reproducing kernel Hilbert space, with the reproducing kernel given by its covariance function [32]. The main difference between them is in the interpretation. While the spline is driven by a minimum norm interpolation based on a Hilbert space structure, the GP is driven by minimizing the expected squared prediction error based on a stochastic model.

In this chapter, emphasis is placed on the cubic spline by considering it in the GP framework via the cubic spline correlation function [4, 31]:

$$R(d) = \begin{cases} 1 - 6\left(\frac{d}{\theta}\right)^2 + 6\left(\frac{|d|}{\theta}\right)^3, & \text{if } |d| < \frac{\theta}{2}, \\ 2\left(1 - \frac{|d|}{\theta}\right)^3, & \text{if } \frac{\theta}{2} \leq |d| < \theta, \\ 0, & \text{if } |d| \geq \theta, \end{cases} \quad (12.3)$$

where $\theta > 0$ is the scale parameter. Currin et al. [5] showed that the BLUP with the function in (12.3) as the correlation function gives the usual cubic spline interpolator. An advantage of the cubic spline correlation is that θ can be made small, which permits prediction to be based on data in a local region around the predicting location [31, p. 38]. This property shall be referred to hereafter as *local prediction*.

In this chapter, a Bayesian version of the Gaussian process approach is introduced for the cubic spline correlation function given in (12.3). One advantage of Bayesian prediction is that the variability of $y(\mathbf{x})$ given observations can be used to provide measures of posterior uncertainty, and designs can be sought to minimize the expected uncertainty [29, 36]. Some empirical studies have shown the superiority of Gaussian processes over the other interpolating techniques, including splines (see Laslett [18]). Here, some potential advantages of using Bayesian cubic spline in the GP model compared to the power exponential correlation function (12.2) is illustrated through simulation studies.

The chapter is organized as follows. In the following section, a brief review of the kriging technique based on GP models is provided. A methodological section is then presented introducing a Bayesian version of the cubic spline method, abbreviated as BCS. This section also outlines methodology for the nugget parameter in BCS for situations where numerical and estimation stability is required. A summary procedure for BCS is also given, and its extension to high dimensions is discussed.

Next, a simulation section compares BCS with two competing procedures: a GP based on the cubic spline correlation function in (12.3), abbreviated as CS, and a GP based on the power exponential Gaussian correlation function in (12.2), abbreviated as GC (CS and GC are explained in more detail in the review section). The performance of BCS and GC is then compared on some real data in an application section. Finally, remarks on the importance of BCS and future research directions are given in a concluding section.

2 A Brief Review on Kriging

The GP model has been used in geostatistics and is known as kriging [3, 6, 20]. Kriging is used to analyze spatially referenced data which have the following characteristics [3]: The observed values y_i are at a discrete set of sampling locations $\mathbf{x}_i, i = 1, \dots, n$, within a spatial region. The observations y_i are statistically related to the values of an underlying continuous spatial phenomenon. Sacks et al. [29] proposed kriging as a technique for developing meta models from a computer experiment. Computer experiments produce a response for a given set of input variables. Our methodology development only considers deterministic computer experiments, i.e., the code produces identical answers if run twice using the same set of inputs.

Suppose the goal is to predict the output of a function $y(\mathbf{x})$ at an untried location \mathbf{x} , given the observed y values at $D = (\mathbf{x}_1, \dots, \mathbf{x}_n)^t$. For the Gaussian process in (12.1), the best linear unbiased estimator (BLUE) of \mathbf{b} is

$$\hat{\mathbf{b}} = (\mathbf{f}'_D \mathbf{R}_D(\hat{\theta})^{-1} \mathbf{f}_D)^{-1} \mathbf{f}'_D \mathbf{R}_D(\hat{\theta})^{-1} \mathbf{Y}_D, \quad (12.4)$$

where $\mathbf{f}_D = \mathbf{f}(D) = (\mathbf{f}(\mathbf{x}_i))_{\mathbf{x}_i \in D}$, the dependence on θ is now explicitly indicated in the notation, and $\hat{\theta}$ is an estimate of θ . The BLUP of $\mathbf{Y}_0 = y(\mathbf{x}_0)$ at $\mathbf{x}_0 \in \mathbb{R}$ is

$$\hat{\mathbf{Y}}_0 = \hat{\mathbf{b}}' \mathbf{f}_0 + \mathbf{R}_0(\hat{\theta})^t \mathbf{R}_D(\hat{\theta})^{-1} (\mathbf{Y}_D - \hat{\mathbf{b}}' \mathbf{f}_D), \quad (12.5)$$

where $\hat{\mathbf{b}}$ is given in (12.4), $\mathbf{f}_0 = \mathbf{f}(\mathbf{x}_0)$, and $\mathbf{R}_0 = (R(\mathbf{x}_0 - \mathbf{x}_1), \dots, R(\mathbf{x}_0 - \mathbf{x}_n))^t$ is the $n \times 1$ vector of correlations between \mathbf{Y}_D and \mathbf{Y}_0 . Letting $\boldsymbol{\mu}_D = \mathbf{b}' \mathbf{f}_D$ and $\boldsymbol{\mu}_0 = \mathbf{b}' \mathbf{f}_0$, then (12.5) becomes

$$\hat{\mathbf{Y}}_0 = \hat{\boldsymbol{\mu}}_0 + \mathbf{R}_0(\hat{\theta})^t \mathbf{R}_D(\hat{\theta})^{-1} (\mathbf{Y}_D - \hat{\boldsymbol{\mu}}_D).$$

One way to estimate θ and σ^2 is by maximum likelihood. Maximum likelihood is a commonly used method for estimating parameters in both computer experiments

and spatial process models [4, 19, 29, 30, 34]. For the power exponential correlation function in (12.2), the estimate of σ^2 yields

$$\hat{\sigma}^2(\theta) = \frac{1}{n}(\mathbf{Y}_D - \boldsymbol{\mu}_D)' \mathbf{R}_D(\theta)^{-1} (\mathbf{Y}_D - \boldsymbol{\mu}_D).$$

Estimation of θ is usually done by a constrained iterative search. This method will be referred to as kriging based on the power exponential Gaussian correlation (GC). If the cubic spline correlation function is adopted in (12.3), the correlation parameter θ is both a scale and truncation parameter. In this case, the estimation method of θ is based on the restricted maximum likelihood method (REML). REML [25] was proposed as a method of obtaining less biased estimates of the variance and covariance parameters than the (unrestricted) maximum likelihood method. This method will be referred to as kriging based on the cubic spline correlation function (CS).

3 Bayesian Cubic Spline

3.1 The Prior and Posterior Processes

With $\mathbf{Y}_D \sim \mathcal{N}(\boldsymbol{\mu}_D, \sigma^2 \mathbf{R}_D(\theta))$, the Bayesian framework for the cubic spline method can now be developed, where \mathbf{R} is the correlation matrix based on the function in (12.3). First assign the non-informative priors to $\boldsymbol{\mu}_D$ and θ and the conjugate prior to σ^2 , and further assume that these priors are independent with each other:

$$\begin{aligned}\boldsymbol{\mu}_D &\propto 1, \\ \sigma^2 | \alpha, \beta &\sim \text{InverseGamma}(\alpha, \beta), \\ \theta | a &\sim \mathcal{U}(0, a), \\ \beta &\propto 1/\beta,\end{aligned}$$

where θ follows the uniform distribution in $(0, a)$ and β^{-1} has a non-informative prior over $(0, \infty)$. Here θ can be viewed as the *knot location* parameter in the spline literature. In the Bayesian spline literature [7, 33], it is a common practice to assign a uniform prior to the knot location parameter. The hyperparameter a is fixed as

$$a = \max_{\mathbf{x}_i, \mathbf{x}_j \in D} \|\mathbf{x}_i - \mathbf{x}_j\|.$$

The reason for choosing this particular a is because the function in (12.3) is truncated and equals zero for $|d| \geq \theta$. Since the local prediction property is desired for the GP, a is chosen to be the largest distance among the \mathbf{x} values in D . A simulation study (not reported here) shows that a larger value of a does not change

overall performance in estimation. Because an unknown shape parameter α will bring unnecessary complication in the computation, α is assumed to be fixed and known.

MCMC was used to perform the Bayesian computation [11, 27]. It samples from probability distributions by constructing a Markov chain that has the desired distribution as its equilibrium distribution. Gibbs sampling can be implemented to obtain the posterior distribution of μ_D and β :

$$\begin{aligned}\mu_D \mid \mathbf{Y}_D, \theta, \alpha, \beta &\propto \int \mathbb{P}(\mathbf{Y}_D \mid \mu_D, \theta, \sigma^2) \mathbb{P}(\mu_D) \mathbb{P}(\sigma^2 \mid \alpha, \beta) d\sigma \\ &\propto \int \mathcal{N}(\mu_D, \mathbf{R}_D(\theta, \sigma^2)) \times \text{InverseGamma}(\alpha, \beta) d\alpha d\beta,\end{aligned}\tag{12.6}$$

$$\begin{aligned}\beta \mid \mathbf{Y}_D, \mu_D, \theta, \alpha &\propto \int \mathbb{P}(\mathbf{Y}_D \mid \mu_D, \theta, \sigma^2) \mathbb{P}(\beta) \mathbb{P}(\sigma^2 \mid \alpha, \beta) d\sigma \\ &\propto \int \mathcal{N}(\mu_D, \mathbf{R}_D(\theta, \sigma^2)) \times \beta^{-1} \times \text{InverseGamma}(\alpha, \beta) d\alpha d\beta.\end{aligned}$$

However, the parameters θ are embedded into the covariance function \mathbf{R} in (12.3) and have no posterior distribution in closed form. Hence, posterior samples of θ are obtained using the Metropolis-Hastings (MH) algorithm [14, 22]. The MH algorithm works by generating a sequence of sample values in such a way that, as more and more sample values are produced, the distribution of values more closely approximates the desired distribution. Specifically, at each iteration, the algorithm picks a candidate for the next sample value based on the current sample value. Then, with some probability, the candidate is either accepted (in which case the candidate value is used in the next iteration) or rejected (in which case the candidate value is discarded and the current value is reused in the next iteration).

Specifically, a new value of θ (denoted as θ_{new}) is sampled using a normal density with respect to the existing θ (denoted as θ_{old}). The normal densities work as a *jumping* distribution, because they choose a new sample value based on the current sample. In theory, any arbitrary jumping probability density $Q(\delta_{\text{old}} \mid \delta_{\text{new}})$ can work, where δ is the parameter of interest. Here, a symmetric jumping density $Q(\delta_{\text{old}} \mid \delta_{\text{new}}) = Q(\delta_{\text{new}} \mid \delta_{\text{old}})$ is chosen for simplicity. The variance term in the normal distribution is the jumping size from the old sample to the new sample of the MH algorithm. Here, the variance is chosen to be one. As this jumping size gets smaller, the deviation of new parameters from previous ones should get smaller. The jumping distribution is therefore

$$\log \theta_{\text{new}} \sim \mathcal{N}(\log \theta_{\text{old}}, 1).\tag{12.7}$$

After getting θ_{new} , the acceptance ratio is defined as

$$\begin{aligned} r_1 &= \frac{\mathbb{P}(\mathbf{Y}_D \mid \boldsymbol{\mu}_D, \theta_{\text{new}}, \sigma^2) \mathbb{P}(\theta_{\text{new}} \mid a)}{\mathbb{P}(\mathbf{Y}_D \mid \boldsymbol{\mu}_D, \theta_{\text{old}}, \sigma^2) \mathbb{P}(\theta_{\text{old}} \mid a)} \\ &= \frac{|\mathbf{R}_D(\theta_{\text{new}}, \sigma^2)|^{-1/2} \exp\left(-\frac{1}{2}(\mathbf{Y}_D - \boldsymbol{\mu}_D)' \mathbf{R}_D(\theta_{\text{new}}, \sigma^2)^{-1} (\mathbf{Y}_D - \boldsymbol{\mu}_D)\right) \mathbb{1}_{\theta_{\text{new}} \in [0, a]}}{|\mathbf{R}_D(\theta_{\text{old}}, \sigma^2)|^{-1/2} \exp\left(-\frac{1}{2}(\mathbf{Y}_D - \boldsymbol{\mu}_D)' \mathbf{R}_D(\theta_{\text{old}}, \sigma^2)^{-1} (\mathbf{Y}_D - \boldsymbol{\mu}_D)\right) \mathbb{1}_{\theta_{\text{old}} \in [0, a]}}. \end{aligned}$$

If $r_1 < 1$, then θ_{new} is accepted with probability r_1 . Otherwise, if $r_1 \geq 1$, then θ_{new} is accepted.

3.2 Nugget Parameter

One possible problem with the kriging approach is the potential numerical instability in the computation of the inverse of the correlation matrix in (12.5). This happens when the correlation matrix is nearly singular. Numerical instability is serious because it can lead to large variability and poor performance of the predictor. The simplest and perhaps most appealing way is to add a nugget effect in the GP modeling. In the spatial statistic literature [3], a nugget effect is introduced to compensate for local discontinuities in an underlying stochastic process. A well-known precursor is the ridge regression in linear regression analysis. Gramacy and Lee [13] gave justifications for the use of nugget in GP modeling for deterministic computer experiments. Here, the option of adding a nugget parameter in GP model is considered by using ridge regression.

Consider the Gaussian model:

$$Y \sim \mathcal{N}(\boldsymbol{\mu}, \mathbf{R}(\sigma^2, \theta) + \tau^2 I),$$

where τ^2 is the nugget parameter. Adding the matrix $\tau^2 I$ to \mathbf{R} makes the covariance matrix nonsingular and helps stabilize the parameter estimate. MH sampling can be used to estimate τ^2 by letting $\gamma^2 = \tau^2/\sigma^2$ and assigning a uniform $[0, \kappa]$ prior on γ^2 , where κ is fixed and known. The correlation matrices \mathbf{R}_D and \mathbf{R}_0 introduced at the start of this section can then be replaced by $\mathbf{V}_D = \mathbf{R}_D + \gamma^2 I$ and $\mathbf{V}_0 = \mathbf{R}_0 + \gamma^2 I$. To use MH sampling for γ^2 , the jumping distribution

$$\log \gamma_{\text{new}}^2 \sim \mathcal{N}(\log \gamma_{\text{old}}^2, 1), \quad (12.8)$$

is used, with the acceptance ratio

$$\begin{aligned} r_2 &= \frac{\mathbb{P}(\mathbf{Y}_D \mid \boldsymbol{\mu}_D, \gamma_{\text{new}}^2, \theta, \sigma^2) \mathbb{P}(\gamma_{\text{new}}^2 \mid \kappa)}{\mathbb{P}(\mathbf{Y}_D \mid \boldsymbol{\mu}_D, \gamma_{\text{old}}^2, \theta, \sigma^2) \mathbb{P}(\gamma_{\text{old}}^2 \mid \kappa)} \\ &= \frac{|\mathbf{V}_D(\gamma_{\text{new}}^2, \theta, \sigma^2)|^{-1/2} \exp\left(-\frac{1}{2}(\mathbf{Y}_D - \boldsymbol{\mu}_D)' \mathbf{V}_D(\gamma_{\text{new}}^2, \theta, \sigma^2)^{-1} (\mathbf{Y}_D - \boldsymbol{\mu}_D)\right) \mathbb{1}_{\gamma_{\text{new}}^2 \in [0, \kappa]}}{|\mathbf{V}_D(\gamma_{\text{old}}^2, \theta, \sigma^2)|^{-1/2} \exp\left(-\frac{1}{2}(\mathbf{Y}_D - \boldsymbol{\mu}_D)' \mathbf{V}_D(\gamma_{\text{old}}^2, \theta, \sigma^2)^{-1} (\mathbf{Y}_D - \boldsymbol{\mu}_D)\right) \mathbb{1}_{\gamma_{\text{old}}^2 \in [0, \kappa]}}. \end{aligned}$$

In our computation, the criterion introduced by Peng and Wu [26] is used to determine whether or not to include a nugget effect. The condition number of a square matrix is used as the primary measure of singularity, that is, the ratio of its maximum eigenvalue over its minimum eigenvalue. In particular, the Linear Algebra PACKage (LAPACK), reciprocal condition estimator in MATrix LABoratory (MATLAB) is employed to determine whether the covariance matrix \mathbf{R} is ill-conditioned. If $(\kappa_1(\mathbf{R}))^{-1} < 10\epsilon$, where $\epsilon = 2^{-8}$ is the floating-point relative accuracy, then \mathbf{R} is ill-conditioned and the nugget effect is introduced into the model. Otherwise, the nugget effect is set to be zero.

With the option of adding a nugget parameter, the steps to perform the Bayesian cubic spline are summarized as follows:

1. Set initial values for μ_D , θ , σ^2 and let $\gamma^2 = 0$.
2. Calculate $\kappa_1(\mathbf{R})$.
3. If $(\kappa_1(\mathbf{R}))^{-1} \geq 10\epsilon$, where ϵ is a specified constant, set $\gamma^2 = 0$; sample μ_D and θ from (12.6) and (12.7), respectively. If the parameters do not converge, go back to step 2.
4. If $(\kappa_1(\mathbf{R}))^{-1} < 10\epsilon$, use $\mathbf{V} = \mathbf{R} + \gamma^2 I$ instead of \mathbf{R} and sample μ_D , θ , and γ^2 from (12.6), (12.7), and (12.8), respectively. Repeat this step until convergence.
5. Calculate the estimate of Y_0 using (12.5) with μ_D , θ , and γ^2 .

In step 1, the posterior mode is chosen as the starting value. This choice is sensible and can avoid the need of doing “burn-in” in MCMC. See its justification in Geyer [10].

3.3 Extension to High Dimensions

For multiple dimensions, let $\mathbf{x} \in \mathbb{R}^k$ and assume the correlation function $\mathbf{R}(\mathbf{x}_i, \mathbf{x}_j) = \prod_{t=1}^k \mathbf{R}_t(\mathbf{x}_{i,t} - \mathbf{x}_{j,t}) = \prod_{t=1}^k \mathbf{R}_t(d_t)$, where \mathbf{x}_i and \mathbf{x}_j are in \mathbb{R}^k , d_t is the distance between \mathbf{x}_i and \mathbf{x}_j on the t th dimension, and \mathbf{R}_t is the correlation function for the t th dimension.

The multidimensional spline correlation function $\mathbf{R}(d)$ is the product of the one-dimension spline correlation function with individual parameter θ_t estimated for each dimension [2, 35]. The corresponding Bayesian computation is done by doing MH sampling for each dimension until convergence. Our criterion for convergence is when the change of $\|\theta\|$ between consecutive iterations of the MCMC computation is smaller than 10^{-4} . In our simulation studies, θ converges within 3 min.

4 Simulation Study and Results

First, the performance of the proposed Bayesian cubic spline (BCS) method is compared with two other methods: GC and CS (described in the review section). The criterion for evaluating the performance of the estimators is the integrated mean squared error (IMSE), defined as

$$\text{IMSE}(\hat{f}) = \int_{\Omega} (\hat{f}(\mathbf{x}) - f(\mathbf{x}))^2 d\mathbf{x},$$

where f and \hat{f} are respectively the true function values and estimated values and Ω is the region of the \mathbf{x} values. The following mean squared error (MSE) is a finite-sample approximation to the IMSE:

$$\text{MSE}(\hat{f}) = \frac{1}{m} \sum_{i=1}^m (\hat{f}(\mathbf{x}_i) - f(\mathbf{x}_i))^2, \quad (12.9)$$

where m is the number of randomly selected points $\{\mathbf{x}_i\}$ from Ω . Three choices of the true function $f(x)$ are considered in Examples 1–3, which range from low to high dimensions and from smooth to non-smooth functions.

Example 1.

$$f_1(\mathbf{x}) = \{1 - \exp(-.5/x_2)\} \frac{2300x_1^3 + 1900x_1^2 + 2092x_1 + 60}{100x_1^3 + 500x_1^2 + 4x_1 + 20}.$$

This two-dimensional function is from Currin et al. [5], where $\mathbf{x} \in [0, 1]^2$ and $f_1 \in [4.1, 13.8]$. The function f_1 is further scaled into $[0, 1]$. Currin et al. [5] studied a 16-run design in their paper. Four designs are considered here: 4^2 design (16 runs) with levels (.125, .375, .628, .875) [15] and (0, .3333, .6667, 1) [5], 5^2 design (25 runs) with levels (0, .25, .5, .75, 1), and 6^2 design (36 runs) with levels (0, 0.2, 0.4, 0.6, 0.8, 1). Four types of noise ϵ are added to $f_1(\mathbf{x})$: $\mathcal{U}(0, 0)$ (no noise), $\mathcal{U}(0, .2)$, $\mathcal{U}(0, .5)$, and $\mathcal{U}(0, 1)$. As the range of the noise increases from 0 to 1, the function $f_1(\mathbf{x}) + \epsilon$ becomes more rugged. It allows us to compare the performance of the three methods as the true function becomes less smooth.

For noise based on $\mathcal{U}(0, 0)$ (and $\mathcal{U}(0, .2)$, $\mathcal{U}(0, .5)$ and $\mathcal{U}(0, 1)$ respectively), the simulation is conducted as follows. First, a noise is randomly sampled from $\mathcal{U}(0, 0)$ (and $\mathcal{U}(0, .2)$, $\mathcal{U}(0, .5)$, and $\mathcal{U}(0, 1)$). For each simulation, the noise is fixed and denoted as $\{\epsilon_1, \dots, \epsilon_n\}$. Here n , the number of design points, is 16, 16, 25, and 36, respectively, for the four designs. Second, the values of $\{f_1(\mathbf{x}_1), \dots, f_1(\mathbf{x}_n)\}$ are calculated. Then the values of $\{f_1(\mathbf{x}_1) + \epsilon_1, \dots, f_1(\mathbf{x}_n) + \epsilon_n\}$ are treated as the response values by GC, BCS, and CS in parameter estimation. The purpose of this step is to facilitate the study of the robustness of estimation against noise of various sizes. Then, the MSE (see (12.9)) is calculated on $m = 100$ of \mathbf{x} randomly sampled from $[0, 1]^2$. The errors $\{\epsilon_1, \dots, \epsilon_n\}$ and inputs $\{\mathbf{x}_1, \dots, \mathbf{x}_m\}$ are sampled repeatedly and independently for each simulation, and the average of the MSE values from 500 simulations for each noise and design setting is recorded in Table 12.1. For each simulation setting, the method with the smallest average MSE is highlighted in boldface.

The MCMC iterations of the BCS terminate if the change of parameter estimate is smaller than 10^{-4} . The running time takes about 20 s for an Intel Xeon CPU with 2.66 GHz and 3.00 GB of RAM to reach convergence. The power exponential method performs best when the noise is small ($\mathcal{U}(0, 0)$ and $\mathcal{U}(0, .2)$) or the design

Table 12.1 Average MSE values for GC, BCS, and CS predictors in Example 1

		$\mathcal{U}(0, 0)$	$\mathcal{U}(0, .2)$	$\mathcal{U}(0, .5)$	$\mathcal{U}(0, 1)$
$4^2(J)$	GC	1.0034	1.0437	1.7192	1.8951
	BCS	1.0901	1.1024	1.6722	1.8642
	CS	1.1036	1.2518	1.6714	1.9854
$4^2(C)$	GC	1.1223	1.3495	1.6545	2.4491
	BCS	1.1651	1.4475	1.5819	2.1270
	CS	1.1710	1.4322	1.6318	2.1476
5^2	GC	0.9087	1.0186	1.3516	1.4845
	BCS	1.0112	1.0574	1.2416	1.3391
	CS	1.0481	1.1204	1.2665	1.5816
6^2	GC	0.2171	0.2588	0.5604	0.6352
	BCS	0.2716	0.3079	0.7008	0.6893
	CS	0.2942	0.2769	0.7479	0.8042

size is large (36 run). This is because the example is relatively smooth when noise is small, and the function f_1 contains the exponential term $\exp(-.5/x_2)$, which is best captured by the nonzero exponential correlation function. GC also benefits from the larger sample size of 6^2 , which helps to stabilize the estimate. For relatively small designs (16 and 25 run) with large noise ($\mathcal{U}(0, .5)$ and $\mathcal{U}(0, 1)$), CS and BCS perform better than GC. When the design is small and noise is large, the response surface tends to be very rugged, and there is not enough data for GC to estimate the surface with good precision. A localized estimate like CS and BCS with truncated correlation function gives smaller MSE. BCS in most cases outperforms CS. The over-smoothing property of GC can result in large estimation errors as will be shown in Example 2 and in the application section.

Example 2.

$$f_2(x) = 0.3 \exp^{-1.4x} |\cos(10\pi x)| + 3x.$$

This is a one-dimension function and contains a non-smooth term $|\cos(10\pi x)|$. Here f_2 is scaled into $[0, 1]$. As in Example 1, four types of random noise are added to f_2 , and 5, 10, 20, and 30 design points (i.e., $\{x_1, \dots, x_n\}$ values) are uniformly sampled from $[0, 1]$. In each simulation, noise is sampled and fixed, denoted as $\{\epsilon_1, \dots, \epsilon_n\}$, where $n = 5$ (and 10, 20, and 30, respectively). Then 5 (and 10, 20, and 30) design locations $\{x_1, \dots, x_n\}$ are uniformly sampled from $[0, 1]$. The values of $\{f_2(x_1) + \epsilon_1, \dots, f_2(x_n) + \epsilon_n\}$ are used as the response values. The MSE for each simulation is calculated on $m = 100$ randomly sampled x values in $[0, 1]$. For each design, this procedure is repeated 500 times by taking random samples of $\{\epsilon_i\}_{i=1}^n$ and $\{\mathbf{x}_i\}_{i=1}^n$. The average MSE based on the 500 simulations is given in Table 12.2 for each noise and design setting. Again, the method with the smallest average MSE is highlighted in boldface.

Table 12.2 Average MSE values for GC, BCS, and CS predictors in Example 2

		$\mathcal{U}(0, 0)$	$\mathcal{U}(0, .2)$	$\mathcal{U}(0, .5)$	$\mathcal{U}(0, 1)$
	GC	0.0026	0.2857	0.7214	0.8147
5	BCS	0.0018	0.0772	0.2135	0.2740
	CS	0.0021	0.0518	0.2768	0.2853
	GC	0.0017	0.0389	0.1626	0.3260
10	BCS	0.0013	0.0261	0.0508	0.1892
	CS	0.0013	0.0259	0.0591	0.1964
	GC	0.0015	0.0092	0.1443	0.1547
20	BCS	0.0004	0.0057	0.0721	0.1208
	CS	0.0011	0.0063	0.1125	0.1248
	GC	0.0011	0.0049	0.0754	0.1853
30	BCS	6.70E-04	0.0032	0.0341	0.1807
	CS	7.20E-04	0.0028	0.0596	0.2005

In all cases, CS and BCS beat GC even when no noise is added to the true function. BCS performs better than CS in most cases. CS performs better than BCS in four cases, three of which the difference is not significant. GC gives much worse results when the design size is small (5, 10) and the noise is large ($\mathcal{U}(0, .5)$ and $\mathcal{U}(0, 1)$). This is due to the global prediction property of GC. For non-smooth functions, this can bring in unnecessarily large errors. On the other hand, the better performance of CS and BCS benefits from their local prediction property.

Example 3.

$$f_3(\mathbf{x}) = \frac{2\pi x_1(x_2 - x_3)}{\ln(x_4/x_5)[1 + \frac{2x_1x_6}{\ln(x_4/x_5)x_5^2x_7} + \frac{x_1}{x_8}]}$$

This is an eight-dimensional smooth function from Morris et al. [23], where $x_1 \in [63070, 115600]$, $x_2 \in [990, 1110]$, $x_3 \in [700, 820]$, $x_4 \in [100, 5000]$, $x_5 \in [.05, .15]$, $x_6 \in [1120, 1680]$, $x_7 \in [9855, 12046]$, and $x_8 \in [63.1, 116]$. It is also referred to as the “borehole” data in the literature. Here, each input x_1, \dots, x_8 , as well as the function f_3 , is scaled into $[0, 1]$. Morris et al. [23] proposed a 10-run design with two levels 0 and 1 based on the maximin distance criterion (see Table 12.3). In the study, this 10-run design together with 10-, 20-, and 50-run Latin hypercube designs [21] is used. A n -run Latin hypercube design in $[0, 1]^k$ is based on the Latin hypercube sampling. For each dimension, each of the n values is sampled randomly and independently from each interval $(0, 1/n), \dots, (1 - 1/n, 1)$ and randomly permutes the n values. Here the maximin criterion is employed in choosing the Latin hypercubes, i.e., maximizing the minimum distance between points. As before, four types of noise are added to the true function. In each simulation, after the noise $\{\epsilon_1, \dots, \epsilon_n\}$ is sampled, one Latin hypercube design is generated, denoted by $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$, where $n = 10, 20, 50$. Then apply GC, CS, and BCS to $\{f_1(\mathbf{x}_1) + \epsilon_1, \dots, f_1(\mathbf{x}_n) + \epsilon_n\}$ for parameter estimation. The MSE is

Table 12.3 A maximin distance design in $[0, 1]^8$ for $n = 10$ [23]

calculated based on $m = 5000$ random samples $\{\mathbf{x}_i\}_{i=1}^{5000}$ in $[0, 1]^8$. The simulations are repeated 1000 times, and the average MSE values are given in Table 12.4. The running time for each simulation of BCS is less than 2 min on the same machine.

The results are similar to those of Example 1. This is expected as they are both smooth functions. GC gives best results among the three methods when the noise is small ($\mathcal{U}(0, 0)$ and $\mathcal{U}(0, .2)$) or the sample size is large (50LH). BCS and CS perform well when sample size is small (10 and 20) and the noise is large ($\mathcal{U}(0, 1)$). BCS generally outperforms CS. Noting that x_4 and x_5 appear in the f_3 function through the \ln function, an alternative simulation is run by taking the log transformation of x_4 and x_5 and rescaling them into $[0, 1]$. Since it does not change the overall picture of comparisons, these results are not reported in the paper.

5 Application

Instead of simulating from known functions, another comparison study is presented using the methane combustion data from Mitchell and Morris [23]. Table 12.5 shows

its 50-run design. In addition, Mitchell and Morris gave 20-, 30-, 40-, 50-, and 7-run variable maximin designs in their paper. The first 20, 30, 40, and 50 runs in Table 12.5 consist of these designs, denoted as D20, D30, D40, and D50. The response y is the logarithm of the ignition delay time.

Before conducting the comparison, a careful data analysis is performed to show some feature of the data. For D20, D30, and D50, 90%, 80%, and 50% of the original data are taken as the response values for GC and BCS to estimate θ . The average values of $\hat{\theta}_j$, $j = 1, \dots, 7$, based on 100 simulations, are calculated and given in Table 12.6 for each setting. For each design, the value of $\hat{\theta}$ from GC increases as the number of input data decreases, while the $\hat{\theta}$ values for BCS are more stable. The divergent behavior between GC and BCS for this data can be partially explained by their respective global and local prediction properties. First, note that a larger $\hat{\theta}$ value indicates a smoother surface. As the size of input data gets smaller, the data

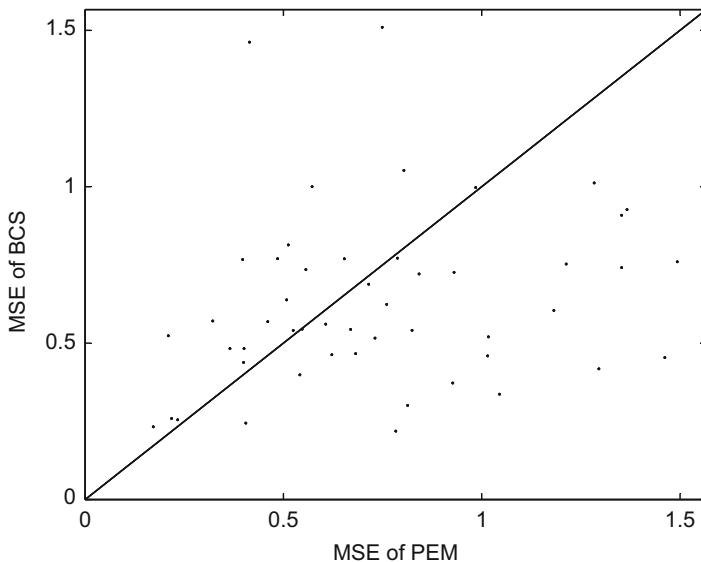

Fig. 12.1 MSE of 40 Training Data in D50

points are spread more thinly in the design region $[0, 1]^7$. The fitted response surface by GC will become more smooth due to its global prediction property. The change will not be as dramatic for BCS, thanks to its local prediction property. Even though the ruggedness of the true response surface is not known, this divergent behavior seems to suggest that BCS is a better method for the data. This is confirmed in the next study based on cross-validation.

The same data and design settings are then used to run cross-validations on D50, D40, and D30 for each of the three methods. One round of cross-validation involves partitioning the data into complementary subsets, performing the analysis on one subset (called the *training set*) and validating the analysis on the other subset (called the *validation set*). To reduce variability, multiple rounds of cross-validation are performed using different partitions, and the validation results are averaged over the rounds [9, 17]. Each time, a fixed number of data out of D50 (and D40, D30 respectively) are used for model fitting. The remaining data are used to calculate the MSE in (12.9). Because CS gives much larger MSE in each case, only the MSE results for GC and BCS are reported. For D50, the results of training data size of 40 and 30 are plotted in Figs. 12.1 and 12.2. In each figure, one dot indicates the MSE from GC versus the MSE from BCS for a given design. The reference line of 45° indicates that the two designs are equally good since they render the same MSE. When the majority of the dots are below the line, it means BCS has smaller MSE. This is evident in Fig. 12.2. GC gives some very bad predictions with MSE as high as 5.5 (dots in the right bottom of Fig. 12.2), while the majority of MSE of BCS center around 1.5. The average of MSE from 100 simulations for each cross-validation

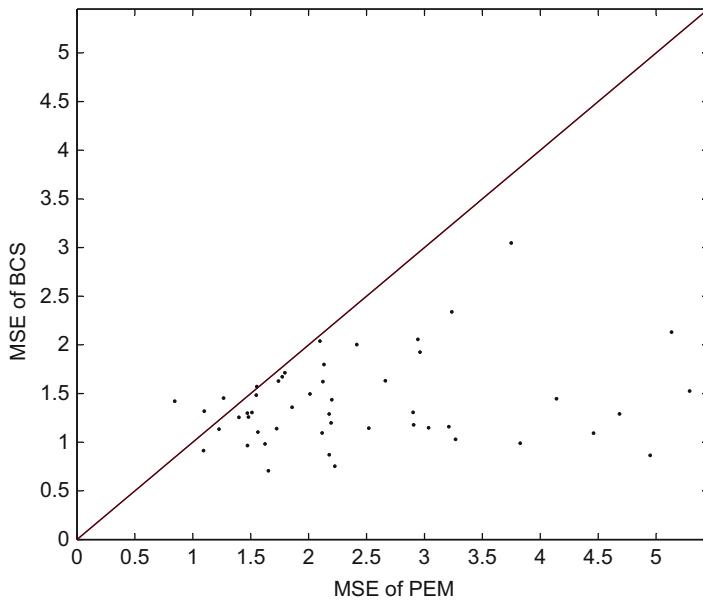

Fig. 12.2 MSE of 30 training data in D50

Table 12.7 Comparison of GC and BCS

Design	Training Data Size	MSE(GC)	MSE(BCS)	% Improvement
D50	40	0.6237	0.6524	-4.6
D50	30	2.4980	1.3908	44.3
D40	30	0.8812	0.7132	19.1
D40	25	2.8516	1.5590	45.3
D30	25	1.6108	0.7888	51.0
D30	20	1.9498	1.2729	34.7

setting for BCS and GC and the percentage of BCS outperforming GC are given in Table 12.7. There is a relatively larger difference between GC and BCS when the training data size is relatively small (20 for D30, 25 for D30, and 30 for D50). This is probably caused by the global prediction and over-smoothing properties of GC. There is no systematic pattern in the percent improvement figures, possibly due to the small number of simulations.

6 Conclusions

The cubic spline is widely used in numerical approximation. In GP modeling, the use of the cubic spline correlation function in (12.3) can lead to a sparse correlation matrix with many zero off-diagonal elements. By comparison, the two commonly

used correlation functions, the Matérn family and the power exponential correlation, do not enjoy this property. A sparse correlation matrix can reduce the cost of computation and enhance its stability. The viability of cubic spline for computer experiment applications received a further boost when JMP 8.0.2 2010 (and its update 11.1.1 2014) provided the power exponential correlation and the cubic spline correlation as its *only* two choices in GP modeling. The prominence that JMP gives to the cubic spline was one motivation for us to develop a Bayesian version of the cubic spline method. By putting a prior on the parameters in the cubic spline correlation function in (12.3), Bayesian computation can be performed by using MCMC. The Bayesian cubic spline should outperform its frequentist counterpart because of its smoothness and shrinkage properties. It also provides posterior estimates, which enable statistical inference on the parameters of interest.

In this chapter, a comparison of BCS with CS and GC is performed in three simulation examples and application to real data. Other correlation functions with compact support have also been considered, such as those from the spherical family:

$$R(d) = \begin{cases} 1 - \frac{3|d|}{2\theta} + \frac{1}{2}\left(\frac{|d|}{\theta}\right)^3, & \text{if } |d| \leq \theta, \\ 0, & \text{if } |d| > \theta. \end{cases}$$

Because the performance of the frequentist version of the spherical family is similar to that of the cubic spline, these results are omitted in the chapter. In the three simulation examples, BCS outperforms CS in most cases. GC performs the best when the true function is smooth or the data size is large. BCS and CS perform better than GC when the true function is rugged and the data size is relatively small. This difference in performance can be explained by the local prediction property of BCS and CS and the global prediction property of GC. Recall that, in global prediction, the prediction at any location is influenced by far-away locations (though with less weights). This leads to over-smoothing, which is not good for a rugged surface. Local prediction does not suffer from this as the prediction depends only on nearby locations. In the real data application, BCS outperforms GC in most choices of design. In summary, when the response surface is non-smooth and/or the input dimension is high, the BCS method can have potential advantages and should be considered for adoption in data analysis.

There are other methods that also attempt to balance between local and global prediction. See, for examples, Kaufman et al. [16] and Gramacy and Apley [12], although the main purpose of these two papers was to leverage sparsity to build emulators for large computer experiments. Comparisons of our proposed method with these and other methods in the literature will require a separate study, and it lies outside our original scope of comparing the Bayesian and the frequentist methods for cubic spline.

Some issues need to be considered in future work. When the dimension is high, the parameter estimation is based on the MH sampling which can be costly. Grouping parameters to reduce computation is an alternative. Also, only non-

informative priors were considered in this chapter. If more information is available, informative prior assignments should be considered.

Propagation of Stochasticity in Heterogeneous Media and Applications to Uncertainty Quantification

13

Guillaume Bal

Abstract

This chapter reviews several results on the derivation of asymptotic models for solutions to partial differential equations (PDE) with highly oscillatory random coefficients. We primarily consider elliptic models with random diffusion or random potential terms. In the regime of small correlation length of the random coefficients, the solution may be described either as the sum of a leading, deterministic, term, and random fluctuations, whose macroscopic law is described, or as a random solution of a stochastic partial differential equation (SPDE). Several models for such random fluctuations or SPDEs are reviewed here.

The second part of the chapter focuses on potential applications of such macroscopic models to uncertainty quantification and effective medium models. The main advantage of macroscopic models, when they are available, is that the small correlation length parameter no longer appears. Highly oscillatory coefficients are typically replaced by (additive or multiplicative) white noise or fractional white noise forcing. Quantification of uncertainties, such as, for instance, the probability that a certain function of the PDE solution exceeds a certain threshold, then sometimes takes an explicit, solvable, form. In most cases, however, the propagation of stochasticity from the random forcing to the PDE solution needs to be estimated numerically. Since (fractional) white noise oscillates at all scales (as a fractal object), its numerical discretization involves a large number of random degrees of freedom, which renders accurate computations extremely expensive. Some remarks on a coupled polynomial chaos – Monte Carlo framework and related concentration (Efron-Stein) inequalities to numerically solve problems with small-scale randomness conclude this chapter.

1 Introduction

Consider a problem modeled by a partial differential equation of the form

$$L([q], x, u) = 0, \quad x \in X \subset \mathbb{R}^d, \quad (13.1)$$

where L is a polynomial in u and its partial derivatives involving a set of parameters $[q]$. When $[q]$ is not known precisely, it may prove useful to model it as a random object, whose statistics are hopefully reasonably well understood. The stochasticity in $[q]$ then propagates to the solution u by means of the constraint (13.1). Decomposing the random variable $[q]$ in a basis of orthogonal polynomials for a measure describing randomness, we can invoke, for instance, the theory of polynomial chaos expansions (PCE), to obtain and numerically compute the decomposition of the random solution u in that basis. The reader is referred to articles in this handbook for an extensive list of presentations and examples.

A major computational difficulty with PCE is that the dimension of the problem is mainly that of the number of degrees of freedom required to represent the random object $[q]$. On a large (spatial or spatio-temporal) domain, that number often proves so overwhelming that direct computations are not feasible. On the other hand, in many situations, an accurate calculation of this propagation of stochasticity may not be necessary. Indeed, the solution u may often be described at a macroscopic scale at which the fine-scale structure of the parameter $[q]$ has been *averaged*. A typical setting for such an averaging process is that of homogenization theory. What we learn from such a theory is that the rapid fluctuations of $[q]$ asymptotically have an *effective* influence on u , essentially by an application of the law of large numbers.

The residual stochasticity in u coming from such rapid fluctuations is then expected to appear as a correction to the law of large numbers, for instance, as an application of a central limit result.

These remarks lead us to the modified modeling of (13.1) given by

$$L([q_0], [q_\varepsilon], x, u_\varepsilon) = 0, \quad x \in X \subset \mathbb{R}^d, \quad (13.2)$$

where $\varepsilon \ll 1$ is a small parameter, $[q_0]$ now represents the low-frequency part of $[q]$ that may be treated numerically by a PCE method, and $[q_\varepsilon]$ is the high-frequency (frequencies larger than $O(\varepsilon^{-1})$) component of $[q]$ whose influence cannot be estimated precisely numerically. The choice of ε is typically driven by computational issues: the number of degrees of freedom characterizing $[q_0]$ is as large as can be computationally managed. It remains to address the influence of $[q_\varepsilon]$, which here we propose to treat asymptotically as $\varepsilon \rightarrow 0$.

As compelling as this program may be, it remains to analyze the asymptotic propagation of stochasticity from the rapidly oscillating coefficients $[q_\varepsilon]$ to the solution u_ε . Unfortunately, the residual stochasticity in u_ε is well understood only for a small class of models. The objective of this contribution is to review the results that have been obtained for some of these models and to stress their applications in uncertainty quantification.

The next section considers elliptic equations of the form $-\nabla \cdot a_\varepsilon \nabla u_\varepsilon = f$ on a domain in \mathbb{R}^d with appropriate boundary conditions. The theory of propagation of stochasticity is well understood in dimension $d = 1$, with current research rapidly shedding light on the higher-dimensional cases. In the subsequent section, we consider equations of the form $P u_\varepsilon + q_\varepsilon u_\varepsilon = 0$ with P typically a (linear) elliptic or parabolic operator. For such models, more is known. As will become clear in the sequel, the propagation of stochasticity critically depends on the random structure of the potential q_ε . The presentation follows in the review paper [9], to which we refer the reader for additional details. The last sections concern the applications of such asymptotic results and their derivation to the field of effective medium models and uncertainty quantification.

2 Propagation of Stochasticity for Elliptic Equations

Consider the elliptic equation

$$\begin{aligned} -\nabla \cdot a\left(\frac{x}{\varepsilon}, \omega\right) \nabla u_\varepsilon &= f, \quad x \in X \subset \mathbb{R}^d \\ u &= g, \quad x \in \partial X, \end{aligned} \quad (13.3)$$

with $a(y, \omega)$ a stationary ergodic random field bounded above and below by positive constants. It is then known that u_ε converges strongly, e.g., in the L^2 sense, to a deterministic, homogenized limit u^* satisfying the same equation as above with a replaced by an effective, deterministic, constant, diffusion tensor a^* ; see, e.g., [29, 31, 33].

As we mentioned earlier, the appearance of this effective tensor may be seen as an application of the law of large numbers. The residual fluctuations in u_ε thus need to be found in the corrections to the homogenized limit u^* . In dimension $d \geq 2$, significantly less is known on the asymptotic structure of $u_\varepsilon - u^*$ than in the much simpler setting with $d = 1$, which we consider first.

2.1 Asymptotic Random Fluctuations in One Dimension

Let us define $a_\varepsilon(x, \omega) = a(\frac{x}{\varepsilon}, \omega)$. When $d = 1$, the above elliptic equation takes the form

$$-\frac{d}{dx} \left(a_\varepsilon(x, \omega) \frac{d}{dx} u_\varepsilon \right) = f(x) \quad \text{in } (0, 1), \quad u_\varepsilon(0, \omega) = 0, \quad u_\varepsilon(1, \omega) = g. \quad (13.4)$$

Here, $a(x, \omega)$ is a stationary ergodic random process satisfying the ellipticity condition $0 < \alpha_0 \leq a(x, \omega) \leq \alpha_0^{-1}$ a.e. for $(x, \omega) \in \mathbb{R} \times \Omega$ where $(\Omega, \mathcal{F}, \mathbb{P})$ is an abstract probability space.

With $F(x) = \int_0^x f(y) dy$, the solution is written using *explicit integrals* of the random coefficient a :

$$u_\varepsilon(x, \omega) = \int_0^x \frac{c_\varepsilon(\omega) - F(y)}{a_\varepsilon(y, \omega)} dy, \quad c_\varepsilon(\omega) = \frac{g + \int_0^1 \frac{F(y)}{a_\varepsilon(y, \omega)} dy}{\int_0^1 \frac{1}{a_\varepsilon(y, \omega)} dy}. \quad (13.5)$$

The stochasticity of u_ε is explicitly characterized by integrals of the random process $a_\varepsilon^{-1}(y, \omega)$. As an application of the law of large numbers, we obtain that u_ε converges strongly in $L^2((0, 1) \times \Omega)$ to its deterministic limit u^* solution of

$$-\frac{d}{dx} \left(a^* \frac{d}{dx} u^* \right) = f(x) \quad \text{in } (0, 1), \quad u^*(0, \omega) = 0, \quad u^*(1, \omega) = g, \quad (13.6)$$

with $a^* = (\mathbb{E}\{a^{-1}(0, \cdot)\})^{-1}$ the harmonic mean of $a(0, \cdot)$. We also have the explicit expression

$$u^*(x) = \int_0^x \frac{c^* - F(y)}{a^*} dy, \quad c^* = ga^* + \int_0^1 F(y) dy. \quad (13.7)$$

The residual stochasticity captured by $u_\varepsilon - u^*$ now depends on the statistical properties of a or equivalently those of $\varphi(x, \omega) := \frac{1}{a(x, \omega)} - \frac{1}{a^*}$. Let R be the correlation function of the stationary random process φ :

$$R(x) = \mathbb{E}\{\varphi(0)\varphi(x)\}. \quad (13.8)$$

The stochastic structure of u_ε strongly depends on the behavior of $R(x)$ as $x \rightarrow \infty$. When $R(x)$ is integrable, then a central limit theory applies. Define $\sigma^2 := \int_{-\infty}^{\infty} R(y)dy > 0$. Then under the additional constraint that φ is strongly mixing, it was shown in [14] that $u_\varepsilon - u^*$ had a variance of order ε and more precisely converged to a Gaussian process after appropriate rescaling:

$$\frac{u_\varepsilon - u^*}{\sqrt{\varepsilon}}(x) \xrightarrow{\varepsilon \rightarrow 0} \sigma \int_0^1 K(x, y)dW_y, \quad (13.9)$$

where $W(y)$ is Brownian motion on $(0, 1)$ and

$$K(x, y) = (\mathbf{1}_{[0,x]}(y) - x)(c^* - F(y)).$$

The above convergence holds in distribution in the space of continuous functions $C[0, 1]$ and may be seen as a functional central limit theorem. When R is integrable, we thus obtain the limit u^* as an application of the law of large numbers and the asymptotic behavior of the random fluctuations $u_\varepsilon - u^*$ beyond homogenization as an application of a central limit.

When $R(x)$ is not integrable, the random variables that are summed in (13.5) are too strongly correlated for the central limit to hold. In some situations, a limiting behavior for $u_\varepsilon - u^*$ can still be obtained. Let us assume that

$$\varphi(x) = \Phi(g_x) \quad (13.10)$$

where g_x is a stationary Gaussian process with mean zero and variance one and Φ is a bounded function such that

$$\begin{aligned} V_0 &= \mathbb{E}\{\Phi(g_0)\} = \int \Phi(g) \frac{e^{-\frac{g^2}{2}}}{\sqrt{2\pi}} dg = 0, \\ V_1 &= \mathbb{E}\{g_0 \Phi(g_0)\} = \int g \Phi(g) \frac{e^{-\frac{g^2}{2}}}{\sqrt{2\pi}} dg > 0. \end{aligned} \quad (13.11)$$

We assume that the correlation function of g :

$$R_g(y) = \mathbb{E}\{g_x g_{x+y}\},$$

decays slowly and is of the form

$$R_g(y) \sim \kappa_g y^{-\alpha} \text{ as } y \rightarrow \infty, \quad (13.12)$$

where $\kappa_g > 0$ and $\alpha \in (0, 1)$. Then we can show [7] that

$$R(y) := \mathbb{E}\{\varphi(x)\varphi(x + y)\} \sim \kappa y^{-\alpha} \text{ as } y \rightarrow \infty \quad \text{with } \kappa = \kappa_g V_1^2. \quad (13.13)$$

We observe that $R(y)$ is no longer integrable. In this setting, we obtain [7] that

$$\frac{u^\varepsilon(x) - u^*(x)}{\varepsilon^{\frac{\alpha}{2}}} \xrightarrow{\varepsilon \rightarrow 0} \sqrt{\frac{\kappa}{H(2H-1)}} \int_{\mathbb{R}} K(x, y) dW_y^H, \quad (13.14)$$

in the space of continuous functions $\mathcal{C}[0, 1]$, where $K(x, y)$ is as above and W_y^H is a fractional Brownian motion with Hurst index $H = 1 - \frac{\alpha}{2}$.

We thus observe that the random fluctuations are of variance $\varepsilon^\alpha \gg \varepsilon$, which is larger than in the case of an integrable correlation function and in fact could be arbitrarily close to $\varepsilon^0 = 1$. Moreover, they are conveniently represented as a stochastic integral with respect to a fractional Brownian motion such that the correlation function of dW_y^H also decays like $y^{-\alpha}$ as $y \rightarrow \infty$.

Note that $\kappa = 0$ when $V_1 = 0$. In such a case, we can also sometimes exhibit a limit for $u_\varepsilon - u^*$, which is no longer Gaussian. Let us assume that $V_0 = V_1 = 0$ and that

$$V_2 = \mathbb{E}\{g_0^2 \Phi(g_0)\} = \int g^2 \Phi(g) \frac{e^{-\frac{g^2}{2}}}{\sqrt{2\pi}} dg > 0, \quad (13.15)$$

in other words, Φ is of Hermite rank 2. Defining $\beta = 2\alpha$, we then observe for $\alpha \in (0, \frac{1}{2})$ [26] that

$$R(y) := \mathbb{E}\{\varphi(x)\varphi(x+y)\} \sim \kappa y^{-\beta} \text{ as } y \rightarrow \infty \quad \text{with } \kappa = \frac{1}{2} \kappa_g^2 V_2^2, \quad (13.16)$$

and obtain the convergence result

$$\frac{u^\varepsilon(x) - u^*(x)}{\varepsilon^{\frac{\beta}{2}}} \xrightarrow{\varepsilon \rightarrow 0} \frac{V_2 \kappa_g}{2} \int_{\mathbb{R}} K(x, y) dR_D(y), \quad (13.17)$$

in the space of continuous functions $\mathcal{C}[0, 1]$, where $K(x, y)$ is as above and $R_D(y)$ is a Rosenblatt process with $D = \frac{\beta}{2} = \alpha$ [36]. The result holds for $\beta \in (0, 1)$ and thus mimics that obtained in (13.14) with a fractional Brownian motion replaced by a non-Gaussian Rosenblatt process.

2.2 Large Deviations in One Dimension

For small enough ε , the homogenized solution u^* captures the bulk of the solution u_ε . The corrector attempts to capture some statistics of the term $u_\varepsilon - u^*$. The above corrector result for integrable correlation R shows that for any $\ell > 0$

$$\mathbb{P}\left[\frac{u_\varepsilon(x) - u^*(x)}{\sqrt{\varepsilon}} \geq \ell\right] \xrightarrow{\varepsilon \rightarrow 0} \mathbb{P}\left[v := \sigma \int_0^1 K(x, y) dW_y \geq \ell\right]. \quad (13.18)$$

More generally, we may ask whether

$$\mathbb{P}[u_\varepsilon(x) \geq \ell] \approx \mathbb{P}[u^*(x) + \sqrt{\varepsilon} v \geq \ell]. \quad (13.19)$$

The answer to the above question is in general negative for $u^*(x) < \ell = O(1)$. This review follows the presentation in [8], to which the reader is referred for additional details, and presents some relevant results in the analysis of (13.19). Let us first recall a few definitions.

Definition 1 (Rate functions). A *rate function* I is a lower semicontinuous mapping (such that for all $\alpha \in [0, \infty)$, the sublevel set $\Psi_I(\alpha) := \{x, I(x) \leq \alpha\}$ is closed) $I : \mathbb{R}^n \rightarrow [0, \infty]$. A *good rate function* is a rate function for which all the sublevel sets $\Psi_I(\alpha)$ are compact.

Definition 2. We say that a family of random vectors $Y_\varepsilon \in \mathbb{R}^n$ satisfy a large deviation principle (LDP) with rate function I if for all $\Gamma \subset \mathbb{R}^n$

$$-\inf_{y \in \Gamma^\circ} I(y) \leq \liminf_{\varepsilon \rightarrow 0} \varepsilon \log P[Y_\varepsilon \in \Gamma] \leq \limsup_{\varepsilon \rightarrow 0} \varepsilon \log P[Y_\varepsilon \in \Gamma] \leq -\inf_{y \in \bar{\Gamma}} I(y).$$

Above, Γ° , $\bar{\Gamma}$ denote the interior and closure of Γ .

Rather than directly analyzing (13.19), we consider the simpler limit for $\ell > \mathbb{E}\{u_\varepsilon\}$:

$$\lim_{\varepsilon \rightarrow 0} \varepsilon \log \mathbb{P}[u_\varepsilon > \ell] = -I_{u_\varepsilon}(\ell) \quad (13.20)$$

assuming such a limit exists. Note that such a limit implies that for all $\delta > 0$ and $\varepsilon < \varepsilon_0(\delta)$, we have

$$e^{-\frac{1}{\varepsilon}(I_{u_\varepsilon}(\ell)+\delta)} \leq \mathbb{P}[u_\varepsilon > \ell] \leq e^{-\frac{1}{\varepsilon}(I_{u_\varepsilon}(\ell)-\delta)}.$$

In $\dim d = 1$, we verify from the explicit above formulas that the solution $u_\varepsilon(x) = g(Z_\varepsilon)$ for $g(z_1, \dots, z_4) = -z_1 + z_2 z_3 z_4^{-1}$ and

$$Z_{\varepsilon,j} = \int_0^1 \frac{H_j(s)}{a_\varepsilon(s)} ds, \quad \mathbf{H} := (H_1, \dots, H_4) = (f 1_{(0,x)}, f, 1_{(0,x)}, 1). \quad (13.21)$$

Let us now describe the main steps of the process leading to a characterization of the rate function $I_{u_\varepsilon}(\ell)$ and first recall two results.

Theorem 1 (Gärtner-Ellis [19]). Suppose

$$\Lambda(\lambda) := \lim_{\varepsilon \rightarrow 0} \varepsilon \log \mathbb{E} e^{\varepsilon^{-1} \lambda \cdot Z_\varepsilon}$$

exists as an extended real number. Furthermore suppose that Λ is essentially smooth, lower semicontinuous and that the origin belongs to the interior of $\mathcal{D}_\Lambda := \{x : \Lambda(x) < \infty\}$. Then Z_ε satisfies an LDP with good convex rate function Λ^* defined by

$$\Lambda^*(\ell) := \sup_{\lambda \in \mathbb{R}^n} [\lambda \cdot \ell - \Lambda(\lambda)].$$

The above theorem allows us to characterize the rate function I_{Z_ε} of the oscillatory integrals in (13.21). From this, we deduce the rate function of I_{u_ε} by means of the following contraction principle:

Theorem 2 (Contraction principle). Suppose $f : \mathbb{R}^n \rightarrow \mathbb{R}^m$ is continuous and $I : \mathbb{R}^n \rightarrow [0, \infty]$ is a good rate function for the family of random variables Z_ε and associated measures μ_ε ($\mu_\varepsilon(A) = P[Z_\varepsilon \in A]$). For $y \in \mathbb{R}^m$, define

$$I'(y) := \inf\{I(x) \text{ s.t. } x \in \mathbb{R}^n, y = f(x)\}.$$

Then I' is a good rate function controlling the LDP associated with the measures $\mu_\varepsilon \circ f^{-1}$ ($\mu_\varepsilon \circ f^{-1}(B) = P[f(Z_\varepsilon) \in B]$).

In other words, the rate function for u_ε is given by

$$I_{u_\varepsilon}(\ell) = \inf_{z \in g^{-1}\{\ell\}} I_{Z_\varepsilon}(z).$$

It thus remains to obtain a characterization of the rate function of Z_ε . Such a characterization is not straightforward and has been carried out in [8] for a few examples of random media.

Consider (13.4) with $a_\varepsilon(x, \omega) = a_0(x) + b(\frac{x}{\varepsilon}, \omega)$, with $a_0(x)$, as a slight generalization of the coefficients consider so far, allowed to depend on x . The formulas in (13.5) still hold. We assume that

$$b(y, \omega) = v_b \sum_{j=1}^{\infty} \theta_j \mathbf{1}_{[n-1, n)}(y), \quad \theta_i \sim_{i.i.d.} \pi_\theta, \quad |\theta| < 1.$$

Here, a_0 and v_b are chosen so that $0 < v_1 < a_\varepsilon(x, \omega) < v_2$. For a random variable Y , we define the logarithmic moment generating function

$$\mathcal{L}(Y, \lambda) := \log \mathbb{E}[e^{\lambda Y}].$$

Then we have the following result: [8]

Theorem 3. *With g , Z_ε , and $\mathbf{H}(s)$, given as above, define*

$$\Lambda(\lambda) := \int_0^1 \mathcal{L}\left(\frac{1}{a_0(s) + v_b \theta}, \lambda \cdot \mathbf{H}(s)\right) ds.$$

Then $\Lambda \in C^\infty(\mathbb{R}^4)$ is a convex function such that when a_ε is defined as above,

$$\lim_{\varepsilon \rightarrow 0} \varepsilon \log \mathbb{E} e^{\varepsilon^{-1} \lambda \cdot Z_\varepsilon} = \Lambda(\lambda).$$

Moreover, for fixed ξ , Z_ε satisfies a large deviation principle with good convex rate function

$$\Lambda^*(\ell) := \sup_{\lambda \in \mathbb{R}^4} [\lambda \cdot \ell - \Lambda(\lambda)],$$

and u_ε satisfies a large deviation principle with good rate function

$$I_{u_\varepsilon}(\ell) := \inf_{z \in g^{-1}\{\ell\}} \Lambda^*(z).$$

The above example and further examples presented in [8] show that a large deviation principle may be obtained for u_ε and asymptotically characterize the probability $\mathbb{P}[u_\varepsilon > \ell]$. However, the derivation of such a rate function is not straightforward and depends on the whole law of the random coefficient a_ε and not only its correlation function as in the application of central limit results.

2.3 Some Remarks on the Higher-Dimensional Case

The above results strongly exploit the integral representation (13.5), which is only available in the one-dimensional setting. Fewer results exist for the higher-dimensional problem, concerning the propagation of stochasticity from $a_\varepsilon(x, \omega) = a(\frac{x}{\varepsilon}, \omega)$ to u_ε in the elliptic equation $-\nabla \cdot a_\varepsilon \nabla u_\varepsilon = f$ on $X \subset \mathbb{R}^d$, augmented with, say, Dirichlet conditions on ∂X .

As we already indicated, homogenization theory states that u_ε converges to a deterministic solution u^* when the diffusion coefficient $a(x, \omega)$ is a stationary, ergodic (bounded above and below by positive constants) function [29, 31, 33]. Homogenization is obtained by introducing a (vector-valued) corrector χ_ε such that $v_\varepsilon := u_\varepsilon - u^* - \varepsilon \chi_\varepsilon \cdot \nabla u^*$ converges to 0 in the strong H^1 sense. In the periodic setting and away from boundaries, $\varepsilon \chi_\varepsilon \cdot \nabla u^*$ also captures the main contribution of the fluctuations $u_\varepsilon - u^*$ with $v_\varepsilon = o(\varepsilon)$ in the L^2 sense [11]. In the random setting, such results no longer hold. It remains true that v_ε converges to 0 in the H^1 sense, but it is no longer necessary of order $O(\varepsilon)$ in the L^2 sense, as may be observed

in the one-dimensional setting. Moreover, $\varepsilon \chi_\varepsilon \cdot \nabla u^*$ may no longer be the main contribution to the error $u_\varepsilon - u^*$, as shown in, e.g., [27].

Concerning the random fluctuations $u_\varepsilon - u^*$, Yurinskii [37] gave the first statistical error estimate, a nonoptimal rate of convergence to homogenization. Recent results, borrowing from (Naddaf, A., Spencer, T.: Estimates on the variance of some homogenization problems. Unpublished Manuscript, 1998), provide optimal rates of convergence of u_ε to its deterministic limit [23–25] in the discrete and continuous settings for random coefficients with short range (heuristically corresponding to a correlation function R with compact support). In [1, 16], rates of convergence for fully nonlinear equations are also provided.

The limiting law of the random fluctuations $u_\varepsilon - \mathbb{E}\{u_\varepsilon\}$ is the object of current active research. Using central limit results of [17], it was shown in [32] that the (normalized) fluctuations of certain functionals of u_ε were indeed Gaussian. Central limit results for the effective conductance have been obtained in [12] in the setting of small conductance contrast and using a martingale CLT method. Convergence of the random fluctuations $u_\varepsilon - \mathbb{E}\{u_\varepsilon\}$ was obtained in the discrete setting in [27].

Rather than describing in detail the results obtained in this rapidly evolving field, we consider in the following section a simpler multidimensional problem with a random (zeroth-order) potential for which a more complete theory is available. We come back to the above elliptic problem briefly in the section devoted to the applications to uncertainty quantifications.

3 Equations with a Random Potential

3.1 Perturbation Theory for Bounded Random Potentials

In this section, we consider linear equations with a random potential of the form

$$P(x, D)u_\varepsilon + q_\varepsilon u_\varepsilon = f, \quad x \in X \tag{13.22}$$

with $u_\varepsilon = 0$ on ∂X , where $P(x, D)$ is a deterministic self-adjoint, elliptic, differential operator and X an open-bounded domain in \mathbb{R}^d . Here, $q_\varepsilon(x, \omega) = q(\frac{x}{\varepsilon}, \omega)$ with q a bounded function. When q defined on $(\Omega, \mathcal{F}, \mathbb{P})$ is ergodic and stationary, its high oscillations ensure that it has a limited influence on u_ε . Define u the solution to

$$P(x, D)u = f, \quad x \in X, \quad u = 0 \text{ on } \partial X, \tag{13.23}$$

which we assume is unique and is defined as

$$u(x) = \mathcal{G}f(x) := \int_X G(x, y)f(y)dy, \tag{13.24}$$

for a Schwartz kernel $G(x, y)$, which we assume is nonnegative, real valued, and symmetric so that $G(x, y) = G(y, x)$.

Then u_ε converges, for instance, in $L^2(X \times \Omega)$, to the unperturbed solution u . We are next interested in a macroscopic characterization of the fluctuations $u_\varepsilon - u$. These fluctuations may be decomposed into the superposition of a deterministic corrector $\mathbb{E}\{u_\varepsilon\} - u$ and the random fluctuations $u_\varepsilon - \mathbb{E}\{u_\varepsilon\}$. The latter contribution dominates when the Green's function $G(x, y)$ is a little more than square integrable in the sense that

$$C_\eta := \sup_{x \in X} \left(\int_X |G(x, y)|^{2+\eta} dy \right)^{\frac{1}{2+\eta}} < \infty \quad \text{for some } \eta > 0. \quad (13.25)$$

The above constraint is satisfied for $P(x, D) = -\nabla \cdot a(x)\nabla + \sigma(x)$ for $a(x)$ bounded and coercive and $\sigma(x) \geq 0$ bounded in dimension $d \leq 3$.

Under sufficient conditions on the decorrelation properties of $q(x, \omega)$, we obtain that $u_\varepsilon - u$ is well approximated by a central limit theory as in the preceding section. We describe the results obtained in [2]; see also [21]. The main idea is to decompose $u_\varepsilon - u$ as a sum of stochastic integrals that can be analyzed explicitly as in the one-dimensional case and negligible higher-order terms. We now present some details of the derivation of such a decomposition.

We define $\tilde{q}_\varepsilon(\mathbf{x}, \omega) = q(\frac{\mathbf{x}}{\varepsilon}, \omega)$, where $q(\mathbf{x}, \omega)$ is a mean zero, strictly stationary, process defined on an abstract probability space $(\Omega, \mathcal{F}, \mathbb{P})$ [15]. We assume that $q(\mathbf{x}, \omega)$ has an integrable correlation function $R(x) = \mathbb{E}\{q(0)q(x)\}$. We also assume that $q(x, \omega)$ is strongly mixing in the following sense. For two Borel sets $A, B \subset \mathbb{R}^d$, we denote by \mathcal{F}_A and \mathcal{F}_B the sub- σ algebras of \mathcal{F} generated by the field $q(x, \omega)$ for $x \in A$ and $x \in B$, respectively. Then we assume the existence of a $(\rho-)$ mixing coefficient $\varphi(r)$ such that

$$\left| \frac{\mathbb{E}\{(\eta - \mathbb{E}\{\eta\})(\xi - \mathbb{E}\{\xi\})\}}{(\mathbb{E}\{\eta^2\}\mathbb{E}\{\xi^2\})^{\frac{1}{2}}} \right| \leq \varphi(d(A, B)) \quad (13.26)$$

for all (real-valued) square integrable random variables η on $(\Omega, \mathcal{F}_A, \mathbb{P})$ and ξ on $(\Omega, \mathcal{F}_B, \mathbb{P})$. Here, $d(A, B)$ is the Euclidean distance between the Borel sets A and B . We then assume that $\varphi^{\frac{1}{2}}(r)$ is bounded and $r^{d-1}\varphi^{\frac{1}{2}}(r)$ is integrable on \mathbb{R}^+ . We also assume that $q(x, \omega)$ is finite ($dx \times \mathbb{P}$)-a.s. and that $\mathbb{E}\{q^6(0, \cdot)\}$ is bounded. This results allows us to show [2, Lemma 3.2] that

$$\mathbb{E}\{\|\mathcal{G}\tilde{q}_\varepsilon \mathcal{G}\tilde{q}_\varepsilon\|_{\mathcal{L}(L^2(X))}^2\} \leq C\varepsilon^d. \quad (13.27)$$

The equation for u_ε may be formally recast as

$$u_\varepsilon = \mathcal{G}f - \mathcal{G}q_\varepsilon \mathcal{G}f + \mathcal{G}q_\varepsilon \mathcal{G}q_\varepsilon u_\varepsilon. \quad (13.28)$$

The above equation may not be invertible for all realizations, even if \mathcal{G} is bounded. We are not interested in the analysis of such possible resonances here and thus modify the definition of our random field q_ε . Let $0 < \rho < 1$. We denote by $\Omega_\varepsilon \subset \Omega$ the set where $\|\mathcal{G}\tilde{q}_\varepsilon \mathcal{G}\tilde{q}_\varepsilon\|_{\mathcal{L}(L^2(X))}^2 > \rho$. We deduce from (13.27) that $\mathbb{P}(\Omega_\varepsilon) \leq C\varepsilon^d$. We thus modify \tilde{q}_ε as

$$q_\varepsilon(\cdot, \omega) = \begin{cases} \tilde{q}_\varepsilon(\cdot, \omega), & \omega \in \Omega \setminus \Omega_\varepsilon, \\ 0, & \omega \in \Omega_\varepsilon, \end{cases} \quad (13.29)$$

and now assume that the above q_ε is a reasonable representation of the physical heterogeneous potential. Note that the process q_ε is no longer necessarily stationary or ergodic. However, since the set of bad realizations Ω_ε is small, all subsequent calculations involving q_ε can be performed using \tilde{q}_ε up to a negligible correction. Now, almost surely, $\|\mathcal{G}q_\varepsilon \mathcal{G}q_\varepsilon\|_{\mathcal{L}(L^2(X))}^2 < \rho < 1$ and u_ε is well defined in $L^2(X)$ \mathbb{P} -a.s. Moreover, we observe that

$$(I - \mathcal{G}q_\varepsilon \mathcal{G}q_\varepsilon)(u_\varepsilon - u) = -\mathcal{G}q_\varepsilon \mathcal{G}f + \mathcal{G}q_\varepsilon \mathcal{G}q_\varepsilon \mathcal{G}f. \quad (13.30)$$

Since $\mathcal{G}q_\varepsilon \mathcal{G}q_\varepsilon$ is small thanks to (13.27), we verify that $\mathbb{E}\{\|\mathcal{G}q_\varepsilon \mathcal{G}q_\varepsilon(u_\varepsilon - u)\|\} \leq C\varepsilon^d$ is also small.

The analysis of $u_\varepsilon - u$ therefore boils down to that of $\mathcal{G}q_\varepsilon \mathcal{G}f$ and $\mathcal{G}q_\varepsilon \mathcal{G}q_\varepsilon \mathcal{G}f$, which are integrals of stochastic field q_ε of a similar nature to those obtained in the preceding section. When (13.25) holds, we obtain that the former term dominates the latter. It thus remains to analyze $\mathcal{G}q_\varepsilon u$, which up to a negligible contribution, is the same as $\mathcal{G}q(\cdot, \omega)u$. This integral may be analyzed as in the one-dimensional setting considered in the preceding section to obtain [2]:

Theorem 4. *Let q satisfy the hypotheses mentioned above. Then we have that*

$$\frac{u_\varepsilon - u}{\varepsilon^{\frac{d}{2}}}(x) \xrightarrow{\varepsilon \rightarrow 0} -\sigma \int_X G(x, y)u(y)dW_y, \quad (13.31)$$

in distribution weakly in space where $\sigma^2 = \int_{\mathbb{R}^d} \mathbb{E}\{q(0)q(x)\}dx < \infty$ and dW_y is a standard multiparameter Wiener measure on \mathbb{R}^d .

Convergence in distribution weakly in space means the following (see below Theorem 5 for a stronger convergence result). Let $\{M_j\}_{1 \leq j \leq J}$ be a finite family of sufficiently smooth functions and define $u_{1\varepsilon} = \varepsilon^{-\frac{d}{2}}(u_\varepsilon - u)$ and $\mathcal{N}(x)$ the right-hand side in (13.31). Then the random vector $(u_{1\varepsilon}, M_j)_{1 \leq j \leq J}$, where (\cdot, \cdot) is the usual inner product on $L^2(X)$, converges in distribution to its limit $(\mathcal{N}, M_j)_{1 \leq j \leq J}$.

When the Green's function $G(x, y)$ is not square integrable, then the deterministic corrector $\mathbb{E}\{u_\varepsilon\} - u$ may be of the same order as or larger than the random fluctuations $u_\varepsilon - \mathbb{E}\{u_\varepsilon\}$. Assuming that $\mathcal{G}q_\varepsilon \mathcal{G}q_\varepsilon$ can still be controlled, then Theorem 4 can be generalized to this setting under additional assumptions on the

random coefficient $q(x, \omega)$. We refer to [10] for such a theory when the operator P is the square root of the Laplacian, which finds applications in cell biology and the diffusion of molecules through heterogeneous membranes.

Assuming now that the random potential has a slowly decaying correlation function, we expect the random fluctuations $u_\varepsilon - u$ to be significantly larger. Let g_x be a stationary-centered Gaussian random field with unit variance and a correlation function that has a heavy tail

$$R_g(x) = \mathbb{E}\{g_0 g_x\} \sim \kappa_g |x|^{-\alpha} \quad \text{as } |x| \rightarrow \infty$$

for $\kappa_g > 0$ and some $0 < \alpha < d$. Let then $\Phi : \mathbb{R} \rightarrow \mathbb{R}$ bounded (and sufficiently small) so that

$$\mathbb{E}\{\Phi(g_0)\} = \int_{\mathbb{R}} \Phi(g) \frac{e^{-\frac{1}{2}g^2}}{\sqrt{2\pi}} dg = 0, \quad \kappa = \kappa_g (\mathbb{E}\{g_0 \Phi(g_0)\})^2 > 0.$$

We also assume that $\hat{\Phi}(\xi)$, the Fourier transform of Φ , decays sufficiently rapidly so that $\hat{\Phi}(\xi)(1 + |\xi|^3)$ is integrable. We also assume that the Green's function of the operator P satisfies $|G(x, y)| \leq C|x - y|^{-(d-\beta)}$ for some $\alpha < 4\beta$. This condition essentially ensures that the deterministic corrector $\mathbb{E}\{u_\varepsilon\} - u$ is smaller than the random fluctuations $u_\varepsilon - \mathbb{E}\{u_\varepsilon\}$. Let us assume that $V(x) = \Phi(g_x)$. Then Theorem 4 generalizes to the following result [6]:

Theorem 5. *With the aforementioned hypotheses on the operator P and random potential q , we obtain that*

$$\frac{u_\varepsilon - \mathbb{E}\{u_\varepsilon\}}{\varepsilon^{\frac{\alpha}{2}}} \xrightarrow{\varepsilon \rightarrow 0} - \int_X G(x, y) u(y) W^\alpha(dy), \quad (13.32)$$

in distribution weakly in space, where $W^\alpha(dy)$ is formally defined as $\dot{W}^\alpha(y)dy$ with $\dot{W}^\alpha(y)$ a centered Gaussian random field such that $\mathbb{E}\{\dot{W}^\alpha(x) \dot{W}^\alpha(y)\} = \kappa |x - y|^{-\alpha}$.

The above “weak in space” convergence may often be improved. Consider, for instance, the case of $P(x, D) = -\Delta + 1$ in dimension $d \leq 3$. Then we can show [6, Theorem 2.7] that $Y_\varepsilon := \varepsilon^{-\frac{\alpha}{2}}(u_\varepsilon - \mathbb{E}\{u_\varepsilon\})$ converges in distribution in the space of functions $L^2(X)$ to its limit Y given on the right-hand side of (13.32). This more precise statement means that for any continuous map f from $L^2(X)$ to \mathbb{R} , we have that

$$\mathbb{E}\{f(Y_\varepsilon)\} \xrightarrow{\varepsilon \rightarrow 0} \mathbb{E}\{f(Y)\}, \quad (13.33)$$

so that, for instance, the L^2 norm of Y_ε converges to that of Y . See [6] for some generalizations of the above convergence result.

3.2 Homogenization Theory for Large Random Potentials

In the preceding section, the elliptic problems involved a highly oscillatory potential q_ε satisfying bounds independent of ε . We saw that the limit of the random solution u_ε was given by the solution u obtained by replacing q_ε by its ensemble average. Such a centered potential is therefore not sufficiently strong to have an influence on the leading term u as $\varepsilon \rightarrow 0$.

In this and the following two sections, we consider the more strongly stochastic case where the potential is rescaled such that it has an influence of order $O(1)$ on the limit as $\varepsilon \rightarrow 0$, assuming the latter exists. In this section, we consider results obtained by a diagrammatic expansion method that converges only for Gaussian potentials q_ε . With this restriction in mind, consider the problem

$$\begin{aligned} \frac{\partial u_\varepsilon}{\partial t} + P(D)u_\varepsilon - \frac{1}{\varepsilon^\beta} q\left(\frac{x}{\varepsilon}\right)u_\varepsilon &= 0, \quad t \geq 0, \quad x \in \mathbb{R}^d \\ u_\varepsilon(0, x) &= u_0(x), \quad x \in \mathbb{R}^d, \end{aligned} \tag{13.34}$$

where $d \geq 1$ is spatial dimension, $P(D) = (-\Delta)^{\frac{m}{2}}$ for some $m > 0$, and $q(x)$ is a stationary-centered Gaussian field with correlation function $R(x) = \mathbb{E}\{q(0)q(x)\}$. We assume the initial condition u_0 sufficiently smooth, deterministic, and compactly supported.

The limit of u_ε and the natural choice of β depend on the decorrelation properties of q . When the correlation function of q decays sufficiently rapidly, then averaging effects are sufficiently efficient to imply that u_ε converges to a deterministic solution u . However, when the correlation function of q decays slowly, stochasticity persists in the limit, and u may be shown to be the solution of a stochastic partial differential equation with multiplicative noise. The threshold rate of decay of the correlation is as follows. Define the power spectrum of q as the Fourier transform (up to a factor $(2\pi)^d$) of the correlation function

$$(2\pi)^d \hat{R}(\xi) = \int_{\mathbb{R}^d} e^{-ix \cdot \xi} R(x) dx. \tag{13.35}$$

When it is finite, let us define

$$\rho := \int_{\mathbb{R}^d} \frac{\hat{R}(\xi)}{|\xi|^m} d\xi. \tag{13.36}$$

When the above quantity is finite, then u_ε converges to the deterministic solution of

$$\begin{aligned} \left(\frac{\partial}{\partial t} + P(D) - \rho \right) u(t, x) &= 0, \quad x \in \mathbb{R}^d, \quad t > 0, \\ u(0, x) &= u_0(x), \quad x \in \mathbb{R}^d. \end{aligned} \tag{13.37}$$

When the above integral diverges (because of the behavior of the integrand at $\xi = 0$), then u_ε converges to a stochastic limit described in (13.43) below.

In the case of convergence to a deterministic limit, we have the following result:

Theorem 6. *Let $m < d$ and $R(x)$ be an integrable function or a bounded function such that $R(x) \sim \kappa|x|^{-p}$ as $|x| \rightarrow \infty$ with $m < p < d$. Let us choose $\beta = \frac{m}{2}$.*

Let $T > 0$ sufficiently small. Then there exists a solution to (13.34) $u_\varepsilon(t) \in L^2(\Omega \times \mathbb{R}^d)$ uniformly in $0 < \varepsilon < \varepsilon_0$ for all $t \in [0, T]$. Moreover, let us assume that $\hat{R}(\xi)$ is of class $C^\gamma(\mathbb{R}^d)$ for some $0 < \gamma$ and let $u(t, x)$ be the unique solution in $L^2(\mathbb{R}^d)$ to (13.37). Then, we have the convergence result

$$\|u_\varepsilon(t) - u(t)\|_{L^2(\Omega \times \mathbb{R}^d)} \xrightarrow{\varepsilon \rightarrow 0} 0, \quad (13.38)$$

uniformly in $0 < t < T$.

More precise rates of convergence are given in [4, Theorem 1]. A similar result of convergence holds in the critical dimension $d = m$ with $R(x)$ integrable. In such a case, ε^β has to be chosen as $\varepsilon^{\frac{m}{2}} |\ln \varepsilon|^{\frac{1}{2}}$ [4]. The same method shows that for any choice of potential rescaling $\beta < \frac{m}{2}$, then ρ is replaced by $\varepsilon^{m-2\beta}\rho$ in (13.37) so that u_ε converges uniformly in time on compact intervals $(0, T)$ (with no restriction on T then) to the unperturbed solution u of (13.37) with ρ replaced by 0.

The residual stochasticity of u_ε can be computed explicitly in the diagrammatic expansion. Let us separate $u_\varepsilon - u$ as $u_\varepsilon - \mathbb{E}\{u_\varepsilon\}$ and $\mathbb{E}\{u_\varepsilon\} - u$. The latter contribution is a deterministic corrector, which could be larger than the random fluctuations. We refer to [4] for its size and how it may be computed. For the random fluctuations $u_\varepsilon - \mathbb{E}\{u_\varepsilon\}$, we have the following convergence result:

Theorem 7. *Under the hypotheses of Theorem 6 and defining $p := d$ when R is integrable, we have*

$$\frac{u_\varepsilon - \mathbb{E}\{u_\varepsilon\}}{\varepsilon^{\frac{p-m}{2}}} \xrightarrow{\varepsilon \rightarrow 0} u_1, \quad (13.39)$$

in distribution and weakly in space, where u_1 is the unique solution of the following stochastic partial differential equation (SPDE) with additive noise

$$\begin{aligned} \left(\frac{\partial}{\partial t} + P(D) - \rho \right) u_1(t, x) &= \sigma u \dot{W}, \quad x \in \mathbb{R}^d, \quad t > 0, \\ u_1(0, x) &= 0, \quad x \in \mathbb{R}^d, \end{aligned} \quad (13.40)$$

where σ is a constant and \dot{W} is a centered Gaussian random field such that

$$\begin{aligned} \sigma^2 &= \int_{\mathbb{R}^d} R(x) dx, & \mathbb{E}\{\dot{W}(x) \dot{W}(x+y)\} &= \delta(y), & p &= d \\ \sigma^2 &= (2\pi)^d \lim_{\xi \rightarrow 0} |\xi|^{d-p} \hat{R}(\xi), & \mathbb{E}\{\dot{W}(x) \dot{W}(x+y)\} &= c_p |y|^{-p}, & m < p < d. \end{aligned} \quad (13.41)$$

Here, we have defined the normalizing constant $c_{\mathfrak{p}} = \frac{\Gamma(\frac{\mathfrak{p}}{2})}{2^{d-\mathfrak{p}} \pi^{\frac{d}{2}} \Gamma(\frac{d-\mathfrak{p}}{2})}$.

The proof of these results may be found in [4] with some extensions in [5]. The convergence result in Theorem 6 was extended to the case of Schrödinger equations (with $\frac{\partial}{\partial t}$ replaced by $i \frac{\partial}{\partial t}$) to arbitrary times $0 < t < T < \infty$ in [39] using the unitarity of the unperturbed solution operator and the decomposition introduced in [20].

3.3 Convergence to Stochastic Limits for Long-Range Random Potentials

The behavior of u_ε is different when the correlation function decays slowly or when $d < \mathfrak{m}$. When \mathfrak{p} tends to \mathfrak{m} , we observe that the random fluctuations (13.39) become of order $O(1)$ and we thus expect the limit of u_ε , when it exists, to be stochastic.

Theorem 8. *Let either $\mathfrak{m} > d$ and $R(x)$ is an integrable function, in which case, we set $\mathfrak{p} = d$, or R is a bounded function such that $R(x) \sim \kappa|x|^{-\mathfrak{p}}$ as $|x| \rightarrow \infty$ with $0 < \mathfrak{p} < \mathfrak{m}$. Let us choose $\beta = \frac{\mathfrak{p}}{2}$.*

Then there exists a solution to (13.34) $u_\varepsilon(t) \in L^2(\Omega \times \mathbb{R}^d)$ uniformly in $0 < \varepsilon < \varepsilon_0$ and $t \in [0, T]$ for all $T > 0$. Moreover, we have the convergence result

$$u_\varepsilon \xrightarrow{\varepsilon \rightarrow 0} u, \quad (13.42)$$

in distribution and in the space of square integrable functions $L^2(\mathbb{R}^d)$, where u is the unique solution (in an appropriate dense subset of $L^2(\mathbb{R}^d \times \Omega)$ uniformly in time) of the following SPDE with multiplicative noise

$$\begin{aligned} \left(\frac{\partial}{\partial t} + P(D) \right) u(t, x) &= \sigma u \dot{W}, \quad x \in \mathbb{R}^d, \quad t > 0, \\ u(0, x) &= u_0(x), \quad x \in \mathbb{R}^d, \end{aligned} \quad (13.43)$$

where σ and \dot{W} are given in (13.41).

The derivation of the above result is presented in [3] with some extensions in [5]. In low dimensions $d < \mathfrak{m}$ and in arbitrary dimension $d \geq \mathfrak{m}$ when the correlation function decays sufficiently slowly that $0 < \mathfrak{p} < \mathfrak{m}$, we observe that the solution u_ε remains stochastic in the limit $\varepsilon \rightarrow 0$. Note that we are in a situation where the integral in (13.36) is infinite. A choice of $\beta = \frac{\mathfrak{m}}{2}$ would generate too large a random potential. Smaller, but with a heavier tail, potentials corresponding to $\beta = \frac{\mathfrak{p}}{2} < \frac{\mathfrak{m}}{2}$ generate an influence of order $O(1)$ on the (limiting) solution u . Any choice $\beta < \frac{\mathfrak{p}}{2}$ would again lead u_ε to converge (in the strong $L^2(\Omega \times \mathbb{R}^d)$ sense then) to the unperturbed solution u of (13.43) with $\sigma = 0$.

Note that it is not obvious that the (Stratonovich) product $u\dot{W}$ is defined *a priori*. \dot{W} is a distribution and as a consequence, u is also singular. It turns out that in order to make sense of a solution to (13.43), we need either a sufficiently low dimension d ensuring that $e^{-tP(D)}$ is an efficient smoothing operator or a sufficiently slow decay $p < m$ ensuring that \dot{W} with statistics recalled in (13.41) is sufficiently regular. When $d < m$ or $m < p$, then the product of the two distributions $u\dot{W}$ in (13.43) cannot be defined as a distribution. From a physical point of view, we may not need such SPDE models since u_ε then converges to the deterministic solution in (13.37) with its random fluctuations described by the well-defined SPDE with additive noise (13.40); see [18] for a general treatment and references to SPDEs.

As for the case of convergence to a deterministic solution, similar results may be obtained for the Schrödinger equation (with $\frac{\partial}{\partial t}$ above replaced by $i\frac{\partial}{\partial t}$); see [30, 38].

The results presented above extend to the setting of time-dependent Gaussian potentials

$$\begin{aligned} \frac{\partial u_\varepsilon}{\partial t} + P(D)u_\varepsilon - \frac{1}{\varepsilon^\beta} q\left(\frac{t}{\varepsilon^\gamma}, \frac{x}{\varepsilon}\right)u_\varepsilon = 0, & \quad t \geq 0, \quad x \in \mathbb{R}^d \\ u_\varepsilon(0, x) = u_0(x), & \quad x \in \mathbb{R}^d, \end{aligned} \quad (13.44)$$

with $0 \leq \gamma \leq m$ and β now chosen as a function of the correlation properties of q , γ , and m . When $\gamma \geq m$, then the temporal fluctuations dominate the spatial fluctuations, and β should be chosen as $\beta = \frac{\gamma}{2}$ when q is sufficiently mixing; see, for instance, [35] when $m = 2$ in one dimension of space for a general mixing coefficient q .

When $0 \leq \gamma \leq m$, then both the spatial and temporal fluctuations of V contribute to the stochasticity of the solution u_ε . Let us define $R(t, x) = \mathbb{E}\{q(s, y)s(s+t, y+x)\}$ the correlation function of q and assume the decay properties

$$R(t, x) \sim \frac{\kappa}{|x|^p t^\beta} \quad \text{as } |x|, t \rightarrow \infty.$$

We restrict ourselves to the setting $0 < \beta < 1$ and $0 < p < d$ with formally $\beta = 1$ when R is integrable in time (uniformly in space) and $p = d$ when R is integrable in space (uniformly in time). Then when p and β are sufficiently small, we again obtain that u_ε converges to the solution of a SPDE, while it converges to a homogenized, deterministic, solution otherwise.

More precisely, when $\beta m + p < m$, then we should choose $\beta = \frac{1}{2}(p + \gamma\beta)$ and u_ε then converges to a SPDE of the form (13.43) with \dot{W} replaced by a spatio-temporal fractional Brownian motion with asymptotically the same correlation function as $R(t, x)$, i.e., such that

$$\mathbb{E}\{\dot{W}(s, x)\dot{W}(s+t, x+y)\} = \frac{c_{p,\beta}}{|y|^p |t|^\beta}, \quad (13.45)$$

for an appropriate constant $c_{p,\beta}$.

When $b m + p > m$, then u_ε converges instead to a homogenized solution given by (13.37). We should choose $\beta = \frac{1}{2}((1-b)m + \gamma b)$ and ρ as

$$\rho = \lim_{\varepsilon \rightarrow 0} \varepsilon^{d-2\beta} \int_0^\infty \int_{\mathbb{R}^d} e^{-t|\xi|^m} \hat{R}\left(\frac{t}{\varepsilon^\gamma}, \varepsilon \xi\right) d\xi dt,$$

with $(2\pi)^d \hat{R}(t, \xi)$ the Fourier transform of $R(t, x)$ with respect to the second variable. We recognize in $e^{-t|\xi|^m}$ the Fourier transform of the fundamental solution of the unperturbed operator $\frac{\partial}{\partial t} + P(D)$. The random fluctuations $u_\varepsilon - \mathbb{E}\{u_\varepsilon\}$ are still given by u_1 solution of the SPDE (13.40) with \dot{W} the spatio-temporal fractional Brownian motion given by (13.45).

We refer to [5] for additional details on these results, which use a diagrammatic expansion that can be applied only to Gaussian potentials. Many results remain valid for non-Gaussian potentials as well; see, e.g., [28, 34, 35].

4 Applications to Uncertainty Quantification

The preceding sections presented problems with different asymptotic models of propagation of stochasticity from the random coefficients to the PDE solutions. Heuristically, we obtain effective medium properties as an application of the law of large numbers and a central limit correction when the random coefficients have sufficiently short-range correlation. For long-range correlations, the random fluctuations of the PDE solution depend more directly on the decay at infinity of the correlation function. In specific cases, we were able to display Gaussian or non-Gaussian asymptotic behaviors for the random fluctuations. In the case of large random potentials, long-range correlations had a more pronounced effect: randomness could not be averaged efficiently and the limiting solution remained stochastic, typically the solution of a stochastic PDE with multiplicative noise.

Such results have direct applications in the quantification of uncertainty. Consider for concreteness the equation

$$-\partial_x \left(a\left(\frac{x}{\varepsilon}, \omega\right) \partial_x u_\varepsilon \right) = f \quad \text{in } (0, 1),$$

with a fluctuation theory given by (13.14) (or (13.9)) $u_\varepsilon(x) = u(x) + \varepsilon^{\frac{\alpha}{2}} \sigma \int_0^1 K(x, t) dW_t^H + r_\varepsilon(x)$, where $\varepsilon^{-\frac{\alpha}{2}} r_\varepsilon$ converges to 0 (in probability in the uniform norm).

From this, we deduce asymptotic results of the form

$$\mathbb{P}\left[u_\varepsilon(x) \geq u^*(x) + \varepsilon^{\frac{\alpha}{2}} \ell\right] = \mathbb{P}\left[\sigma \int_0^1 K(x, t) dW_t^H \geq \ell\right] + o(1). \quad (13.46)$$

We also observed in the one-dimensional case that such results no longer held for $\varepsilon^{\frac{\alpha}{2}} \ell$ of order $O(1)$, where more complex large deviation results needed to be developed.

4.1 Application to Effective Medium Models

How such asymptotic results may be used for computational purposes is less clear. Consider again the above one-dimensional model. We can formally write the limiting model (with dW_t^H formally written as $\dot{W}^H dt$)

$$-\partial_x \left(\frac{a^*}{1 + \varepsilon^{\frac{\alpha}{2}} \tau \dot{W}^H} \partial_x \tilde{u}_\varepsilon \right) = f, \quad (a^*)^{-1} = \mathbb{E}a^{-1},$$

and verify that asymptotically, u_ε and \tilde{u}_ε have the same limiting random fluctuations. The above model is heuristic, and $\varepsilon^{\frac{\alpha}{2}} \tau \dot{W}^H$ should be appropriately smoothed out and truncated to preserve the ellipticity of the diffusion coefficient in the above equation, without significantly changing the law of the fluctuations for $\varepsilon \ll 1$.

From this formal expression preserving the leading contribution to the stochasticity of u_ε , we can draw two conclusions: (i) upscaling of diffusion coefficient involves a small-scale limit taking the form of white noise (when $\alpha = H = \frac{1}{2}$) in short-range case or colored noise (when $\alpha > \frac{1}{2}$) in the long-range case and (ii) the small-scale structure of “homogenized” coefficient makes it very difficult to solve such equations by polynomial chaos expansions since the rapid spatial fluctuations of $\dot{W}^H(x)$ requires a very large number of polynomials in the expansion.

4.2 Concentration Inequalities and Coupled PCE-MC Framework

Let us come back to the general problem (13.2) presented in the introduction and the propagation of stochasticity from $q_0 = q_0(x, \xi)$ and $q_\varepsilon = q_\varepsilon(x, \zeta)$ to $u_\varepsilon = u_\varepsilon(x, \xi, \zeta)$. We assume here that q_0 corresponds to the low-frequency component of the random coefficients and q_ε to their high-frequency component, which means that ξ is relatively *low dimensional*, whereas ζ lives in a high-dimensional space. The asymptotic models presented earlier in this paper allow us to estimate the influence of the parameters ζ on the distribution of u_ε . Unfortunately, the latter propagation can be obtained theoretically only in a very limited class of problems.

When such theoretical results are not available, we would like to devise computational tools that respect the above multi-scale decomposition. One such model consists of combining a PCE method to model the effect of the random variables ξ with a Monte Carlo (MC) method to estimate that of ζ .

Although the theoretical asymptotic results mentioned in the preceding sections involve technical derivations that are problem specific, a central idea underlying the validity of several of them is the following type of inequalities, which we will refer to as Efron-Stein inequalities. We follow here the presentation in [13]. Let

us assume that $\zeta = (\zeta_1, \dots, \zeta_n)$ with n large, which is the case in the asymptotic regimes considered earlier, where typically $n \sim \varepsilon^{-d}$ in dimension d . Now let us assume that the variables ζ_j are *independent* and that they each have an influence on the solution u proportional to their physical volume of order $\varepsilon^d \sim n^{-1}$ and hence small. This means that

$$\sup_{\zeta, \zeta'_i} |u(\zeta_1, \dots, \zeta_n) - u(\zeta_1, \dots, \zeta_{i-1}, \zeta'_i, \zeta_{i+1}, \dots, \zeta_n)| \leq \frac{c_i}{n}, \quad 1 \leq i \leq n, \quad (13.47)$$

for some positive constants c_i , $1 \leq i \leq n$. In other words, variations of ζ_i has an influence on the PDE solution $u(\zeta; \xi, x)$ (say uniformly in (ξ, x)) to simplify the presentation) bounded by c_i/n . If $Z = u(\zeta)$ was the mean of the random variables ζ_j , i.e., $\frac{1}{n} \sum_{j=1}^n \zeta_j$, then the central limit would indicate that Z was approximately Gaussian with variance given by $\frac{1}{n^2} \sum_{j=1}^n \sigma_j^2$ with σ_j the variance of ζ_j . The Efron-Stein inequality [13] states that a similar estimate on the variance holds for a large class of *nonlinear* functionals $Z = u(\zeta)$, including those satisfying the bounded differences constraint (13.47) and for which we have:

$$\text{Var}(Z) \leq \frac{c^2}{2n}, \quad c^2 = \frac{1}{n} \sum_{j=1}^n c_j^2. \quad (13.48)$$

The above result is consistent with those presented in (13.9) in the one-dimensional setting and in Theorem 4, although the latter results do not require a stochastic model involving independent random variables. The results obtained for long-range random fluctuations in Theorem 5, for instance, correspond to random variables that have an effect that is larger than their physical volume. However, another similar averaging mechanism ensures that the global effect of n variables decays as n increases.

Results such as (13.48) do not provide an explicit characterization of the variance of $u(\zeta)$ but rather an upper bound. In general, the effect of these n random variables is not straightforward to describe and hence needs to be obtained by computational means. In settings, where an estimate such as (13.48) may be obtained, we claim that the Monte Carlo method is particularly well suited. Indeed, for $\zeta^{(k)}$, $1 \leq k \leq K$ realizations of ζ and $Z_k = u(\zeta^{(k)})$, we obtain for the empirical mean $S = \frac{1}{K} \sum_{k=1}^K Z_k$ using (13.48) that

$$\text{Var}(S) \leq \frac{c^2}{2Kn},$$

in other words is small even for moderately large values of K provided that n is large.

Coming back to $u = u(x; \xi, \zeta)$ as the solution of an equation of the form

$$L([q_0(\xi)], [q_\varepsilon(\zeta)], x, u) = 0, \quad (13.49)$$

we may envision a PCE-MC coupled method, where ξ involves those random variables for which a bound of the form (13.47) does not hold, which is typically the case if ξ models randomness in the low-frequency component q_0 of the constitutive coefficients, and ζ modeling the high-frequency part q_ε are those (ideally independent) random variables that (ideally) we know as not having an effect larger than the (small) physical volume they represent. Let then u_k for $1 \leq k \leq K$ be the solution of

$$L([q_0(\xi)], [q_\varepsilon(\zeta_k)], x, u_k) = 0.$$

It may formally be written as

$$u_k(x; \xi) = \mathcal{F}_k(x, [q_0(\xi)]),$$

which may then be approximated by representing the solution operator \mathcal{F}_k as a suitable polynomial in the low-frequency random variables ξ (e.g., polynomial chaos expansion); see also [22].

5 Conclusions

The first part of this chapter reviewed several macroscopic models that describe the propagation of stochasticity from (highly oscillatory) random coefficients to random solutions of partial differential equations. Although not exhaustive, the set of examples covered above displays the main features of the problem: (i) the explicit, analytic derivation of macroscopic model is a difficult task that has been completed for a relatively small set of examples and (ii) the propagation of stochasticity depends on the correlation function of the random fluctuations. In the presence of long-range fluctuations, stochasticity may still dominate in the limit of vanishing correlation length and the macroscopic model takes the form of a stochastic partial differential equation. For short-range fluctuations in some models and independent of the correlation function in other models, averaging (law of large number) effects dominate the propagation process, and the limiting model takes the form of a homogenized, effective medium equation. The residual stochasticity may then be characterized as a central limit correction to homogenization when randomness is sufficiently short range. In the presence of long-range fluctuations, the random fluctuations of the solutions are often described by means of integrals of fractional white noise.

The advantages of analytically tractable macroscopic models in uncertainty quantification are clear. When they can be derived, such models provide an explicit expression for the probability density of many functionals of the PDE solution of interest. Moreover, these explicit models typically involve a very small number of parameters, such as the integral or the asymptotic decay of the correlation function.

A notable exception is the case of large deviation results (see, e.g., Theorem 3), which involve the fine structure of the random process. Finally, these models show that the random fluctuations of PDE solutions typically involve functionals of (fractional) white noise.

The presence of such fractal processes is, however, problematic when the propagation of stochasticity needs to be performed computationally: white noise requires a large number of degrees of freedom to be modeled accurately. In such a situation, the last part of this chapter presented a combined PCE-MC computational framework in which large-scale random coefficients are treated by polynomial chaos expansions, while the large number of small-scale coefficients is handled by Monte Carlo. In the event that each small-scale random coefficient has a small influence on the final solution, concentration (Efron-Stein) inequalities, which are consistent with a central limit scaling, show that the collective influence of these random coefficients has a relatively small variance that can be accurately predicted by a reasonable number of MC samples.

Polynomial Chaos: Modeling, Estimation, and Approximation

14

Roger Ghanem and John Red-Horse

Abstract

Polynomial chaos decompositions (PCE) have emerged over the past three decades as a standard among the many tools for uncertainty quantification. They provide a rich mathematical structure that is particularly well suited to enabling probabilistic assessments in situations where interdependencies between physical processes or between spatiotemporal scales of observables constitute credible constraints on system-level predictability. Algorithmic developments exploiting their structural simplicity have permitted the adaptation of PCE to many of the challenges currently facing prediction science. These include requirements for large-scale high-resolution computational simulations implicit in modern applications, non-Gaussian probabilistic models, and non-smooth dependencies and for handling general vector-valued stochastic processes. This chapter presents an overview of polynomial chaos that underscores their relevance to problems of constructing and estimating probabilistic models, propagating them through arbitrarily complex computational representations of underlying physical mechanisms, and updating the models and their predictions as additional constraints become known.

1 Introduction

Uncertainty quantification is an age-old scientific endeavor that has been reshaped in recent years in response to emerging technologies relevant to sensing and computing. Indeed, scientists' ability to make experimental observations of physical nature over a wide range of length scales is now matched by their ability to numerically resolve comprehensive mathematical formulations of the relevant physical phenomena and their interactions. This convergence of technologies has raised expectations that prediction science is now equipped to support critical decisions that have long eluded rigorous analysis. Examples of these decisions permeate such fields as climate science, material science, manufacturing, urban science, coupled interacting infrastructures, and reaction kinetics, to name only a few. An examination of the unresolved logical, conceptual, and technical questions relevant to prediction science identifies uncertainties as hurdles at several stages of the analysis process. These uncertainties enter at the very beginning with the selection of the mathematical model that is chosen to represent the physics-based constraints in the scenario of interest. Uncertainty characterizations for the parameters contained in that model are themselves models of information and are subject to additional, information-induced limitations, such as those associated with the conversion of available raw information into inference about the parameters in question. These conversions include least squares, maximum likelihood estimation methods, Bayesian strategies, or maximum entropy methods. Additional uncertainties are induced by limits on the amount of experimental evidence or in the particular form this evidence takes. All of these are factors that influence the inverse problems associated with parameter estimation. Yet another source of uncertainty stems from approximating the “push forward” of assumed input uncertainties into outputs of interest using the mathematical model describing the physics. In science and engineering, these mathematical models consist of mixtures of ordinary and partial differential equations, of integral equations, and of algebraic equations that are

eventually further constrained through an optimization problem involving chance constraints.

A critical challenge for organizing this mathematical medley is to formulate a logical, consistent, and operational perspective together with associated mathematical constructs for characterizing all the uncertainties present in a typical prediction/assessment/decision workflow.

On the logical side, a mathematical theory should reflect a clear interpretation of uncertainty against which the behavior of corresponding models can be validated. Such an interpretation must be grounded in physics and technology, since uncertainty can be reduced by augmenting information through modeling and sensing. Mathematical models of uncertainty should therefore be parameterized so as to behave consistently as new knowledge is acquired. In many instances this may require the derivation of new physics models and not merely probabilistic re-parameterization of existing models. Random operator models provide a hint as to what these new models may look like, as they provide stochastic operator-valued perturbations to deterministic models [13, 62, 81].

One of the critical objectives of uncertainty quantification is to strike a rigorously quantifiable balance between the weight of experimental evidence, the magnitude of numerical errors, and the credibility of related decisions. The first of these is associated with the paucity and quality of experimental data as well as the choice of physical and mathematical models. Numerical errors can be attributed to discretization errors, convergence tolerance of algorithms (e.g., linear and nonlinear solvers), and finite (numerical) sample statistics. Credibility of decisions is clearly increased as various errors are assessed and their influence on said decisions estimated. Clearly, the significance of this credibility is a function of the criticality of the object of decision and subsequent consequences of unplanned failure or suboptimal performance.

The polynomial chaos expansion (PCE) methodology [40] is an approach that emerged over the past 20 years with the promise of the simultaneous and consistent mathematical characterization of data errors and numerical errors by relating them both to an analogous treatment grounded in white noise calculus. This approach essentially embeds the problem in a high-dimensional setting that is sufficiently structured to describe all uncertain parameters and all square-integrable mappings on them. A challenge with this approach has been the “curse of dimensionality” that stems from the need to characterize arbitrary nonlinear mappings in high-dimensional spaces and which is manifested in the form of high-order multivariate polynomial expansions in high dimensions. This challenge is exacerbated manyfold in the context of decision-making and design, both manifestations of an optimization problem that iterates on an already very expensive stochastic function evaluator. Mathematical problems with uncertainty can generally be understood, and treated, as involving alternate independent possible realities. This perspective is very appealing in that it permits the formulation of this class of problems as a collection of standard deterministic problems. Imposing a probabilistic structure on the uncertainty is then manifested by a statistical treatment of this collection of problems. Thus if the general solution to these problems is symbolically denoted by

$u(x, \omega)$, where $x \in \mathcal{D}$ and $\omega \in \Omega$ reference, respectively, the “usual” deterministic domain of u and the sample space of the underlying experiment, one is led to approximating the solution, independently, for each value of ω . The ω -related errors can subsequently be analyzed through a statistical analysis of these approximations. Within the same probabilistic framework, mathematical problems with uncertainty have an alternative formulation. Specifically, $u(x, \omega)$ can be viewed as a function of two variables, and approximation schemes over a corresponding product space can then be pursued. Pursuing this line of inquiry requires a detailed understanding of the structure of the function spaces associated with the domains \mathcal{D} and Ω and the behavior of operators acting on them.

Operators of mathematical physics and other dynamical systems are generally construed as mappings between function spaces, with the domain of the mapping typically defined by the boundary and initial data. The smoothness and stability of the solutions to these equations are then explored in terms of the properties of these function spaces and operators. As indicated above, the introduction of uncertainty in the mathematical formulation replaces the standard operators with new ones defined on new function spaces with a domain that now represents the extended data which includes probabilistic reference to the parameters.

Even the simplest linear operators of mathematical physics exhibit nonlinear dependence on their parameters. These new operators on the extended domain are thus generally nonlinear, and methods of nonlinear analysis have been brought to bear on their mathematical exploration. The initial development of nonlinear analysis tools was fashioned for deterministic nonlinear differential equations and consisted of Taylor expansions that were generalized to infinite dimensions by Volterra [100]. The extension of these ideas to nonlinear problems with stochastic forcing was initiated by Wiener [102] and Itô [49], culminating in the construction of polynomial chaos decompositions (also known as multiple Wiener integrals) and the Wiener-Itô-Segal isomorphism ultimately laying the foundation for the development of white noise calculus [46, 47]. In all of these approaches, the essential mathematical challenge was the need for new measure and convergence constructs suitable for infinite dimensional analysis. Wiener began to work on this by first developing an abstraction of Brownian motion [102], extending the work of Paul Lévy [55], and eventually setting up an analysis framework in the particular infinite dimensional space endowed with the Gaussian measure [103]. Following the seminal work of Cameron and Martin [18] in which convergence of infinite dimensional approximations in Wiener’s Gaussian space was established, a flurry of activity ensued applying Wiener’s ideas to various nonlinear systems. In particular, a series of PhD dissertations at the Research Laboratory of Electronics at MIT explored a wide range of mathematical issues that were focused mainly on physical realizability of these systems [15, 17, 31]. Issues of causal discretization of the Brownian motion using Laguerre polynomials were investigated as were issues of adaptive refinement in the probability space, a precursor of recent multielement and h -type refinements of polynomial chaos expansions [59, 101]. Inspired by the pioneering work of Volterra and Wiener, nonlinear problems from across

science and engineering were successfully tackled, and a very strong foundation for nonlinear system theory was forged [19, 48, 49, 51, 52, 65, 75].

Extensions of Wiener's formalism to non-Gaussian measures have been pursued with some success. In particular, those ideas were readily extended to functionals of Lévy processes [50, 78, 79, 104]. Methods based on Jacobi fields [58] and bi-orthogonal expansions [3, 53] have provided a systematic approach for these extensions to other processes [12, 54].

Interest in treating problems with random coefficients, as opposed to problems with random external forcing, was initially motivated by waves propagating in heterogeneous media [13, 16, 82]. This work relied upon perturbation methods and low-order Taylor expansions as essential means for treating the nonlinearities introduced by parametric dependence. The adaptation of these expansions to general random operators soon followed in the form of stochastic Green's functions [1, 2] and Neumann expansions of the inverse operator [107]. Integration of these approaches into finite element formalisms enabled their application to a much wider range of problems [11, 44, 45, 57, 63, 80, 87]. In spite of their algorithmic and computational simplicity, issues of convergence and statistical significance limited the applicability of these methods to problems with relatively small dependence on the random coefficients. It is critical to note here that during this time period, Monte Carlo sampling methods were challenged with limited computational resources, thus motivating the development of alternative formalisms.

The adaptation of the Wiener-based approaches to problems of parametric dependence required a change of perspective from Wiener and Volterra's initial efforts. Parametric noise as motivated by the initial physical problems described above fluctuates in space and does not exhibit the non-anticipative behavior, i.e., the clear distinction between past and future, implicit in time-dependent processes. Pioneering efforts in this direction were carried out by Ghanem and Spanos [40] where the Karhunen-Loëve expansion of a correlated Gaussian process was used to embed the problem in an infinite dimensional Gaussian space. This embedding enabled the use of the polynomial chaos development of Wiener to represent the various stochastic processes involved. That work also introduced a Galerkin projection scheme to integrate polynomial chaos expansions into an approximation formalism for algebraic and differential equations with random coefficients. Extensions of that work with basis adaptation [56], hybrid expansions [32], geometric uncertainties [35], dynamic model reduction [39], and nonlinear partial differential equations and coupled physics [24, 33, 36, 60] were also developed around that time. Given its reliance on Wiener's discretization of Brownian motion, these initial applications of polynomial chaos expansions to parametric uncertainty were limited to parameters with Gaussian measure or models that are simple transformation of Gaussian processes, such as lognormal processes. The Karhunen-Loëve expansion provides a natural discretization of a stochastic process into a denumerable set of jointly distributed random variables. Other settings with denumerable random variables are common in science and engineering and are typically associated with a collection of generally dependent scalar or vector random variables used to parameterize

the problem. In these cases, a specialization of the Stone-Weierstrass theorem [92] can be readily used, resulting in a tensor product construction using one-dimensional orthogonal polynomials. For stochastically independent dimensions, these polynomials would be orthogonal with respect to the probability density function corresponding to their respective dimensions, giving rise to the so-called generalized polynomial chaos (gPC) [105]. While gPC were initially constructed to pair weights and polynomials from the Askey scheme, this limitation is unnecessary and can be easily relaxed using standard arguments from the theory of polynomial approximations [94]. Corrections to account for statistical dependence when only a finite number of random variables are retained for the analysis (finite stochastic dimension) have also been introduced [84]. It should be emphasized that these recent additions to the polynomial chaos literature do not extend the results of Wiener or the Cameron-Martin theorem as the main challenge in that earlier work was the discretization and limiting behavior of an infinite dimensional object, namely, the Brownian motion. It should also be noted that since this more recent work emphasizes finite stochastic dimensions, it has served to facilitate critical linkages between stochastic analysis, numerical analysis, statistics, and applications which almost certainly explains the magnitude of its continuing impact on the field of uncertainty quantification.

Several contributions to this Uncertainty Quantification Handbook report on current research related to various aspects of polynomial chaos in uncertainty quantification. The present article reviews a selection of recent developments related to estimating, propagating, and updating polynomial chaos representations in the context of model-based predictions.

2 Mathematical Setup

We will be concerned with the characterization of random variables and processes directly and their behavior under either deterministic or stochastic transformations. Information for these random entities often originates from data acquired through experimentally obtained measurements. Regardless of whether or not such data are available, a large part of the characterization process is the development of appropriate uncertainty models. In science and engineering applications, the transformations under consideration typically represent equilibrium and conservation laws as embodied by algebraic or differential equations with random coefficients and forcing or a combination of such equations. Some minimal mathematical structure is required for describing this setting in a manner that is conducive to the useful analysis of related problems.

Let (Ω, \mathcal{F}, P) denote the probability triple that defines the mathematical context for an experiment. Random variables are defined as measurable functions from Ω into a measurable space, which is itself a probability triple. The measure induced by the mapping in this new probability triple is known as the distribution of the random variable. Thus, if X denotes a random variable, $X : (\Omega, \mathcal{F}) \mapsto (\mathbb{G}, \mathcal{G}(X))$ where \mathbb{G} is a topological vector space and $\mathcal{G}(X)$ is that subset of the Borel σ -algebra \mathcal{G}

on \mathbb{G} induced by X , then the measure or distribution of X is denoted by $\mu_X(A)$. This distribution is such that, for every event $A \subset \mathcal{G}(X)$, its measure is given by $\mu_X(A) = P(X^{-1}(A))$. The requirement that X be measurable ensures that $X^{-1}(A) \in \mathcal{F}$. The induction process for μ_X using the above definition is often referred to as a “push forward” operation on P , here through the mapping X . The collection of all P -measurable random variables from (Ω, \mathcal{F}) to $(\mathbb{G}, \mathcal{G}(X))$ with finite expectation defines the space of \mathbb{G} -valued integrable functions. Although the space \mathbb{G} is most often identified with the real number line, \mathbb{R}^1 , other realizations of \mathbb{G} are useful, as, for example, in characterizing model errors where nonparametric methods based on random matrices have been used [21, 43, 83, 86]. Characterizing these random variables as L_1 maps is typically constrained by data, and measures of proximity between different representations are relegated to a comparison of probability measures.

In addition to random variables defined on the original probability triple, the action on these random variables of various operators describing the physics of the problem is also often of interest. Accordingly, denote by $L_2(\mathbb{G}, \mathbb{V})$ by the space of μ -square-integrable functions from topological vector space, \mathbb{G} , to another topological vector space, \mathbb{V} , where μ is a probability measure on \mathbb{G} . Here, both \mathbb{G} and \mathbb{V} are assumed to be equipped with their respective Borel σ -fields, \mathcal{G} and \mathcal{V} . We are specially interested in the case where the range, \mathbb{V} , of these random variables is a function space corresponding to the solution of a partial differential equation, or a finite dimensional Euclidean space, or a reproducing kernel Hilbert space. The probability measure on \mathbb{V} induced by an element of $L_2(\mathbb{G}, \mathbb{V})$ is therefore also of interest. We should note, however, that under sufficient smoothness conditions on the mapping, the measure on \mathbb{V} will generally be absolutely continuous [14] with respect to the measure μ on \mathbb{G} , permitting one to express the probability of all events on $(\mathbb{V}, \mathcal{V})$ in terms of the probability of corresponding events on $(\mathbb{G}, \mathcal{G})$ and hence on (Ω, \mathcal{F}) . The L_2 structure of the mappings $\mathbb{G} \mapsto \mathbb{V}$ is usually associated with their deterministic nature as they are induced primarily by conservation laws and so-called first principles.

Clearly, attributing model uncertainty to these laws and principles necessitates the co-mingling of L_1 and L_2 structure of function spaces. Some aspects of this coupling are described subsequently in this article.

3 Polynomial Chaos

We adopt a polynomial chaos expansion (PCE) [40] form for the uncertainty models as they provide the means to develop flexible representations of random variables that can be easily constrained either by observations or by governing equations. These representations serve also as highly efficient generators of random variables, permitting on-the-fly sampling from complex distributions and the real-time implementation of Approximate Bayesian Computation (ABC) methods [26, 95]. A polynomial chaos decomposition of a random variable, X , involves two stages.

In the first of these stages, the input set of system random variables, $X \in \mathbb{G}$, is described as function of an underlying set of basic random variables, $\xi \in \mathbb{R}^d$, which we refer to as the “germ” of the expansion [4, 40, 84]. The probability description of ξ is assumed to be given by a probability density function, ρ_ξ , and the functional dependence is denoted by $X = X(\xi)$. The second stage consists of developing this general functional dependence in a polynomial expansion with respect to the germ that is convergent in $L_2(\mathbb{R}^d, \mathbb{G}, \rho_\xi)$ and estimating the corresponding expansion coefficients. The structure of this L_2 space was detailed elsewhere [84].

The polynomial chaos expansion (PCE) of random variable X thus takes the form

$$X = \sum_{|\alpha| > 0} X_\alpha \psi_\alpha(\xi), \quad (14.1)$$

where $\alpha = (\alpha_1 \dots, \alpha_d)$, $|\alpha| = \sum_{i=1}^d \alpha_i$, and $\{\psi_\alpha\}$ are polynomials orthonormal with respect to the measure of ξ . The coefficients can thus be readily expressed as

$$X_\alpha = \int_{\mathbb{R}^d} X(\xi) \psi_\alpha(\xi) \rho_\xi d\xi, \quad (14.2)$$

where the mathematical expectation indicated by this last integral can be shown to be the scalar product in $L_2(\mathbb{R}^d, \mathbb{G}, \rho_\xi)$ between X and ψ_α and will be denoted as $\langle X \psi_\alpha \rangle_\xi$. While the case where ξ is a discretization of the Brownian motion would align this development with Wiener’s theory, the infinite dimensional problem is usually discretized and truncated in a preprocessing step as part of modeling and data assimilation. This preprocessing obviates the need for an infinite dimensional analysis allowing far simpler concepts from multivariate polynomial approximation to be utilized. The summation in the above expansion is typically truncated after some polynomial order p . To be consistent with current research on efficient PCE representations, however, we will replace such a truncation with a projection on a subspace spanned by an indexing set \mathcal{I} and thus replace Eq. (14.1) with the following equation:

$$X = \sum_{\alpha \in \mathcal{I}} X_\alpha \psi_\alpha(\xi). \quad (14.3)$$

It is understood, of course, that convergence is only achieved in the limit of infinite summation.

If X is only available through experimental observations, then a functional dependence of X on random variables ξ can be constructed to match the statistics of the observed data, through, for example, a Rosenblatt transform [73, 76] or a Cornish-Fisher expansion [20, 29, 93]. In this case, the coefficients X_α can be viewed as statistics of the data [23, 38] and their estimation as a task of statistical inference which can be accomplished using standard methods of statistical estimation such as Maximum Likelihood [25, 37], Maximum Entropy [22], or Bayesian procedures [8, 77]. We will elaborate further on this point later in this chapter.

If X is the solution of some governing equation with random parameters $\xi \in \mathbb{R}^d$, then its functional dependence on ξ is through the governing equation. Much of recent research on polynomial chaos methods has been to effectively express this dependence, expanding it in compressed and projected polynomial forms or compositions of such forms. In many instances, the combined mathematical structure associated with the governing equations and the polynomial chaos expansions permits a rigorous analysis of these approximations. Other sections in this chapter and several other contributions to this Handbook expand further on this point.

Regardless of whether the PCE is constrained by experimental data, by governing equations, or a composition of both operations, it embeds the variable X into a d -dimensional space defined by the random variables ξ , with d often termed the stochastic dimension of the approximation. In particular, the joint probability density function of ξ is critical for defining orthogonality and projections in that space. The PCE thus provides a parameterization of random variables that construes them as the output of a nonlinear filter representing either hidden unobservable dynamics or explicitly modeled physical processes.

Furthermore, the form of the PCE is crucial as it facilitates the use of the representation as generator for the random variable, as well as for ease of coupling across mathematical and computational models. In some situations, the underlying variables are stochastic processes, resulting in an infinite dimensional polynomial representation. The coefficients in this expansion are deterministic with a similar mathematical character to that of X , that is, they are scalar, vector, function, etc. The range of PCE representations includes random variables that possess probability measures with bounded support, are multimodal, or exhibit various degrees of skewness and peak sharpness; there is no need for the regularity for a probability density function to exist for them. In fact, the probability triples for the range spaces of these random variables include push forward induced distributions that can be shown to converge to a fixed distribution, μ_X , as the PCE expansion itself converges, using machinery of the function space L_2 . This is a key aspect of the PCE methodologies since it means that rigorous error analysis is possible, even for functionals on product spaces that include uncertainty subdomains. An additional consequence of this is that these approximations are representations that are known to also converge in probability.

We will assume that a system of possibly coupled operators, parameterized with random variables $X_i \in \mathbb{G}_i$, ($i = 1, \dots, r$), yields a random variable $U \in \mathbb{H}$ and that further processing of U yields $Q \in \mathbb{V}$, the final quantity of interest (QoI) to be used in decision or design settings. In several cases of interest, \mathbb{H} will refer to a function space associated with the solution of the coupled operator equations, while \mathbb{V} will be identified with \mathbb{R}^n or even more simply with \mathbb{R} .

In computational settings, each $X_i \in \mathbb{G}_i$ will be expressed in terms of a finite dimensional $\xi_i \in \mathbb{R}^{d_i}$. Thus if X_i is a stochastic process, ξ_i would denote its discretization, possibly through a Karhunen-Loëve expansion; or if X_i is a correlated random vector, then ξ_i could denote either its associated Karhunen-Loëve random variables or its map through the Rosenblatt transform or a similar measure transport map [22, 72]. While it is not imperative for the components

of ξ_i to be statistically independent [5–7, 84], they will be assumed to be so in the sequel in order to simplify notation. Carrying out this substitution of X_i in terms of ξ_i results in a system of governing equations that is parameterized with $\xi = (\xi_1, \dots, \xi_r) \in \mathbb{R}^d$ where $d = d_1 + \dots + d_r$. In general, then, we have the following situation:

$$\begin{aligned} h(U, X(\xi)) &= 0, & h : \mathbb{H} \times \mathbb{R}^d &\mapsto \mathbb{R}^m \\ Q = q(U(\xi)), & & q : \mathbb{R}^d &\mapsto \mathbb{R}^n. \end{aligned} \quad (14.4)$$

A common step in a UQ analysis procedure entails characterizing U and Q as PCEs. This essentially consists in evaluating the coefficients in the following two expansions:

$$U = \sum_{\alpha \in \mathcal{I}} U_\alpha \psi_\alpha \quad Q = \sum_{\alpha \in \mathcal{I}} Q_\alpha \psi_\alpha. \quad (14.5)$$

At first sight it would seem that the QoI, Q , should be expressed in terms of ξ . This would require the characterization of a nonlinear multivariate map, a task closely associated with the curse of dimensionality.

Capitalizing on the simplicity of Q relative to X_i and U has been shown to lead to adapted algorithms that significantly enhance the efficiency of associated computational models. This topic will be further elaborated in a separate section below.

Two algorithmic methodologies have been pursued for characterizing the PCE of U and Q . In a first of these, an approximation for U is substituted into the governing equations, and the resulting error is constrained to be orthogonal to the operator input space which yields the following equation:

$$\left\langle \psi_k h \left(\sum_{j \in \mathcal{I}} U_j \psi_j, X \right) \right\rangle_\xi = 0, \quad \forall k \in \mathcal{I}. \quad (14.6)$$

This last equation is a system of coupled nonlinear equations for the coefficients U_j in the PCE representation of U . Linearizing h with respect to U , which is typically done as part of nonlinear solution algorithms, results in the following where l denotes the linearized operator:

$$\sum_{j \in \mathcal{I}} \langle \psi_k \psi_j l(U_j, X) \rangle_\xi = 0, \quad \forall k \in \mathcal{I}. \quad (14.7)$$

In some instances, l may be linear in X , while in other instances it may be expressed in the form

$$l(U_j, X) = \sum_{i \in \mathcal{I}} l_i(U_j) \psi_i(\xi), \quad l_i(U_j) = \langle l(U_j, X), \psi_i \rangle_\xi. \quad (14.8)$$

In either case, Eq. (14.7) can be rewritten in the form

$$\sum_{j \in \mathcal{I}} \sum_{i \in \mathcal{I}} \langle \psi_i \psi_j \psi_k \rangle_{\xi} l_i(U_j) = 0, \quad \forall k \in \mathcal{I}, \quad (14.9)$$

which is a system of linear equations to be solved for the coefficients U_j . These equations can consist of a combination of algebraic, integral, and differential equations. For the case where the operator h belongs to a limited class of partial differential equations, the projection in Eq. (14.6) can be combined with the deterministic projection, such as a finite element projection, associated with discretizing the differential operator. Once a PCE decomposition for U has been computed, an expansion for Q can be achieved by applying the mapping q on the PCE of U .

The class of algorithm just described is typically referred to as the “intrusive approach,” involving the solution of a new system of equations obtained from a stochastic Galerkin projection on the operator input space. Accordingly, there is generally a significant code development that accompanies the development of these new system equations. Other characteristics of the approach are that the stochastic integration is determined exactly since the expectation of the triple products in Eq. (14.9) is available either analytically or numerically. This fact means that a significant portion of the approximation error in the stochastic result for the response originates in the formation of the linearized building blocks, l_i , in Eq. (14.9). Also, in Eq. (14.9), the global system matrices for the PCE coefficients in the case of discretized deterministic operators are compound; each coefficient vector, U_j , is the size of the discretized deterministic solution. The result is that the system matrices for the stochastic solution can be extraordinarily large. Finally, this approach is a generalized Fourier method and as for generalized Galerkin methods permits a priori and some a posteriori error analyses [9, 10]. A perspective on recent methods for solving the (very) large system of linear algebraic equations associated with Eq. (14.9) is presented subsequently in this article.

The second class of procedures for characterizing the PCE of Q is based on projecting in response space, that is, on Q and its PCE approximation. These procedures exploit orthogonality of the polynomials $\{\psi_{\alpha}\}$, yielding an expression for Q_{α} in the form

$$Q_{\alpha} = \langle Q \psi_{\alpha} \rangle_{\xi}, \quad \alpha \in \mathcal{I} \quad (14.10)$$

which can be approximated as the following quadrature:

$$Q_{\alpha} \approx \sum_{r=1}^{nq} Q(\xi^{(r)}) \psi_{\alpha}(\xi^{(r)}) w_q, \quad (14.11)$$

where $\{\xi^{(r)}\}$ are the nq quadrature points in \mathbb{R}^d and $\{w_q\}$ their associated weights. The number of quadrature points required in the above approximation depends

on the dimension of ξ and on the required level of fidelity. Using tensorized quadrature rules in d , dimensions quickly becomes prohibitive, and adapted rules have been developed [30, 38, 41, 106] and are elaborated in other contributions to this Handbook. The procedures described by Eq. (14.11) require only function evaluations from deterministic codes and are thus often referred to as “nonintrusive.” Further, since PCE expansions for parameters are not incorporated into the operator itself, they can generally be implemented more readily into existing deterministic analysis codes, where the error is carried in the expansion coefficients for the stochastic system response, which are projections based on expectation operators shown in Eq. (14.10). Regardless in the limit where all response calculations are equally accurate and by using the general L_2 theoretical structure, the solutions using either of the procedure classes will yield the same final stochastic answer. Other nonintrusive approaches have been developed that rely on interpolation and least squares arguments.

4 Representation of Stochastic Processes

Stochastic processes are significant in the context of uncertainty quantification as they are often crucial for describing stochastic inputs that vary in space or time, or both, as well as for characterizing spatially and temporally varying solutions of differential equations.

A number of mathematical conceptualizations can be pursued in describing stochastic processes that, while all consistent, are mathematically nuanced usually differing by their identification of sets of measure zero and can be adapted to nuanced requirements of various applications. Thus, the standard approach for describing a stochastic process, as a set of indexed random variables, emphasizes the topological and metric properties of the indexing set at the expense of the sample path properties of the process [91]. An alternative approach consists of describing stochastic processes by constructing probability measures on function spaces, thus implicitly describing several sample path properties [69]. The reproducing kernel Hilbert space (RKHS) associated with the process is a natural common by-product of either of these two constructions.

Clearly, a particular representation for stochastic processes is already embedded in the PCE by taking the random variable X to be an element in a function space. This is typical of situations where the stochastic process represents the solution of a stochastic differential equation where dependence of the process on the underlying variables ξ is inherited from the parameterization of the governing equations by these variables. In this case, the statistical properties of the stochastic process are completely determined by the initial parameterization of the governing equation.

In other situations, a stochastic process is inferred either from a statistical inverse problem or from experimental observations of functionals of the process, typically in the form local averages of the process. In this case, a covariance kernel of the process can be estimated, and the corresponding RKHS can be associated with the process. A by-product of this mathematical construction is

the Karhunen-Loëve expansion of the stochastic process in terms of the eigen-decomposition of its covariance kernel. The Karhunen-Loëve expansion provides a mean-square convergent representation of the stochastic process, permitting its characterization in terms of a denumerable set of jointly dependent uncorrelated random variables [40, 70, 84].

Thus, the covariance operator C_X of the random variable X can be defined as the bilinear map $C_X : \mathbb{G}' \mapsto \mathbb{G}$ defined implicitly by

$$(f, C_X g)_{\mathbb{G}', \mathbb{G}} = E \{(f, X)_{\mathbb{G}', \mathbb{G}} (g, X)_{\mathbb{G}', \mathbb{G}}\} = E \{f(X)g(X)\}, \quad f, g \in \mathbb{G}' \quad (14.12)$$

where $(., .)_{\mathbb{G}', \mathbb{G}}$ denotes duality pairing between \mathbb{G}' and \mathbb{G} and the second equality is shown for notational clarity. The bilinear form given by Eq. (14.12) defines a scalar product which transforms \mathbb{G}' into a Hilbert space \mathbb{H}_X , namely, the RKHS associated with X . This, in turn, determines the isometric map, $\eta = (f, X)_{\mathbb{G}', \mathbb{G}}$, from \mathbb{H}_X to Hilbert space \mathbb{H}_V such that $\|\eta\|_{\mathbb{H}_V} = \|f\|_{\mathbb{H}_X}$. Let $\{f_i\}$ denote an orthonormal basis in \mathbb{H}_X , then it can be shown [70] that the representation

$$X = \sum_{i=1}^{\infty} \eta_i X_i, \quad (14.13)$$

where $\eta_i = (f_i, X)_{\mathbb{G}', \mathbb{G}}$ and $X_i = C_X f_i$, is mean-square convergent in the weak topology of \mathbb{G} . In this expansion, the set $\{\eta_i\}$ is clearly orthonormal in \mathbb{H}_V . For the case in which the space \mathbb{G} is itself a Hilbert space, the duality pairing defines a scalar product in \mathbb{G} denoted by $(., .)$. The covariance operator is then a positive Hilbert-Schmidt operator admitting a convergent expansion in terms of its orthonormal eigenvectors which form a complete orthonormal system in \mathbb{G} . In that case, the expansion given by Eq. (14.13) can be rewritten in the form

$$X = \sum_{i=1}^{\infty} \sqrt{\lambda_i} \eta_i e_i \quad (14.14)$$

where η_i has the same meaning as above and where

$$(v, C_X e_i) = \lambda_i (v, e_i), \quad \forall v \in \mathbb{G}. \quad (14.15)$$

Convergence is both pointwise and in mean square. Equation (14.14) is known as the Karhunen-Loëve expansion of random variable X . Clearly, the random variables η_i can be expressed in terms of the random variable X in the form

$$\eta_i = \frac{1}{\sqrt{\lambda_i}} (e_i, X), \quad (14.16)$$

thus providing an explicit transformation from realizations of X to realizations of η_i . These realizations can be used to estimate the joint density function of the

random vector $\boldsymbol{\eta}$ [22,23]. For the special case where the Hilbert space \mathbb{G} is identified with $L_2(T)$ for some subset T of a metric space, the eigenproblem specified in Eq.(14.15) is replaced by

$$\int_T k(t,s)e_i(s)ds = \lambda_i e_i(t), \quad t \in T \quad (14.17)$$

where $k(t,s) = E\{X(t)X(s)\}$ is the covariance kernel of X . In addition, for the case where $k(t,s) = R(t-s)$ for some symmetric function R , the rate of decay of the eigenvalues of Eq.(14.17) is related to the smoothness of the function R and the decay of its Fourier transform at infinity [71]. If domain T is also unbounded, then the point spectrum from Eq.(14.17) becomes continuous, and the Karhunen-Loève expansion is replaced by an integral representation in terms of the independent increments of a Brownian motion [42]. Recent developments have permitted the expression of the Karhunen-Loève random variables, $\{\eta_i\}$, as polynomials in independent random variables ξ [23,27]

$$\boldsymbol{\eta} = \sum_{\alpha} \boldsymbol{\gamma}_{\alpha} \psi_{\alpha}(\xi), \quad (14.18)$$

simultaneously permitting both their sampling and their integration with other simulation codes that rely on polynomial chaos representations for their input parameters.

A challenge with inferring a stochastic process from data is the very large number of constraints required on any probabilistic representation of the process. In the case of a Karhunen-Loève expansion, these constraints take the form of specifying the covariance operator and also specifying the joint probability density function of the random variables $\boldsymbol{\eta}$. Under the added assumption of a Gaussian process, $\boldsymbol{\eta}$ is a vector of independent standard Gaussian variables. Even in this overly simplified setting, any assumption concerning the form of the covariance function presumes the ability to observe the process over a continuum of scales within the domain T of the process, a feat that is likely to remain elusive. Alternative procedures for characterizing stochastic processes that are not predicated on knowledge of covariance functions are required for stochastic models to bridge the gap between predictions and reality. This point is addressed in a subsequent section in this chapter.

5 Polynomial Chaos with Random Coefficients: Model Error

As with any probabilistic representation, a PCE describes a set of knowledge that is necessarily incomplete. As the state of knowledge changes, for example, by acquiring additional experimental evidence and by revising the underlying physical assumptions or the associated mathematical and measurement instruments, the PCE representations of any quantity of interest (QoI) should be updated accordingly.

Given its structure, there are several manners in which the PCE can be viewed as a prior model, and the associated update method can take on at least one of the following three distinct forms. First, the germ can be updated, thus assimilating the new knowledge into the motive source of uncertainty. This can be achieved by either updating the measure of the same germ or by introducing new components into the germ, thus increasing the underlying stochastic dimension of the PCE. The first of these germ update methods maintains the same physical conceptualization of uncertainty, while modifying its measure. The second germ update approach introduces new observables and in the process necessitates more elaborate physical interpretations, typically through multiscale and multiphysics formulations.

A second prior update method is to update the numerical values of the coefficients in the PCE with the goal of minimizing some measure of discrepancy between predictions and observations. Even with such a deterministic update of the coefficients, predictions from the PCE remain probabilistic in view of their dependence on the stochastic germ. This second update approach can be achieved through a Bayesian MAP, a Maximum Likelihood estimation, or even a least squares setting.

A third alternative update method consists of maintaining the probability measure of the germ at its prior value while updating a probabilistic model of the coefficients. This last option presupposes that a prior model of the PCE coefficients can be constructed.

Each of these three update alternatives is associated with a distinctly different perspective on interpreting and managing uncertainty.

A unique feature of a PCE that differentiates it among other probabilistic representations is that both parameters, X , the solution to governing equations, U , and the QoI, Q , are all represented with respect to the same germ ξ . This gives rise to interesting additional options for updating prior PCE models. Specifically, the representation of X can be updated and subsequently propagated through the model to obtain a correspondingly updated representation of Q . Alternatively, the representation of Q can itself be directly updated with the implicit understanding that the coefficients in the PCE of Q already encapsulate a numerical resolution of the prior governing equations.

Equation (14.3) is thus replaced by the following equation:

$$X = \sum_{\alpha \in \mathcal{I}} X_\alpha(\mu) \psi_\alpha(\xi), \quad (14.19)$$

where the new random variables $\mu \in \mathbb{R}^{n_v}$ describe the uncertainty about the probabilistic model. Typically, each X_α depends on a proper subset of μ . The QoI can thus be expressed as $Q(\xi, \mu)$ to underscore its dependence on the (d, n_v) -dimensional random vectors (ξ, μ) . Clearly, the uncertainty captured by the random variables, μ , can be reduced by assimilating more data into the estimation problem, and increasing the size of ξ suggests more subscale details. In the limit, the asymptotic distributions of X_α and their posterior probability densities become concentrated. The uncertainty reflected by the ξ variables, on the other hand, is a property of the selected uncertainty model form and characterizes the limits on

predictability of the model. Thus, while the underlying mathematical uncertainty model of the physical processes is only parameterized by ξ , the quantity of interest Q can be represented in the form

$$Q = q(\xi, \mu) = \sum_{\alpha \in \mathcal{I}} Q_\alpha(\mu) \psi_\alpha(\xi), \quad (14.20)$$

where $\{\psi_\alpha\}$ are polynomials orthogonal with respect to the measure of ξ . Dependence of the coefficients Q_α on μ reflects their sensitivity to modeling errors [8, 37, 38, 85, 96] and can be inferred as part of their statistical estimation. Once the probability measure of Q_α has been constructed, dependence of Q on μ can in turn be expressed through a Rosenblatt transform and then in its own polynomial chaos decomposition in terms of polynomials orthogonal with respect to the joint measure of μ . This results in the following expression:

$$Q(\xi, \mu) = \sum_{\alpha \in \mathcal{I}} \sum_{\beta \in \mathcal{I}} Q_{\alpha, \beta} \phi_\beta(\mu) \psi_\alpha(\xi). \quad (14.21)$$

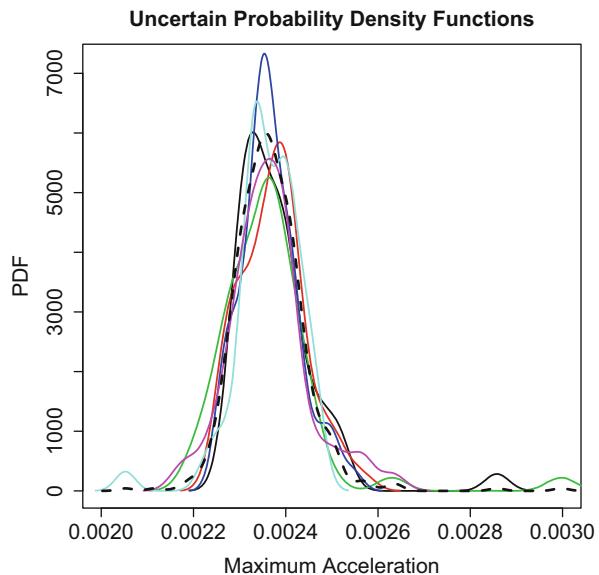

Equations (14.20) and (14.21) provide two different, yet consistent, representations. Given the orthogonality of the polynomials appearing in these representations, the coefficients Q_α can be obtained via projection and quadrature in the form

$$Q_\alpha(\mu) = \sum_{r=1}^{nq} w_r q(\xi^{(r)}) \psi_\alpha(\xi^{(r)}), \quad (14.22)$$

where w_r are quadrature weights, while $\xi^{(r)}$ are multidimensional abscissas: realizations of the random vectors ξ associated with the integration rules used. The quantity $q(\xi^{(r)})$ appearing in Eq. (14.22) is obtained as the solution of a deterministic operator evaluated at realizations $\xi^{(r)}$.

Figure 14.1 shows results associated with an implementation of the foregoing analysis [38]. In that implementation, properties of a mechanical device are estimated from a limited number of samples, each observed at a finite number of spatial locations, and represented mathematically using a Karhunen-Loëve representation. The material itself consists of foam, which exhibits an intricate microstructure resulting in an inherent uncertainty (labeled by ξ). Additional uncertainty due to limited sample size and coverage induces uncertainty in the covariance kernel of the material properties which result in a stochastic covariance function and associated eigenvalues and eigenvectors. This uncertainty, labeled by μ , is then propagated into the behavior of the mechanical device which is subjected to a mechanical shock. The Maximum Acceleration within the device, during the shock event, is then a stochastic process, indexed by both ξ and μ . For each realization of μ , the Maximum Acceleration is a random variable with a probability measure that can be readily inferred from its PCE representation. Figure 14.1 shows a family of such density functions as μ is itself sampled from its own distribution function. It is

Fig. 14.1 Scatter in probability density function associated with randomness in coefficients

clear from this figure that inferences about Maximum Acceleration, in particular near the tail of its distribution, are quite sensitive to additional samples of material properties.

6 Adapted Representations of PCE

A PCE of total degree p in d random variables is an expansion with P terms where

$$P = \frac{(d + p)!}{d! p!}. \quad (14.23)$$

This factorial growth in the number of terms has motivated the pursuit of compact representations which typically select a subset of terms in the expansions. Another recent approach, reviewed in this section, capitalizes on properties of Gaussian germs to developed representations that are uniquely adapted to specific quantities of interest. This approach is based on the observation that irrespective of how large the stochastic dimension is, the quantity of interest q is typically very low dimensional, spanning a manifold of significantly lower intrinsic dimension than the ambient Euclidean space. Recently, algorithms were developed for identifying two such manifolds, namely, a one-dimensional subspace and a sequence of one-dimensional subspaces [98]. Identifying these manifolds involves computing an isometry, A , in Gaussian space that rotates the Gaussian germ so as to minimize the concentration of the measure of the QoI away from the manifold. For problems involving non-Gaussian germ, a mapping back to Gaussian variables is typically

implemented as a preprocessing step. This step is both highly efficient and accurate. According to this basis adaptation approach, Eq. (14.5) is first rewritten as follows:

$$Q = Q_0 + \sum_{i=1}^d Q_i \xi_i + \sum_{|\alpha|>1} Q_\alpha \psi_\alpha(\xi). \quad (14.24)$$

Under conditions of a Gaussian germ ξ , the first summation in this last equation is a Gaussian random variable. The idea then is to rotate the germ ξ into a new germ η where the first coordinate, η_1 , is aligned with $\sum_{i=1}^d Q_i \xi_i$. To that end, let η be such a transformed germ expressed as

$$\eta = A\xi, \quad (14.25)$$

where A is an isometry in \mathbb{R}^d such that $\eta_1 = \sum_{i=1}^d Q_i \xi_i$. The other rows of A can be completed through a Gram-Schmidt orthogonalization procedure which may be supplemented by additional constraints. The same PCE for Q can then be expressed either in terms of ξ or in terms of η leading to the following two expressions:

$$\begin{aligned} Q &= Q_0 + \sum_{i=1}^d Q_i \xi_i + \sum_{|\alpha|>1} Q_\alpha \psi_\alpha(\xi) \\ &= Q_0 + Q_1^A \eta_1 + \sum_{|\alpha|>1} Q_\alpha^A \psi_\alpha^A(\xi) \end{aligned} \quad (14.26)$$

where $\psi_\alpha^A(\xi) = \psi_\alpha(A\xi)$. Equation (14.26) can be rewritten as follows:

$$Q = Q_0 + Q_1^A \eta_1 + \sum_{i=2}^p Q_i^A \psi_i(\eta_1) + \sum_{|\alpha|>1} Q_\alpha^A \psi_\alpha(\eta), \quad (14.27)$$

where the second summation involves polynomials in the random variables (η_2, \dots, η_d) , while the terms prior to that reflect a p order one-dimensional expansion in η_1 . A one-dimensional approximation of Q is then obtained by neglecting the last summation. Thus knowledge of the Gaussian (i.e., linear) components of a PCE representation permits the construction of a rotation of the germ such that a significant portion of the QoI probabilistic content is concentrated along a single coordinate. One justification for the possibility of a one-dimensional construction, specially when Q is a scalar quantity, is as follows. Let $F_Q(q)$ denote the distribution function of Q and $\Phi(\eta)$ denote the one-dimensional standard Gaussian distribution function. One then has

$$Q = F_Q^{-1}(\Phi(\eta)), \quad (14.28)$$

where the equality is in distribution and the equation provides a map from a Gaussian variate to a Q -variate. According to the Skorokhod representation theorem [14], a version of η can be defined in the same probability triple as Q . Thus η appearing in the inverse CDF expression above can be defined in the linear span of the germ ξ . Other constructions of the isometry, A , with alternative probabilistic arguments and justifications have also been presented [98].

The construction of the adapted bases requires an initial investment of resources for the evaluation of the “Gaussian” components of the QoI Q . These components are used to construct the isometry, A , and thus the dominant direction η_1 that is adapted to Q . Following that, a high-order expansion in η_1 is sought and can be evaluated using either intrusive or nonintrusive procedures.

An extension to the case where Q is a stochastic process (i.e., infinite dimensional) has also been implemented [99].

7 Stochastic Galerkin Implementation of PCE

A salient feature of the mathematical setup underlying PCE is the L_2 setting induced by the germ. This permits L_2 -convergent representations of random variables in contradistinction to representations of their statistical moments or distributions. A by-product of this L_2 structure is the ability to characterize the convergence of solutions to stochastic operator equations in an appropriate stochastic operator norm. For bounded linear operators, this results in an immediate extension of Céa’s lemma and a corresponding interpretation of the Lax-Milgram theorem [9]. This is typically implemented according to the so-called “intrusive” approach described in Eqs. (14.6), (14.7), (14.8), and (14.9).

These intrusive implementations face two challenges, both of which were touched upon briefly earlier in this chapter. First, the intrusive nature of the algorithms presents an implementation challenge as it necessitates the development of new software or significant revisions to existing code. Second, the size of these linear problems is much larger than the size of the corresponding deterministic problems, thus requiring careful attention to algorithmic implementations and the development of adapted preconditioners. These two challenges are briefly discussed in this section.

7.1 Nonintrusive Evaluation of the Stochastic Galerkin Solution

Equation (14.9) can be rewritten as

$$\sum_{j \in \mathcal{I}} \sum_{i \in \mathcal{I}} \langle \psi_i \psi_j \psi_k \rangle_\xi \mathbf{L}_i \mathbf{U}_j = \mathbf{f}_k, \quad \forall k \in \mathcal{I}, \quad (14.29)$$

where the deterministic linear operators $\{l_i\}$ have been projected on a suitable finite dimensional space and are represented by the associated matrices $\{\mathbf{L}_i\}$ with \mathbf{U}_j and \mathbf{f}_k denoting, respectively, the corresponding projections of U_j and of boundary conditions. We further distinguish a special case where Eq. (14.8) can be written as

$$l(\mathbf{U}_j, \mathbf{X}) = \sum_{i=0}^d l_i(\mathbf{U}_j) \xi_i, \quad l_i(\mathbf{U}_j) = \langle l(\mathbf{U}_j, \mathbf{X}), \xi_i \rangle_{\xi}, \quad (14.30)$$

for which case Eq. (14.29) becomes

$$\sum_{j \in \mathcal{I}} \sum_{i=0}^d \langle \xi_i \psi_j \psi_k \rangle_{\xi} \mathbf{L}_i \mathbf{U}_j = \mathbf{f}_k, \quad k \in \mathcal{I}. \quad (14.31)$$

Equations (14.29) and (14.31) can be rewritten as

$$\sum_{j \in \mathcal{I}} \mathbf{L}_{jk} \mathbf{U}_j = \mathbf{f}_k, \quad k \in \mathcal{I}, \quad \mathbf{L}_{jk} = \sum_i c_{ijk} \mathbf{L}_i \quad (14.32)$$

where c_{ijk} is equal to either $\langle \xi_i \psi_j \psi_k \rangle_{\xi}$ or $\langle \psi_i \psi_j \psi_k \rangle_{\xi}$ and the summation over i extends either over \mathcal{I} or over $(0, \dots, d)$, depending on whether Eq. (14.29) or (14.31) is being represented. It is clear from this last equation that matrix-vector (MATVEC) multiplications involving \mathbf{L}_{jk} can be affected using MATVEC operations on \mathbf{L}_i , thus alleviating the need to store the block matrices \mathbf{L}_{jk} , $j, k \in \mathcal{I}$ [67]. Equation (14.29) can be rearranged to take the following form [34]:

$$\mathbf{L}_0 \mathbf{U}_k = \mathbf{f}_k - \sum_{j \in \mathcal{I}} \sum_{i \in \mathcal{I}^+} c_{ijk} \mathbf{L}_i \mathbf{U}_j, \quad k \in \mathcal{I} \quad (14.33)$$

where \mathcal{I}^+ denotes the set \mathcal{I} without 0. This last equation serves two purposes. First, it describes one of the most robust preconditioners for the system given by Eq. (14.29), namely, a preconditioning via the inverse of the mean operator \mathbf{L}_0 [67]. Second, it provides a path for evaluating the solution of the intrusive approach via a nonintrusive algorithm. Specifically, as long as an analysis code exists for solving the mean operator, Eq. (14.33) describes how to evaluate the polynomial chaos coefficients \mathbf{U}_k by updating the right-hand side of the equations and iterating until convergence is achieved. Block-diagonal preconditioning has also been proposed [67, 68] as well as preconditioning with truncated PCE solutions [88, 89].

7.2 Adapted Preconditioners for the Stochastic Galerkin Equations

Given the desirable mathematical properties of a stochastic Galerkin solution, the associated matrices have recently received significant attention [28, 61, 74]. A key role in their block structure is played by the constants c_{ijk} . In general, there are two types of block patterns associated, respectively, with Eqs. (14.31) and (14.29). The first type is typically regarded as block sparse with a typical block structure depicted in Fig. 14.2a. It is noted that, for general forms of the set \mathcal{I} , the block sparse matrix has additional structure, as seen in the figure, whereby larger blocks around its diagonal are themselves block diagonal. This is a consequence of the recursion formula for orthogonal polynomials. The second type, block dense, corresponds to $c_{ijk} = \langle \psi_i \psi_j \psi_k \rangle$, and its block structure is depicted in Fig. 14.2b.

The structure of the global stochastic Galerkin matrix is induced by the matrix c_P with entries $c_{jk}^P = \sum_{i \in \mathcal{I}} c_{ijk}$ where $j, k \in \mathcal{I}$. To fix the presentation, let us consider some ℓ -th order polynomial expansion, such that $1 \leq \ell \leq p$. Thus the set \mathcal{I} consists of all d -dimensional multi-indices such that $|\ell| \leq p$. It is easy to see that the corresponding coefficient matrix c_ℓ will have a hierarchical structure

$$c_\ell = \begin{bmatrix} c_{\ell-1} & b_\ell^T \\ b_\ell & d_\ell \end{bmatrix}, \quad \ell = 1, \dots, p, \quad (14.34)$$

where $c_{\ell-1}$ are the first principal submatrices corresponding to the $(\ell - 1)$ -th order polynomial expansion. We note that even though the matrices c_ℓ are symmetric, the global stochastic Galerkin matrix will be symmetric only if each one of the matrices

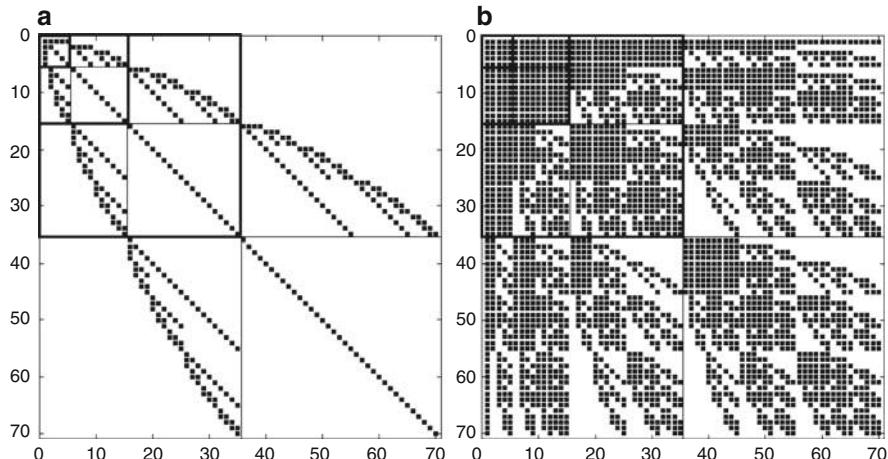

Fig. 14.2 Typical sparsity patterns of the coefficient matrices for different c_{ijk} . (a) $c_{ijk} = \langle \xi_i \psi_j \psi_k \rangle$. (b) $c_{ijk} = \langle \psi_i \psi_j \psi_k \rangle$

\mathbf{L}_i is symmetric. Clearly, all matrices \mathbf{L}_i will have the same sparsity pattern. In either case, the block sparse or the block dense, the linear system (14.29) can be written as

$$\mathbf{A}_P \mathbf{U}_P = \mathbf{f}_P, \quad (14.35)$$

where the global Galerkin matrix \mathbf{A}_P has the hierarchy specified as

$$\mathbf{A}_\ell = \begin{bmatrix} \mathbf{A}_{\ell-1} & \mathbf{B}_\ell \\ \mathbf{C}_\ell & \mathbf{D}_\ell \end{bmatrix}, \quad \ell = P, \dots, 1, \quad (14.36)$$

and $\mathbf{A}_0 = \mathbf{L}_0$. Note that in general, $\mathbf{C}_\ell = \mathbf{B}_\ell^T$, for $\ell = 1, \dots, P$. It is clear from Fig. 14.2a that the decomposition (14.36) provides a path for a hierarchical Schur complement solution for the block sparse case [90]. In the block dense case, this approach still provides an effective preconditioner [89, 90]. The number of linear solves required by these preconditioners is equal to the number of terms included in the PCE (P in Eq. (14.23)). Additional computational effort is required for MATVEC operations required for evaluating the Schur complements and for iterating in the block dense case.

It is important to note that algorithms adapted to the peculiar structure of the global stochastic Galerkin matrices continue to improve the efficiency of these methods.

8 Embedded Quadratures for Stochastic Coupled Physics

As indicated previously, several nonintrusive approaches for evaluating the PCE representations to the solution of stochastic equations are challenged with the need to evaluate high-dimensional integrals. Many problems of recent interest involve the numerical solution of large-scale coupled problems, such as multistage, multiphysics, and multiscale, which at first sight seem to significantly exacerbate this difficulty. On closer inspection, however, several of these problems are equipped with structure, often inherited from the physics and system-level requirements, whereby the bulk of the uncertainty remains localized within each subproblem, thus reducing the dimension of the stochastic information linking the subproblems and consequently alleviating the overall computational burden. This idea was recently explored and observed to yield orders of magnitude reduction in computational prerequisites [5–7].

A first step is to imagine the collection of subsystems as forming a graph, with each node i having parent nodes P_i . Denoting the output from the i th model by $u^{(i)}$, we typically have the following structure (with overloading of notation):

$$u^{(i)}(\mathbf{X}) = u^{(i)}(\mathbf{X}_i, u^{P_i}), \quad \mathbf{X} \in \mathbb{R}^d, \quad \mathbf{X}_i \in \mathbb{R}^{d_i} \quad (14.37)$$

where u^{P_i} refers to the set of stochastic outputs over P_i . This notation highlights the fact that significant smoothing takes place as uncertainty propagates through each model component in the overall system model. It is thus clear that rather than carrying out the high-dimensional integrals over d -space, a subspace which contains the fluctuations of X_i together with those of u^{P_i} should be sufficient. It is a challenge to efficiently characterize the probability measure on this space and to compute the associated quadrature rules. Instead, we will rely on an embedded quadrature approach [6]. A first step in this approach is to reduce the functions u^{P_i} , whenever they are described as random fields, via their Karhunen-Loève decomposition. Let the number of terms retained for these functions be equal to t_i . Clearly, these terms will generally be dependent, and hence the current approach, which is described next, is conservative as they are presumed independent. Let \mathcal{Q}_d denote the coordinates of a quadrature rule in d -space. We then identify a quadrature rule $\mathcal{Q}_{d_i+t_i}$ in the space of dimension $d_i + t_i$ that is a subset of \mathcal{Q}_d with an L_1 constraint on the weights. We demonstrate this idea for a two-model problem below.

Consider two physical processes, u and v , governed by the following functional relationships:

$$f(\kappa, \mu(v), u) = 0, \quad g(\chi, v(u), v) = 0 \quad (14.38)$$

where κ and χ denote random parameters implicit to the first and second physics relationships, respectively. We will assume that these have been discretized into random vectors using, for instance, a Karhunen-Loève expansion. Also, $\mu(v)$ and $v(u)$ are additional parameters that describe the coupling between the two physical processes. A complete solution of the problem would require an analysis over a stochastic space that is large enough to characterize κ and χ simultaneously. We will approach this challenge in two steps. First, we reduce the stochastic character of each of u and v through decorrelation, by describing their respective dominant Karhunen-Loève expansions. Our goal is to express u , v , μ , and ν . To begin, we take

$$u = \sum_{\alpha=0}^{K_u} u_{\alpha} \hat{\xi}_{\alpha}, \quad v = \sum_{\alpha=0}^{K_v} v_{\alpha} \hat{\xi}_{\alpha}, \quad (14.39)$$

where $\hat{\xi}$ and $\hat{\zeta}$ are the Karhunen-Loève variables which, for now, are assumed to be independent. Note that each of these variables can be described independently using an inverse CDF mapping, as a function of a Gaussian variable. This results in the following representations:

$$\begin{aligned} u &= \sum_{\alpha=0}^{L_u} u_{\alpha} E_{\alpha}(\xi), & v &= \sum_{\alpha=0}^{L_v} v_{\alpha} E_{\alpha}(\zeta) \\ v(u) &= \sum_{\alpha=0}^{L_{\mu}} m_{\alpha} E_{\alpha}(\xi), & \mu(v) &= \sum_{\alpha=0}^{L_{\nu}} n_{\alpha} E_{\alpha}(\zeta) \end{aligned} \quad (14.40)$$

where $\xi \in \mathbb{R}^{K_u}$ and $\zeta \in \mathbb{R}^{K_v}$ are independent Gaussian random vectors, E_α are normalized multidimensional Hermite polynomials, and (L_v, L_μ) are such that all summations are converged within specified tolerance. The solutions to Eq. (14.38) can thus be written as

$$\begin{aligned} u(\kappa, \chi) &\equiv u(\kappa, \xi) = \sum_{\beta=0}^{L_v} \sum_{\alpha=0}^K u_{\alpha\beta} \psi_\alpha(\kappa) E_\beta(\xi) \\ v(\kappa, \chi) &\equiv v(\xi, \chi) = \sum_{\beta=0}^{L_\mu} \sum_{\alpha=0}^K v_{\alpha\beta} \Phi_\alpha(\chi) E_\beta(\xi) \end{aligned} \quad (14.41)$$

where ψ_α and Φ_β are multidimensional polynomials orthonormal with respect to the probability density of κ and χ , respectively, and the upper limit on the summation, K , is sufficient for the representation of dependence of u and v and κ and χ . In these representations, the deterministic coefficients for each solution, $u_{\alpha\beta}$ and $v_{\alpha\beta}$, depend on the solution of the other problem. Given the orthogonality of all the above polynomials, the coefficients $u_{\alpha\beta}$ and $v_{\alpha\beta}$ can be obtained as follows:

$$u_{\alpha\beta}(v) = \mathbb{E}\{u \psi_\alpha E_\beta\}, \quad v_{\alpha\beta}(u) = \mathbb{E}\{v \Phi_\alpha E_\beta\}, \quad (14.42)$$

which are evaluated as multidimensional integrals. We address the important challenge of evaluating these integrals efficiently by taking advantage of their composite structure. We elaborate on that point next.

Consider a function $f(\kappa_1, \dots, \kappa_p)$ of p parameters where κ_i is a μ_i -square-integrable \mathbb{R}^{m_i} -valued random variable with density relative to Lebesgue measure given by μ_i , and let the joint density of all the κ_i parameters be denoted by μ_κ . Thus, $\kappa_i : (\Omega, \mathcal{F}, P) \mapsto \mathbb{R}^{m_i}$ and $f : \mathbb{R}^{m_1} \times \dots \times \mathbb{R}^{m_p} \mapsto \mathbb{R}^m$. We are interested in evaluating the mathematical expectation, $E\{f\}$, of the function f , where in general f can be decomposed as

$$f(\kappa_1, \dots, \kappa_p) = g(\kappa_1, \dots, \kappa_p) h(\kappa_1, \dots, \kappa_p). \quad (14.43)$$

If the function h is an indicator function for a set A , then $E\{f\}$ evaluates the probability of g being in A . We are also interested in situations where the function, h , is an orthogonal polynomial in the random variables, κ_i , in which case $E\{f\}$ evaluates to the polynomial chaos coefficient in the expansion of g in a basis consisting of these polynomials. In some instances, we will also be interested in situations where the random variables κ are themselves functions of another set of random variables $\xi \in \mathbb{R}^N$. Thus, in general, we will consider

$$\begin{aligned} I = \mathbb{E}\{f\} &= \int_{\mathbb{R}^m} f(\kappa) \mu_\kappa(\kappa) d\kappa = \int_{\mathbb{R}^N} f(\kappa(\xi)) \mu_\xi(\xi) d\xi \approx \sum_{q=1}^{nq} w_q f(\xi^q), \\ \xi^q &\in \mathbb{R}^N, f \in \mathbb{V}, \end{aligned} \quad (14.44)$$

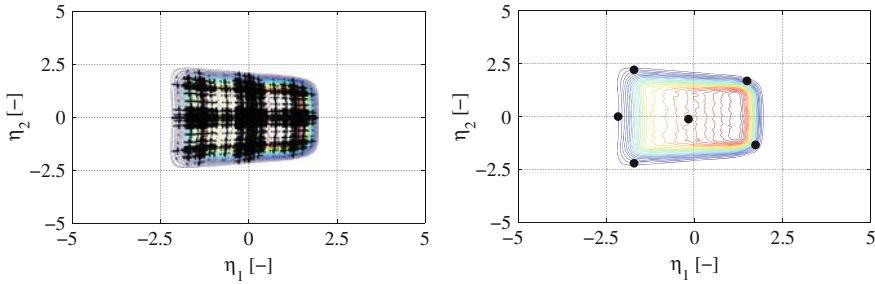

Fig. 14.3 Quadrature points in original space and embedded quadratures in reduced space

where \mathbb{V} denotes a functional space specified by the physics of the problem, μ_ξ is the probability density function of the N -dimensional random variable ξ , and (w_q, ξ_q) are weight/coordinate pairs of some particular quadrature rule. The integral I can thus be evaluated either over \mathbb{R}^m with respect to the measure of κ or over \mathbb{R}^N with respect to the measure of ξ . In most cases of interest, quadrature with respect to ξ , while easier to compute (since the ξ are usually statistically independent), is in a much higher dimension. On the other hand, quadrature with respect to κ , while over a much lower dimension, is with respect to a dependent measure and does not conform to standard quadrature rules. Recent algorithms [6] select quadrature points for κ -integration as a very small subset from the points required for the ξ -integration. The selection is based on an optimality requirement for the L_1 norm of the weights of the selected subset. Figure 14.3a, b show a comparison between the required quadrature points using full tensor products and the method that was just described. The results in these figures pertain to an application involving stationary transport of neutrons with thermal coupling [5]. The figures show the projection onto a two-dimensional plane of all quadrature points used for evaluating the PCE coefficients of the temperature field, to within similar accuracy. The number of required quadrature points is reduced from over a 1000 to 6.

9 Constructing Stochastic Processes

As already mentioned above when discussing Karhunen-Loëve expansions, the infinite dimensional nature of stochastic processes gives rise to modeling and computational challenges. For instance, when selecting the form for covariance functions of stochastic processes, the behavior of the processes at very small and very large length scales is implicitly decided by the selection. The statistical measure and dependence between these scales must be determined from additional observations of the process. In many instances, the complexity inherited from the infinite dimensional construction of the stochastic process belies a regularity that permits its assimilation into design and decision processes. One rational

approach to simplify the construction of stochastic processes without giving up mathematical rigor can be gleaned from multiscale modeling. For example, emerging properties on any scale can often be deduced from fluctuations on a finer scale. Thus, if we are in a position to characterize fluctuations on the finest scale in terms of a collection of experimentally observed random variables, emerging properties on coarser scales will be possible to deduce through an upscaling procedure. Since any result is dependent on the specific upscaling procedure adopted, it is not unique. However, that result does have the important benefit of having produced a stochastic process for derived properties that are commensurate with that particular procedure. An additional benefit for such a construction is the ability to deduce several coarse-scale processes as dependent stochastic processes [97] related through their dependence on the same germ.

As an example, we consider the problem of two-dimensional flow past circular thermal inclusions [97]. Uncertainty in the system is considered by modeling the thermal conductivity of the discs in terms of ten random variables. Fluid flow and heat transfer at the fine scale are described with the Navier-Stokes equations augmented by conservation of energy and utilized temperature-dependent fluid viscosity and fluid density. At the coarse scale, a Darcy-Forchheimer model of a porous medium is constructed, and the spatial variability of its hydraulic and thermal properties are deduced from the fine scale through homogenization.

The stochastic fine-scale problem, with ten-dimensional stochastic input, was solved using quadrature rules as implemented in Albany [66]. This results in a polynomial chaos characterization of the temperature and flow fields in the fine scale.

The coarse-scale permeability tensor, k_{ij} , was computed using volume averaging [64]. Thus, at low velocities, Darcy's law can be used to compute the permeability as

$$-\frac{\partial \langle P \rangle_V}{\partial x_i} = \mu k_{ij}^{-1} \langle u_j \rangle_V \quad (14.45)$$

where $\langle P \rangle_V$ and $\langle u \rangle$ are volume averaged pressure and velocity obtained from fine-scale solution. The volume average is computed as

$$\langle a \rangle = \frac{1}{V} \int_V a dV. \quad (14.46)$$

In this manner, a PCE representation is constructed of the coarse-scale permeability and conductivity tensors in terms of the germ describing the fine-scale properties. This construction can serve to generate realizations of the process as well as to investigate the correlation structure induced by fine-scale variability and prevailing physical processes. Furthermore, since both coarse-scale properties are described in terms of the same germ, their statistical dependence is built into their models.

10 Conclusion

A number of analogies have been drawn between polynomial chaos representations and a number of other procedures including response surface models, surrogate models, reduced models, mean-square approximations, hierarchical models, white noise models, stochastic differential equations, and infinite dimensional analysis. The standing of PCE methods at such a diverse intersection underscores its versatility and its coherent mathematical structure.

The basis of polynomial chaos formalism is the direct approximation, and coincidentally the parametrization, of stochastic variables and processes. This formalism provides a particular probabilistic packaging of evidence and constraints that is well adapted to computational and algorithmic requirements of evolving large-scale computational problems. The underlying mathematical framework enables a seamless extension of numerical analysis from deterministic to stochastic problems, while also providing a general enough characterization to encompass general multivariate stochastic processes. The historical roots of PCE methods in infinite dimensional probabilistic analysis provide them with sufficient mathematical structure and flexibility to characterize a very wide range of uncertainties and to serve as proper representations for prior and posterior knowledge as postulated by probabilistic updating rules. Finally, their foundation in functional analysis equips them naturally for innovation at the interface between physics modeling, computational science, and statistical science.

This flexibility in modeling and representation comes at a cost, namely, the scientific or engineering problem is embedded into a Euclidean space that is prone to the so-called curse of dimensionality. In spite of a number of recent methods for tackling this challenge, for instance, in the guise of basis adaptation along both spatial and stochastic coordinates, significant challenges remain. An important issue to be addressed by PCE approaches, as well as other UQ representations and methodologies, is that of sufficient complexity. Specifically, ascertaining the sensitivity of ultimate decisions and designs to increases in mathematical complexity is a nascent idea, which must be addressed with regard to, simultaneously, the complexity of physics models, probabilistic and statistical models, and numerical discretization and solvers.

Part III
Forward Problems

Ilias Bilionis and Nicholas Zabaras

Abstract

Classic non-intrusive uncertainty propagation techniques, typically, require a significant number of model evaluations in order to yield convergent statistics. In practice, however, the computational complexity of the underlying computer codes limits significantly the number of observations that one can actually make. In such situations the estimates produced by classic approaches cannot be trusted since the limited number of observations induces additional epistemic uncertainty. The goal of this chapter is to highlight how the Bayesian formalism can quantify this epistemic uncertainty and provide robust predictive intervals for the statistics of interest with as few simulations as one has available. It is shown how the Bayesian formalism can be materialized by employing the concept of a Gaussian process (GP). In addition, several practical aspects that depend on the nature of the underlying response surface, such as the treatment of spatiotemporal variation, and multi-output responses are discussed. The practicality of the approach is demonstrated by propagating uncertainty through a dynamical system and an elliptic partial differential equation.

1 Introduction

National laboratories, research groups, and corporate R&D departments have spent decades in time and billions in dollars to develop realistic multi-scale/multi-physics computer codes for a wide range of engineered systems such as aircraft engines, nuclear reactors, and automobile vehicles. The driving force behind the development of these models has been their potential use for designing systems with desirable properties. However, this potential has been hindered by the inherent presence of uncertainty attributed to the lack of knowledge about initial/boundary conditions, material properties, geometric features, the form of the models, as well as the noise present in the experimental data used in model calibration.

This chapter focuses on the task of propagating parametric uncertainty through a given computer code ignoring the uncertainty introduced by discretizing an ideal mathematical model. This task is known as the *uncertainty propagation* (UP) problem. Even though the discussion is limited to the UP problem, all the ideas presented can be extended to the problems of model calibration and design optimization under uncertainty, albeit this is beyond the scope of this chapter.

The simplest approach to the solution of the UP problem is the Monte Carlo (MC) approach. When using MC, one simply samples the parameters, evaluates the model, and records the response. By post-processing the recorded responses, it is possible to quantify any statistic of interest. However, obtaining convergent statistics via MC for computationally expensive realistic models is not feasible, since one may be able to run only a handful of simulations.

The most common way of dealing with expensive models is to replace them with inexpensive surrogates. That is, one evaluates the model on a set of design points and then tries to develop an accurate representation of the response surface based on what he observes. The most popular such approach is to expand the response in a generalized polynomial chaos basis (gPC) [4, 51–53] and approximate its coefficients with a Galerkin projection computed with a quadrature rule, e.g., sparse grids [44]. In relatively low-dimensional parametric settings, these techniques

outperform MC by orders of magnitude. In addition, it is possible to prove rigorous convergence results for gPC. However, the quality of the estimates when using a very limited number of simulations is questionable. The main reason is that they do not attempt to quantify the epistemic uncertainty induced by this very fact.

The quantification of the epistemic uncertainty induced by the limited number of simulations requires statistical methodologies and, specifically, a Bayesian approach. The first statistical approach to computer code surrogate building was put forward by Currin et al. [16] and Sacks et al. [42], both using Gaussian processes (GP). This work was put in a Bayesian framework by Currin et al. [17] and Welch et al. [50]. The first fully Bayesian treatment of the UP problem has its roots in the Bayes-Hermite quadrature of O'Hagan [36], and it was put on the modern context in O'Hagan et al. [38] and Oakley and O'Hagan [34]. Of great relevance is the Gaussian emulation machine for sensitivity analysis (GEM-SAM) software of O'Hagan and Kennedy [37]. The work of the authors in [7, 10] constitutes a continuation along this path. The present chapter is a comprehensive review of the Bayesian approach to UP as of now.

The outline of the chapter is as follows. It starts with a generic description of physical models and the computer emulators used for their evaluation, followed by the definition of the UP problem. Then, it discusses the Bayesian approach to UP introducing the concept of a Bayesian surrogate and showing how the epistemic uncertainty induced by limited observations can be represented. Then, it shows how the Bayesian framework can be materialized using GPs, by providing practical guidelines for the treatment of spatiotemporal multi-output responses, training the hyper-parameters of the model, and quantifying epistemic uncertainty due to limited data by sampling candidate surrogates. The chapter ends with three demonstrative examples, a synthetic one-dimensional example that clarifies some of the introduced concepts, a dynamical system with uncertain initial conditions, and a stochastic partial differential equation.

2 Methodology

2.1 Physical Models

A *physical model* is mathematically equivalent to a multi-output function,

$$\mathbf{f}: \mathcal{X} = \mathcal{X}_s \times \mathcal{X}_t \times \mathcal{X}_{\xi} \rightarrow \mathcal{Y}, \quad (15.1)$$

where $\mathcal{X}_s \subset \mathbb{R}^{d_s}$, with $d_s = 0, 1, 2$, or 3 , is the *spatial* domain; $\mathcal{X}_t \subset \mathbb{R}^{d_t}$, with $d_t = 0$, or 1 , is the *time* domain; $\mathcal{X}_{\xi} \subset \mathbb{R}^{d_{\xi}}$ is the *parameter* domain; and $\mathcal{Y} \subset \mathbb{R}^{d_y}$ is the *output* space. Note that under this notation, $d_s = 0$, or $d_t = 1$, is interpreted as if $\mathbf{f}(\cdot)$ has no spatial or time components, respectively. One thinks of $\mathbf{f}(\mathbf{x}_s, t, \boldsymbol{\xi})$ as the model response at the spatial location $\mathbf{x}_s \in \mathcal{X}_s$ at time $t \in \mathcal{X}_t$ when the parameters $\boldsymbol{\xi} \in \mathcal{X}_{\xi}$ are used. The parameters, $\boldsymbol{\xi}$, should specify everything that is

required in order to provide a complete description of the system. This covers any physical parameters, boundary conditions, external forcings, etc.

2.1.1 Example: Dynamical Systems

Let $\mathbf{f}(t, \xi) = \mathbf{z}(t; \mathbf{z}_0(\xi_1), \xi_2)$ be the solution of the initial value problem

$$\begin{aligned}\dot{\mathbf{z}} &= \mathbf{h}(\mathbf{z}, \xi_2), \\ \mathbf{z}(0) &= \mathbf{z}_0(\xi_1),\end{aligned}\tag{15.2}$$

with $\xi = (\xi_1, \xi_2)$, and $\mathbf{h} : \mathbb{R}^q \times \mathcal{X}_\xi \rightarrow \mathbb{R}^q$. Here ξ_1 and ξ_2 are any parameters that affect the dynamics and the initial conditions, respectively. One has $n_s = 0$, $n_t = 1$, and $d_y = q$.

2.1.2 Example: Partial Differential Equation

In flow through porous media applications, ξ parametrizes the permeability and the porosity fields, e.g., via a Karhunen-Loeve Expansion (KLE). Here, $d_s = 3$, $d_t = 1$, and $d_y = 4$, with

$$\mathbf{f}(\mathbf{x}_s, t, \xi) = (p(\mathbf{x}_s, t, \xi), v_1(\mathbf{x}_s, t, \xi), v_2(\mathbf{x}_s, t, \xi), v_3(\mathbf{x}_s, t, \xi)),\tag{15.3}$$

where $p(\mathbf{x}_s, t, \xi)$ and $v_i(\mathbf{x}_s, t, \xi)$, $i = 1, 2, 3$ is the pressure and the i -th component of the velocity field of the fluid, respectively.

2.2 Computer Emulators

A *computer emulator*, $\mathbf{f}_c(\cdot)$, of a physical model, $\mathbf{f}(\cdot)$, is a function that reports the physical model at a given set of spatial locations,

$$\mathbf{X}_s = \{\mathbf{x}_{s,1}, \dots, \mathbf{x}_{s,n_s}\},\tag{15.4}$$

and at specific times,

$$\mathbf{X}_t = \{t_1, \dots, t_{n_t}\},\tag{15.5}$$

for any realization of the parameters, ξ . That is,

$$\mathbf{f}_c : \mathcal{X}_\xi \rightarrow \mathcal{Y}^{n_s n_t} \subset \mathbb{R}^{n_s n_t d_y},\tag{15.6}$$

with

$$\mathbf{f}_c(\xi) = (\mathbf{f}(\mathbf{x}_{s,1}, t_1, \xi)^T \dots \mathbf{f}(\mathbf{x}_{s,1}, t_{n_t}, \xi)^T \dots \mathbf{f}(\mathbf{x}_{s,n_s}, t_1, \xi)^T \dots \mathbf{f}(\mathbf{x}_{s,n_s}, t_{n_t}, \xi)^T)^T.\tag{15.7}$$

For example, for the case of dynamical systems, \mathbf{X}_t may be the time steps on which the numerical integration routine reports the solution. In the porous flow example \mathbf{X}_s may be the centers of the cells of a finite volume scheme and \mathbf{X}_t the time steps on which the numerical integration reports the solution.

Alternatively, the computer code represents the physical model in an internal basis, e.g., spectral elements. In this case,

$$\mathbf{f}(\mathbf{x}_s, t, \xi) \approx \sum_{i=1}^{n_c} \mathbf{c}_i(t, \xi) \psi_i(\mathbf{x}_s), \quad (15.8)$$

where $\psi_i(\mathbf{x}_s)$ are known spatial basis functions. Then, one may think of the computer code as the function that returns the coefficients $\mathbf{c}_i(t, \xi) \in \mathbb{R}^{d_y}$, i.e.,

$$\mathbf{f}_c : \mathcal{X}_\xi \rightarrow \mathbb{R}^{n_c n_t d_y} \quad (15.9)$$

$$\mathbf{f}_c(\xi) = (\mathbf{c}_1(t_1, \xi)^T \dots \mathbf{c}_1(t_{n_t}, \xi)^T \dots \mathbf{c}_{n_c}(t_1, \xi)^T \dots \mathbf{c}_{n_c}(t_n, \xi)^T)^T. \quad (15.10)$$

2.3 The Uncertainty Propagation Problem

In all problems of physical relevance, the parameters, ξ , are not known explicitly. Without loss of generality, uncertainty about ξ may be represented by assigning to it a probability density, $p(\xi)$. Accordingly, ξ is referred to as the *stochastic* input. The goal of uncertainty propagation is to study the effects of $p(\xi)$ on the model output $\mathbf{f}(\mathbf{x}_s, t, \xi)$. Usually, it is sufficient to be able to compute low-order statistics such as the *mean*,

$$\mathbb{E}_\xi[\mathbf{f}(\cdot)](\mathbf{x}_s, t) = \int \mathbf{f}(\mathbf{x}_s, t, \xi) p(\xi) d\xi, \quad (15.11)$$

the *covariance* matrix function:

$$\begin{aligned} \mathbb{C}_\xi[\mathbf{f}(\cdot)]((\mathbf{x}_s, t); (\mathbf{x}'_s, t')) &= \mathbb{E}_\xi \left[\{\mathbf{f}(\mathbf{x}_s, t, \xi) - \mathbb{E}_\xi[\mathbf{f}(\cdot)](\mathbf{x}_s, t)\} \right. \\ &\quad \left. \{\mathbf{f}(\mathbf{x}'_s, t', \xi) - \mathbb{E}_\xi[\mathbf{f}(\cdot)](\mathbf{x}'_s, t')\}^T \right], \end{aligned} \quad (15.12)$$

the *variance* of component i as a function of space and time:

$$\mathbb{V}_{\xi,i}[\mathbf{f}(\cdot)](\mathbf{x}_s, t) = \mathbb{C}_{\xi,ii}[\mathbf{f}(\cdot)]((\mathbf{x}_s, t); (\mathbf{x}'_s, t')), \quad (15.13)$$

for $i = 1, \dots, d_y$, low-dimensional full statistics, e.g., point-wise probability densities of one component of the response.

The focus of this chapter is restricted to *non-intrusive* uncertainty propagation methods. These techniques estimate the statistics of the physical model using the computer code $\mathbf{f}_c(\cdot)$ as a black box. In particular, a fully Bayesian approach using Gaussian processes is developed.

2.4 The Bayesian Approach to Uncertainty Propagation

Assume that one has made n simulations and collected the following data set:

$$\mathcal{D} = \{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^n, \quad (15.14)$$

where $\mathbf{x}_i \in \mathcal{X}$, i.e., $\mathbf{x}_i = (\mathbf{x}_{s,i}, \xi_i, t_i)$, and $\mathbf{y}_i = \mathbf{f}(\mathbf{x}_i)$. The problem is to estimate the statistics of the response, \mathbf{y} , using only the simulations in \mathcal{D} .

Classic approaches to uncertainty propagation use \mathcal{D} to build a surrogate surface $\hat{\mathbf{f}}(\mathbf{x})$ of the original model $\mathbf{f}(\mathbf{x})$. Then, they characterize the uncertainty on the response \mathbf{y} by propagating the uncertainty of the stochastic inputs, ξ , through the surrogate. In some cases, e.g., gPC [26], this can be done analytically. In general, since the surrogate surface is cheap to evaluate, the uncertainty of the stochastic inputs, ξ , is propagated through via a simple Monte Carlo procedure [31, 41]. Such a procedure can provide point estimates of any statistic. However, what can one say about the accuracy of these estimates? This question becomes important especially when the number of simulations, n , is very small. The Bayesian approach to uncertainty propagation can address this issue, by providing confidence intervals for the estimated statistics.

2.4.1 Bayesian Surrogates

The Bayesian approach is based on the idea of a *Bayesian surrogate*. A Bayesian surrogate is a probability measure on the space of surrogates which is compatible with one's prior beliefs about the nature of $\mathbf{f}(\mathbf{x})$ as well as the data \mathcal{D} . A precise mathematical meaning of these concepts is given in the Gaussian process section. For the moment – and without loss of generality – assume that one has a parameterized family of surrogates, $\hat{\mathbf{f}}(\cdot; \boldsymbol{\theta})$, where $\boldsymbol{\theta}$ is a finite dimensional random variable, with PDF $p(\boldsymbol{\theta})$. Intuitively, think of $\hat{\mathbf{f}}(\cdot; \boldsymbol{\theta})$ as a candidate surrogate with parameters $\boldsymbol{\theta}$ and that, before observing any data, $\boldsymbol{\theta}$ may take any value compatible with the *prior* probability $p(\boldsymbol{\theta})$. In addition, let $p(\mathcal{D}|\boldsymbol{\theta})$ be the *likelihood* of the simulations under the model. Using Bayes rule, one may characterize his state of knowledge about $\boldsymbol{\theta}$ via the *posterior* PDF:

$$p(\boldsymbol{\theta}|\mathcal{D}) = \frac{p(\mathcal{D}|\boldsymbol{\theta})p(\boldsymbol{\theta})}{p(\mathcal{D})}, \quad (15.15)$$

where the normalization constant,

$$p(\mathcal{D}) = \int p(\mathcal{D}|\boldsymbol{\theta})p(\boldsymbol{\theta})d\boldsymbol{\theta}, \quad (15.16)$$

is known as the *evidence*. The posterior of $\boldsymbol{\theta}$, Equation (15.15), neatly encodes everything one has learned about the true response, $\mathbf{f}(\cdot)$, after seeing the simulations in \mathcal{D} . How can one use this information to characterize his state of knowledge about the statistics of $\mathbf{f}(\cdot)$?

2.4.2 Predictive Distribution of Statistics

A *statistic* is an operator $\mathcal{Q}[\cdot]$ that acts on the response surface. Examples of statistics are the mean, $\mathbb{E}_{\xi}[\cdot]$, of Equation (15.11); the covariance, $\mathbb{C}_{\xi}[\cdot]$, of Equation (15.12); and the variance, $\mathbb{V}_{\xi}[\cdot]$, of Equation (15.13). Using the posterior of $\boldsymbol{\theta}$ (see Equation (15.15)), the state of knowledge about an arbitrary statistic $\mathcal{Q}[\cdot]$ is characterized via

$$p(\mathcal{Q}|\mathcal{D}) = \int \delta \left(\mathcal{Q} - \mathcal{Q}[\hat{\mathbf{f}}(\cdot; \boldsymbol{\theta})] \right) p(\boldsymbol{\theta}|\mathcal{D}) d\boldsymbol{\theta}. \quad (15.17)$$

Equation (15.17) contains everything that is known about the value of $\mathcal{Q}[\cdot]$, given the observations in \mathcal{D} . The quantity $p(\mathcal{Q}|\mathcal{D})$ is known as the *predictive distribution* of the statistic $\mathcal{Q}[\cdot]$ given \mathcal{D} . The uncertainty in $p(\mathcal{Q}|\mathcal{D})$ corresponds to the *epistemic uncertainty* induced by one's limited-data budget. The Bayesian approach is the only one that can naturally characterize this epistemic uncertainty.

Equation (15.17) applies generically to any Bayesian surrogate and to any statistic $\mathcal{Q}[\cdot]$. For the case of a Gaussian process surrogate, it is possible to develop semi-analytic approximations to Equation (15.17) when $\mathcal{Q}[\cdot]$ is the mean or the variance of the response. However, in general one has to think of Equation (15.17) in a generative manner in the sense that it enables sampling of possible statistics in a two-step procedure:

1. Sample a $\boldsymbol{\theta}$ from $p(\boldsymbol{\theta}|\mathcal{D})$ of Equation (15.15).
2. Evaluate $\mathcal{Q}[\hat{\mathbf{f}}(\cdot; \boldsymbol{\theta})]$.

2.5 Gaussian Process Regression

For simplicity, the section starts by developing the theory for one-dimensional outputs, i.e., $n_y = 1$.

2.5.1 Modeling Prior Knowledge About the Response

An experienced scientist or engineer has some knowledge about the response function, $f(\cdot)$, even before running any simulations. For example, he might know that $f(\cdot)$ cannot exceed, or be smaller than, certain values, that it satisfies translation invariance, that it is periodic along certain inputs, etc. This knowledge is known as *prior knowledge*.

Prior knowledge can be *precise*, e.g., the response is exactly twice differentiable, the period of the first input is 2π , etc., or it can be *vague*, e.g., the probability that the period T takes any particular value is $p(T)$, the probability that the length-scale ℓ_1 of the first input takes any particular value is $p(\ell_1)$, etc. When one is dealing with vague prior knowledge, he may refer to it as *prior belief*. Almost always, one's prior knowledge about a computer code is a prior belief.

Prior knowledge about $f(\cdot)$ can be modeled by a probability measure on the space of functions from \mathcal{X} to \mathbb{R} . This probability measure encodes one's prior

beliefs, in the sense that it assigns probability one to the set of functions that are consistent with it. A Gaussian process is a great way to represent this probability measure.

A Gaussian process is a generalization of a multivariate Gaussian random variable to infinite dimensions [39]. In particular, $f(\cdot)$ is a Gaussian process with *mean function* $m : \mathcal{X} \rightarrow \mathbb{R}$ and *covariance function* $k : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$, i.e.,

$$f(\cdot) \sim \text{GP}(f(\cdot)|m(\cdot), k(\cdot, \cdot)), \quad (15.18)$$

if and only if for any collection of input points $\mathbf{X} = \{\mathbf{x}_1, \dots, \mathbf{x}_n\} \subset \mathcal{X}$, the corresponding outputs $\mathbf{Y} = \{y_1 = f(\mathbf{x}_1), \dots, y_n = f(\mathbf{x}_n)\}$ are distributed according to:

$$\mathbf{Y}|\mathbf{X} \sim \mathcal{N}_n(\mathbf{Y}|\mathbf{m}(\mathbf{X}), \mathbf{k}(\mathbf{X}, \mathbf{X})), \quad (15.19)$$

where $\mathbf{m}(\mathbf{X}) = (m(\mathbf{x}_i))_i$, $\mathbf{k}(\mathbf{X}, \mathbf{X}') = (k(\mathbf{x}_i, \mathbf{x}'_j))_{ij}$, and $\mathcal{N}_n(\cdot|\boldsymbol{\mu}, \boldsymbol{\Sigma})$ are the probability density function of a n -dimensional multivariate normal random variable with mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$.

But how does Equation (15.18) encode one's prior knowledge about the code? It does so through the choice of the mean and the covariance functions. The mean function can be an arbitrary function. Its role is to encode any generic trends about the response. The covariance function can be any semi-positive-definite function. It is used to model the signal strength of the response and how it varies across \mathcal{X} , the similarity (correlation) of the response at two distinct input points, noise, regularity, periodicity, invariance, and more. The choice of mean and covariance functions is discussed more elaborately in what follows.

Vague prior knowledge, i.e., prior beliefs, may be modeled by parameterizing the mean and covariance functions and assigning prior probabilities to their parameters. In particular, the following generic forms for the mean and covariance functions are considered:

$$m : \mathcal{X} \times \Psi_m \rightarrow \mathbb{R}, \quad (15.20)$$

and

$$k : \mathcal{X} \times \mathcal{X} \times \Psi_k \rightarrow \mathbb{R}, \quad (15.21)$$

respectively. Here

$$\Psi_m \subset \mathbb{R}^{d_m} \text{ and } \Psi_k \subset \mathbb{R}^{d_k}, \quad (15.22)$$

and for all $\boldsymbol{\psi}_k \in \Psi_k$ the function $k(\cdot, \cdot; \boldsymbol{\psi}_k)$ is positive definite. The parameters $\boldsymbol{\psi}_m \in \Psi_m$ and $\boldsymbol{\psi}_k \in \Psi_k$, of the mean and covariance functions, respectively, are

known as *hyper-parameters* of the model. Using this notation, the most general model considered in this work is:

$$f(\cdot) | \psi_m, \psi_k \sim \text{GP}(f(\cdot) | m(\cdot; \psi_m), k(\cdot, \cdot; \psi_k)), \quad (15.23)$$

$$\psi_m \sim p(\psi_m), \quad (15.24)$$

$$\psi_k \sim p(\psi_k). \quad (15.25)$$

For notational economy one writes:

$$\psi := \{\psi_m, \psi_k\}, \quad (15.26)$$

and

$$p(\psi) := p(\psi_m)p(\psi_k). \quad (15.27)$$

Choosing the Mean Function

The role of the mean function is to model one's prior beliefs about the existence of systematic trends. One of the most common choices for the mean function is the *generalized linear model*:

$$m(\mathbf{x}; \mathbf{b}) = \mathbf{b}^T \mathbf{h}(\mathbf{x}), \quad (15.28)$$

where $\mathbf{h} : \mathbb{R}^d \rightarrow \mathbb{R}^{d_h}$ is an arbitrary function and $\mathbf{b} =: \psi_m \in \Psi_m = \mathbb{R}^{d_m}$, $d_m = d_h$, are the hyper-parameters known as *weights*. A popular prior for the weights, \mathbf{b} , is the improper, “non-informative,” uniform:

$$p(\psi_m) = p(\mathbf{b}) \propto 1. \quad (15.29)$$

Another commonly used prior is the multivariate normal:

$$p(\mathbf{b} | \mu_{\mathbf{b}}, \Sigma_{\mathbf{b}}) = \mathcal{N}_{d_m}(\mathbf{b} | \mu_{\mathbf{b}}, \Sigma_{\mathbf{b}}), \quad (15.30)$$

where $\mu_{\mathbf{b}} \in \mathbb{R}^{d_m}$, and $\Sigma_{\mathbf{b}} \in \mathbb{R}^{d_m \times d_m}$ is positive definite. It can be shown that in both choices, Equation (15.29) or Equation (15.30), it is actually possible to integrate \mathbf{b} out of the model [15]. Some examples of generalized linear models are:

1. The *constant* mean function, $d_h = 1$,

$$\mathbf{h}(\mathbf{x}) = 1; \quad (15.31)$$

2. The *linear* mean function, $d_h = d + 1$,

$$\mathbf{h}(\mathbf{x}) = (1, x_1, \dots, x_d); \quad (15.32)$$

3. The *generalized polynomial chaos* (gPC) mean function in which $\mathbf{h}(\cdot) = (h_1(\cdot), \dots, h_{d_h}(\cdot))$, with the $h_i : \mathbb{R}^d \rightarrow \mathbb{R}, i = 1, \dots, d_h$ being polynomials with degree up to ρ and orthogonal with respect to a measure $\mu(\cdot)$, i.e.

$$\int h_i(x)h_j(x)d\mu(x) = \delta_{ij}. \quad (15.33)$$

For uncertainty propagation applications, $\mu(\cdot)$ is usually a probability measure. For many well-known probability measures, the corresponding gPC is known [53]. For arbitrary probability measures, the polynomials can only be constructed numerically, e.g., [24]. Excellent Fortran code for the construction of orthogonal polynomials can be found in [25]. An easy-to-use Python interface is available by Bilionis [6].

4. The *Fourier* mean function defined for $d = 1$ in which $\mathbf{h}(\cdot) = (h_1(\cdot), \dots, h_{d_h}(\cdot))$, with the $h_i : \mathbb{R} \rightarrow \mathbb{R}, i = 1, \dots, d_h$ being trigonometric functions supporting certain frequencies ω_i , i.e.,

$$h_{2i}(x) = \sin(\omega_i x), \text{ and } h_{2i+1}(x) = \cos(\omega_i x). \quad (15.34)$$

Choosing the Covariance Function

Discussing the choice of the covariance function in great depth is beyond the scope of the chapter. Instead, the interested reader is pointed to the excellent account by Rasmussen and Williams [39]. Here, some remarkable aspects that relate directly to representing prior beliefs for computer codes are discussed:

1. Modeling measurement noise. Assume that measurements of $f(\mathbf{x})$ are noisy and that this noise is Gaussian with variance σ^2 . GPs can account for this fact if one adds a Kronecker delta-like function to the covariance, i.e., if one works with a covariance of the form:

$$k(\mathbf{x}, \mathbf{x}'; \boldsymbol{\psi}_k) = k_0(\mathbf{x}, \mathbf{x}'; \boldsymbol{\psi}_{k_0}) + \sigma^2 \delta(\mathbf{x} - \mathbf{x}'). \quad (15.35)$$

Note that $\delta(\mathbf{x} - \mathbf{x}')$ here is one if and only if \mathbf{x} and \mathbf{x}' correspond to exactly the same measurement. Even though most computer simulators do not return noisy outputs, some do, e.g., molecular dynamics simulations. So, being able to model noise is useful. Apart from that, it turns out that including a small σ^2 , even when there is no noise, is beneficial because it can improve the stability of the computations. When σ^2 is included for this reason, it is known as a “nugget” or as a “jitter.” In addition to the improved stability, the nugget can also lead to better predictive accuracy [27].

2. Modeling regularity. It can be shown that the regularity properties of the covariance function are directly associated to the regularity of the functions sampled from the probability measure induced by the GP (Equations (15.18) and (15.23)). For example, if $k(\mathbf{x}, \mathbf{x}; \boldsymbol{\psi}_k)$ is continuous at \mathbf{x} , then samples $f(\cdot)$ from Equation (15.23) are continuous almost surely (a.s.) at \mathbf{x} . If $k(\mathbf{x}, \mathbf{x}; \boldsymbol{\psi})$ is ρ

times differentiable at \mathbf{x} , then samples $f(\cdot)$ from Equation (15.23) are ρ times differentiable a.s. at \mathbf{x} .

3. Modeling invariance. If $k(\cdot, \cdot; \psi_k)$ is invariant with respect to a transformation T , i.e., $k(\mathbf{x}, T\mathbf{x}'; \psi_k) = k(T\mathbf{x}, \mathbf{x}'; \psi_k) = k(\mathbf{x}, \mathbf{x}'; \psi_k)$, then samples $f(\mathbf{x})$ from Equation (15.23) are invariant with respect to the same transformation a.s. In particular, if $k(\cdot, \cdot; \psi)$ is periodic, then samples $f(\mathbf{x})$ from Equation (15.23) are periodic a.s.
4. Modeling additivity. Assume that the covariance function is additive, i.e.,

$$k(\mathbf{x}, \mathbf{x}'; \psi_k) = \sum_{i=1}^d k_i(x_i, x'_i; \psi_{k_i}) + \sum_{1 \leq i < j \leq d} k_{ij}((x_i, x_j), (x'_i, x'_j); \psi_{k_{ij}}) + \dots, \quad (15.36)$$

with $\psi_k = \{\psi_{k_i}\} \cup \{\psi_{k_{ij}}\}$. If $f_i(\mathbf{x}), f_{ij}(\mathbf{x}), \dots$ are samples from Equation (15.23) with covariances $k_i(\cdot, \cdot; \psi_{k_i}), k_{ij}(\cdot, \cdot; \psi_{k_{ij}}), \dots$, respectively, then

$$f(\mathbf{x}) = \sum_{i=1}^d f_i(x_i) + \sum_{1 \leq i < j \leq d} f_{ij}(x_i, x_j) + \dots,$$

is a sample from Equation (15.23) with the additive covariance defined in Equation (15.36). These ideas can be used to deal effectively with high-dimensional inputs [22, 23].

The most commonly used covariance function for representing one's prior knowledge about a computer code is of the form of Equation (15.35) with $k_0(\cdot, \cdot; \psi_{k_0})$ being the squared exponential (SE) covariance function:

$$k_0(\mathbf{x}, \mathbf{x}'; \psi_{k_0}) = s^2 \exp \left\{ - \sum_{i=1}^d \frac{(x_i - x'_i)^2}{2\ell_i^2} \right\}, \quad (15.37)$$

where $\psi_{k_0} = \{s, \ell_1, \dots, \ell_d\}$. Note that $s > 0$ may be interpreted as the *signal strength* and $\ell_i > 0$ as the *length scale* of the $i = 1, \dots, d$ input dimension. Prior beliefs about $\psi_k = \{\sigma^2\} \cup \{\psi_{k_0}\}$ are modeled by:

$$p(\psi_k) = p(\sigma)p(\psi_{k_0}), \quad (15.38)$$

with

$$p(\psi_{k_0}) = p(s) \prod_{i=1}^d p(\ell_i). \quad (15.39)$$

Typically, $p(\sigma), p(s), p(\ell_1), \dots, p(\ell_d)$ are chosen to be Jeffreys priors or exponential probability densities with fixed parameters.

2.5.2 Conditioning on Observations of the Response

As seen in the previous section, one's prior knowledge about the response can be modeled in terms of a generic GP defined by Equations (15.23), (15.24), and (15.25). Now, assume that one makes n simulations at inputs $\mathbf{x}_1, \dots, \mathbf{x}_n$ and that he observes the responses $y_1 = f(\mathbf{x}_1), \dots, y_n = f(\mathbf{x}_n)$. Write $\mathbf{X} = \{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ and $\mathbf{Y} = \{y_1, \dots, y_n\}$ for the observed inputs and outputs, respectively. Abusing the mathematical notation slightly, the symbol \mathcal{D} is used to denote \mathbf{X} and \mathbf{Y} collectively (see Equation (15.14)). We refer to \mathcal{D} as the (*observed*) data. How does the observation of \mathcal{D} alter one's state of knowledge about the response surface?

The answer to the aforementioned question comes after a straightforward application of Bayes rule and use of Kolmogorov's theorem on the existence of random fields. One's state of knowledge is characterized by a new GP,

$$f(\cdot) | \mathcal{D}, \psi \sim \text{GP}\left(f(\cdot) | m^*(\cdot; \psi, \mathcal{D}), k^*(\cdot, \cdot; \psi, \mathcal{D})\right), \quad (15.40)$$

with mean function:

$$m^*(\mathbf{x}; \psi, \mathcal{D}) := m(\mathbf{x}; \psi_m) + \mathbf{k}(\mathbf{x}, \mathbf{X}; \psi_k) \mathbf{k}(\mathbf{X}, \mathbf{X}; \psi_k)^{-1} (\mathbf{Y} - \mathbf{m}(\mathbf{X}; \psi_m)), \quad (15.41)$$

covariance function:

$$k^*(\mathbf{x}, \mathbf{x}'; \psi, \mathcal{D}) := k(\mathbf{x}, \mathbf{x}'; \psi_k) - \mathbf{k}(\mathbf{x}, \mathbf{X}; \psi_k) \mathbf{k}(\mathbf{X}, \mathbf{X}; \psi_k)^{-1} \mathbf{k}(\mathbf{X}, \mathbf{x}'; \psi_k), \quad (15.42)$$

and the *posterior* of the hyper-parameters:

$$p(\psi | \mathcal{D}) = \frac{p(\mathcal{D} | \psi) p(\psi)}{p(\mathcal{D})}, \quad (15.43)$$

where

$$p(\mathcal{D} | \psi) := p(\mathbf{Y} | \mathbf{X}, \psi) = \mathcal{N}_n(\mathbf{Y} | \mathbf{m}(\mathbf{X}; \psi_m), \mathbf{k}(\mathbf{X}, \mathbf{X}; \psi_m)), \quad (15.44)$$

is the *likelihood* of \mathcal{D} induced by the defining property of the GP (Equation (15.19)) and $p(\mathcal{D}) = \int p(\mathcal{D} | \psi) p(\psi) d\psi$ the evidence.

2.5.3 Treating Space and Time by Using Separable Mean and Covariance Functions

The input \mathbf{x} may include spatial \mathbf{x}_s ; time, t ; and stochastic, ξ , components (see Equation (15.1)). A computer code reports the response for a given ξ (see Equation (15.7)) at a fixed set of n_s spatial locations, \mathbf{X}_s , and n_t time instants \mathbf{X}_t (see Equations (15.4) and (15.5), respectively). Now suppose that n_ξ observations of ξ are to be made. Then, the size of the covariance matrix $\mathbf{k}(\mathbf{X}, \mathbf{X}; \psi_k)$ used in Equation (15.19) becomes $(n_\xi n_s n_t) \times (n_\xi n_s n_t)$. Since the cost of inference and prediction is $O((n_s n_t n_\xi)^3)$, one encounters insurmountable computational issues even for moderate values of n_ξ, n_s , and n_t . In an attempt to remedy this problem,

simplifying assumptions must be made. Namely, one has to assume that the mean is a generalized linear model (see Equation (15.28)) with a *separable* set of basis functions, $\mathbf{h}(\cdot)$, and that the covariance function is also separable.

The mean function $\mathbf{h} : \mathcal{X}_s \times \mathcal{X}_t \times \mathcal{X}_\xi \rightarrow \mathbb{R}^{d_h}$ is separable if it can be written as:

$$\mathbf{h}(\mathbf{x}) = \mathbf{h}_s(\mathbf{x}_s) \otimes \mathbf{h}_t(t) \otimes \mathbf{h}_\xi(\xi), \quad (15.45)$$

where “ \otimes ” denotes the Kronecker product, $\mathbf{h}_s : \mathcal{X}_s \rightarrow \mathbb{R}^{d_{h_s}}$, $\mathbf{h}_t : \mathcal{X}_t \rightarrow \mathbb{R}^{d_{h_t}}$, and $\mathbf{h}_\xi : \rightarrow \mathbb{R}^{d_{h_\xi}}$, with $d_h = d_{h_s} d_{h_t} d_{h_\xi}$.

The covariance function, $k : \mathcal{X}_s \times \mathcal{X}_t \times \mathcal{X}_\xi \rightarrow \mathbb{R}$, is separable if it can be written as:

$$k(\mathbf{x}, \mathbf{x}'; \boldsymbol{\psi}_k) = k_s(\mathbf{x}_s, \mathbf{x}'_s; \boldsymbol{\psi}_{k,s}) k_t(t, t'; \boldsymbol{\psi}_{k,t}) k_\xi(\xi, \xi'; \boldsymbol{\psi}_{k,\xi}), \quad (15.46)$$

where $k_s(\cdot, \cdot; \boldsymbol{\psi}_{k,s})$, $k_t(\cdot, \cdot; \boldsymbol{\psi}_{k,t})$, and $k_\xi(\cdot, \cdot; \boldsymbol{\psi}_{k,\xi})$ are spatial, time, and stochastic domain covariance functions, respectively; $\boldsymbol{\psi}_{k,s}$, $\boldsymbol{\psi}_{k,t}$, and $\boldsymbol{\psi}_{k,\xi}$ are the corresponding hyper-parameters; and $\boldsymbol{\psi}_k = \{\boldsymbol{\psi}_{k,s}, \boldsymbol{\psi}_{k,t}, \boldsymbol{\psi}_{k,\xi}\}$. Then, as shown in Bilionis et al. [10], the covariance matrix can be written as the Kronecker product of a spatial, a time, and a stochastic covariance, i.e.,

$$\mathbf{k}(\mathbf{X}, \mathbf{X}; \boldsymbol{\psi}_k) = \mathbf{k}_s(\mathbf{X}_s, \mathbf{X}_s; \boldsymbol{\psi}_{k,s}) \otimes \mathbf{k}_t(\mathbf{X}_t, \mathbf{X}_t; \boldsymbol{\psi}_{k,t}) \otimes \mathbf{k}_\xi(\mathbf{X}_\xi, \mathbf{X}_\xi; \boldsymbol{\psi}_{k,\xi}). \quad (15.47)$$

Exploiting the fact that factorizations (e.g., Cholesky or QR) of a matrix formed by Kronecker products are given by the Kronecker products of the factorizations of the individual matrices [47], inference and predictions can be made in $O(n_s^3) + O(n_t^3) + O(n_\xi^3)$ time. For the complete details of this approach, the reader is directed to the appendix of Bilionis et al. [10]. It is worth mentioning that exactly the same idea was used by Stegle et al. [46].

2.5.4 Treating Space and Time by Using Output Dimensionality Reduction

In this section an alternative way to deal with space and time inputs, first introduced by Higdon et al. [30], is presented. Assume that the computer code reports the response at specific spatial locations and time instants exactly as in the previous subsection (see also Equation (15.7)). The idea is to perform a dimensionality reduction on the output matrix $\mathbf{Y} \in \mathbb{R}^{n_\xi \times (n_s n_t)}$,

$$\mathbf{Y} = \begin{pmatrix} \mathbf{f}_c(\xi_1)^T \\ \mathbf{f}_c(\xi_{n_\xi})^T \end{pmatrix}, \quad (15.48)$$

and then learn the map between ξ the reduced variables. For notational convenience, let $n_y = n_s n_t$ denote the number of outputs of the code, $\mathbf{y} \in \mathbb{R}^{n_y}$ the full output, and $\mathbf{z} \in \mathbb{R}^{n_z}$ the reduced output. The choice of the right dimensionality reduction map is an open research problem. Principal component analysis (PCA) [12, Chapter 12] is

going to be used for the identification of the dimensionality reduction map. Consider the empirical covariance matrix $\mathbf{C} \in \mathbb{R}^{n_y \times n_y}$:

$$\mathbf{C} = \frac{1}{n_\xi - 1} \sum_{i=1}^{n_\xi} (\mathbf{Y}_i - \mathbf{m})(\mathbf{Y}_i - \mathbf{m})^T, \quad (15.49)$$

where \mathbf{Y}_i is the i -th row of the output matrix \mathbf{Y} and $\mathbf{m} \in \mathbb{R}^{n_y}$ is the empirical mean of the observed outputs:

$$\mathbf{m} = \frac{1}{n_\xi} \sum_{i=1}^{n_\xi} \mathbf{Y}_i. \quad (15.50)$$

One proceed by diagonalizing \mathbf{C} :

$$\mathbf{C} = \mathbf{V}\mathbf{D}\mathbf{V}^T, \quad (15.51)$$

where $\mathbf{V} \in \mathbb{R}^{n_y \times n_y}$ contains the eigenvectors of \mathbf{C} as columns, and $\mathbf{D} \in \mathbb{R}^{n_y \times n_y}$ is a diagonal matrix with the eigenvalues of \mathbf{C} on its diagonal. The PCA connection between \mathbf{y} and \mathbf{z} (reconstruction map) is given by:

$$\mathbf{y} = \mathbf{V}\mathbf{D}^{1/2}\mathbf{z} + \mathbf{m}. \quad (15.52)$$

In this equation, the reduced outputs corresponding to very small eigenvalues can be eliminated to a very good approximation. Typically, one keeps n_z eigenvalues of \mathbf{C} so that 95%, or more, of the observed variance of \mathbf{y} is explained. This is achieved by removing columns from \mathbf{V} and columns and rows from \mathbf{D} . The inverse of Equation (15.52) (reduction map) is given by:

$$\mathbf{z} = \mathbf{V}^T \mathbf{D}^{-1/2}(\mathbf{y} - \mathbf{m}). \quad (15.53)$$

The map between ξ and the reduced variables \mathbf{z} can be learned by any of the multi-output GP regression techniques to be introduced in subsequent sections.

2.6 Training the Parameters of the Gaussian Process

Training the parameters of a GP requires the characterization of the posterior distribution $p(\psi | \mathcal{D})$. A very general way to describe this posterior is via a *particle approximation*. A particle approximation is a collection of weights, $w^{(s)}$, and samples, $\psi^{(s)}$, with which one may represent the posterior as:

$$p(\psi | \mathcal{D}) \approx \sum_{s=1}^S w^{(s)} \delta(\psi - \psi^{(s)}). \quad (15.54)$$

Here, $w^{(s)} \geq 0$ and $\sum_{s=1}^S w^{(s)} = 1$. The usefulness of Equation (15.54) relies on the fact that it allows one to approximate expectations with respect to $p(\psi|\mathcal{D})$ in a straightforward manner.

$$\mathbb{E}_{\psi}[g(\psi)] := \int g(\psi) p(\psi|\mathcal{D}) d\psi \approx \sum_{s=1}^S w^{(s)} g(\psi^{(s)}). \quad (15.55)$$

There are various ways in which a particle approximation can be constructed. The discussion below includes the most common approaches.

2.6.1 Maximization of the Likelihood

The most widespread approach to training the GP parameters is to obtain a point estimate of the hyper-parameters by maximizing the likelihood of the data as given in Equation (15.44) [39, Ch. 5]. This is known as the maximum likelihood estimator (MLE) of the hyper-parameters:

$$\psi_{\text{MLE}}^* = \arg \max_{\psi \in \Psi} p(\mathcal{D}|\psi). \quad (15.56)$$

The MLE can be thought as single-particle approximation, i.e., $S = 1, w^{(1)} = 1, \psi^{(1)} = \psi_{\text{MLE}}^*$,

$$p(\psi|\mathcal{D}) \approx \delta(\psi - \psi_{\text{MLE}}^*), \quad (15.57)$$

if the prior is relatively flat and the posterior is sharply peaked around ψ_{MLE}^* .

2.6.2 Maximization of the Posterior

If the prior information is not flat but the posterior is expected to be sharply peaked, then it is preferable to use the maximum a posteriori (MAP) estimate of the hyper-parameters:

$$\psi_{\text{MAP}}^* = \arg \max_{\psi \in \Psi} p(\psi|\mathcal{D}), \quad (15.58)$$

where the posterior $p(\psi|\mathcal{D})$ was defined in Equation (15.43). This is also a single-particle approximation:

$$p(\psi|\mathcal{D}) \approx \delta(\psi - \psi_{\text{MAP}}^*). \quad (15.59)$$

2.6.3 Markov Chain Monte Carlo

Markov chain Monte Carlo (MCMC) techniques [29, 31, 33] can be employed to sample from the posterior of Equation (15.43). These techniques result in a series of uncorrelated samples $\psi^{(s)}, s = 1, \dots, S$ from Equation (15.43). The particle approximation is built by picking $w^{(s)} = 1/S, s = 1, \dots, S$. MCMC is useful when the posterior is unimodal.

2.6.4 Sequential Monte Carlo

Sequential Monte Carlo (SMC) is a nonlinear extension of Kalman filters [19, 21]. These algorithms can be also used in order to sample from the posterior of a Bayesian model. For example, Bilionis and Zabaras [9], Bilionis et al. [11], Wan and Zabaras [48] use them to sample from the posterior of a stochastic inverse problem. One introduces a family of probability densities on ψ parameterized by γ :

$$p(\psi | \gamma, \mathcal{D}) \propto p(\psi | \mathcal{D})^\gamma p(\psi). \quad (15.60)$$

Notice that for $\gamma = 0$ one obtains the prior and for $\gamma = 1$ one obtains the posterior. The idea is to start a particle approximation $\left\{ w_0^{(s)}, \psi_0^{(s)} \right\}_{s=1}^S$ from the prior ($\gamma = 0$) which is very easy to sample from and gradually move it to the posterior ($\gamma = 1$). This can be easily achieved if there is an underlying MCMC routine for sampling from Equation (15.60). In addition, the schedule of γ 's can be picked adaptively. The reader is directed to the appendix of Bilionis and Zabaras [9] for the complete details. SMC-based methodologies are suitable for multimodal posteriors. Another very attractive attribute is that they are embarrassingly parallelizable.

2.7 Multi-output Gaussian Processes

In what follows, the treatment of generic d_y -dimensional response functions $\mathbf{f}(\cdot)$ is considered. The collection of all observed outputs is denoted by $\mathbf{Y}_d = (\mathbf{y}_1^T, \dots, \mathbf{y}_n^T) \in \mathbb{R}^{n \times d_y}$. The proper treatment of multiple-outputs in a computationally efficient way is an open research problem. Even though there exist techniques that attempt to capture nontrivial dependencies between the various outputs, e.g., [2, 3, 13, 46], here the focus is on computationally simple techniques that treat outputs as either independent or linearly dependent. These techniques tend to be the easiest to use in practice.

2.7.1 Completely Independent Outputs

In this model the outputs are completely independent, i.e.,

$$\mathbf{f}(\cdot) | \psi \sim \prod_{i=1}^{d_y} \text{GP} \left(f_i(\cdot) | m_i(\cdot; \psi_{m,i}), k_i(\cdot, \cdot; \psi_{k,i}) \right), \quad (15.61)$$

with

$$\psi = \bigcup_{i=1}^{d_y} \{\psi_{m,i}, \psi_{k,i}\}, \quad (15.62)$$

where $m_i(\cdot, \cdot)$, $k_i(\cdot, \cdot)$ are the mean and the covariance function and $\psi_{m,i}$, $\psi_{k,i}$ the parameters of the mean and the covariance function, respectively, of the i -th output of $\mathbf{f}(\cdot)$. The likelihood of the model is:

$$\begin{aligned} p(\mathcal{D} | \psi) &= p(\mathbf{Y} | \mathbf{X}, \psi) \\ &= \prod_{i=1}^{d_y} p(\mathbf{y}_i | \mathbf{X}, \psi_i), \end{aligned} \quad (15.63)$$

where $\psi_i = \{\psi_{m,i}, \psi_{k,i}\}$ and $p(\mathbf{y}_i | \mathbf{X}, \psi_i)$ is a multivariate Gaussian exactly the same as the one in Equation (15.19) with $m_i(\cdot; \psi_{m,i})$ and $k_i(\cdot, \cdot; \psi_{k,i})$ instead of $m(\cdot; \psi_m)$ and $k(\cdot, \cdot; \psi_k)$, respectively. A typical choice of a prior for ψ assumes a priori independence of the various parameters, i.e.,

$$p(\psi) = \prod_{i=1}^{d_y} (p(\psi_{m,i}) p(\psi_{k,i})) . \quad (15.64)$$

There is nothing special about this model. Essentially, it is equivalent to carrying out a Gaussian process regression independently on each one of the outputs.

2.7.2 Independent, but Similar, Outputs

In this model, the outputs are correlated only via the parameters of the covariance function, i.e.,

$$\mathbf{f}(\cdot) | \psi \sim \prod_{i=1}^{d_y} \text{GP}(f_i(\cdot) | m(\cdot; \psi_{m,i}), \psi_{s,i}^2 k(\cdot, \cdot; \psi_k)) , \quad (15.65)$$

with

$$\psi = \{\psi_k\} \cup \bigcup_{i=1}^{d_y} \{\psi_{m,i}, \psi_{s,i}\} , \quad (15.66)$$

where $\psi_{m,i}$ and $\psi_{s,i}$ are the parameters of the mean and the signal strength, respectively, of the i -th outputs, and ψ_k are the parameters of the covariance function shared by all outputs. The likelihood of this model is given by an equation similar to Equation (15.63) with an appropriate mean and covariance function. The prior of ψ is assumed to have an a priori independence structure similar to Equation (15.64). The advantage of this approach compared with the fully independent approach is that all outputs share the same covariance function, and, hence, its computational complexity is the same as that of a single-output Gaussian process regression.

2.7.3 Linearly Correlated Outputs

Conti and O'Hagan [15] introduce a simple multi-output model in which the outputs are correlated using a positive-definite covariance matrix $\Sigma \in \mathbb{R}^{d_y \times d_y}$ via a d_y -dimensional Gaussian random field, i.e.,

$$\mathbf{f}(\cdot) | \psi \sim \text{GP}(\mathbf{f}(\cdot) | \mathbf{m}(\cdot; \psi_m), k(\cdot, \cdot; \psi_k), \Sigma) , \quad (15.67)$$

with

$$\psi = \{\psi_m, \psi_k, \Sigma\} , \quad (15.68)$$

where $\mathbf{m}(\cdot; \psi_m)$ is the mean-vector function with d_y -outputs, and $k(\cdot, \cdot; \psi_k)$ is a common covariance function. Equation (15.67) essentially means that, a priori,

$$\mathbb{E}[\mathbf{f}(\mathbf{x})|\psi] = \mathbf{m}(\mathbf{x}; \psi_m), \quad (15.69)$$

and

$$\mathbb{C}[\mathbf{f}(\mathbf{x}), \mathbf{f}(\mathbf{x}')|\psi] = k(\mathbf{x}, \mathbf{x}'; \psi_k) \Sigma. \quad (15.70)$$

Notice that there is no need to include a signal parameter in the covariance function, since it will be absorbed by Σ . Therefore, in this model, one can identically take the signal strength of the response to be identically equal to one. Equation (15.70) provides the intuitive meaning of Σ as the matrix capturing the linear part of the correlations of the various outputs. In this case, the likelihood is given via a matrix normal [18]:

$$\begin{aligned} p(\mathcal{D}|\psi) &= p(\mathbf{Y}|\mathbf{X}, \psi) \\ &= \mathcal{N}_{n \times d_y} (\mathbf{Y} | \mathbf{m}(\mathbf{X}; \psi_m), \Sigma, \mathbf{k}(\mathbf{X}, \mathbf{X}; \psi_k)). \end{aligned} \quad (15.71)$$

The prior of ψ is assumed to have the form:

$$p(\psi) = p(\psi_m)p(\psi_k)p(\Sigma), \quad (15.72)$$

with the prior of Σ being “non-informative” [15]:

$$p(\Sigma) \propto |\Sigma|^{-\frac{d_y+1}{2}}. \quad (15.73)$$

Alternatively, Σ could follow an inverse Wishart distribution [28]. As shown in [10] and [14], if in addition to the prior assumptions for Σ , the mean $m(\cdot; \psi_m)$ is chosen to be a generalized linear model with a priori flat weights ψ_m , then both Σ and ψ_m can be integrated out of the model analytically. This feature makes inference in this model as computationally efficient as single-output Gaussian process regression (GPR). For the complete details of this approach, the reader is directed to [10].

2.8 Sampling Possible Surrogates

The purpose of this section is to demonstrate how the posterior Gaussian process defined by Equations (15.40) and (15.43) can be represented as $\hat{f}(\cdot; \theta)$, where θ is a finite dimensional random variable with probability density $p(\theta|\mathcal{D})$. There are two ways in which this can be achieved. The first way is based on a truncated Karhunen-Loëve expansion [26, 32, 45] (KLE) of the Equation (15.40). The second way is

based on the idea introduced in O'Hagan et al. [38], further discussed in Oakley and O'Hagan [34, 35], and revisited in Bilionis et al. [10] as well as in Chen et al. [14]. In both approximations, $\hat{f}(\cdot; \boldsymbol{\theta})$ is given *analytically*. In particular, it can be expressed as

$$\hat{f}(\mathbf{x}; \boldsymbol{\theta}) = m^*(\mathbf{x}; \boldsymbol{\psi}) + \mathbf{k}^*(\mathbf{x}, \mathbf{X}_d; \boldsymbol{\psi}) \mathbf{C}(\boldsymbol{\psi}) \boldsymbol{\omega}, \quad (15.74)$$

where $m^*(\cdot; \boldsymbol{\psi})$ is the posterior mean given in Equation (15.41) and $\mathbf{k}^*(\mathbf{x}, \mathbf{X}_d; \boldsymbol{\psi})$ is the posterior cross covariance, defined generically via

$$\mathbf{k}^*(\mathbf{X}, \mathbf{X}'; \boldsymbol{\psi}) := \begin{pmatrix} k^*(\mathbf{x}_1, \mathbf{x}'_1; \boldsymbol{\psi}) & \dots & k^*(\mathbf{x}_1, \mathbf{x}'_{n'}; \boldsymbol{\psi}) \\ \vdots & \ddots & \vdots \\ k^*(\mathbf{x}_n, \mathbf{x}'_1; \boldsymbol{\psi}) & \dots & k^*(\mathbf{x}_n, \mathbf{x}'_{n'}; \boldsymbol{\psi}) \end{pmatrix}, \quad (15.75)$$

with $k^*(\cdot, \cdot; \boldsymbol{\psi})$ being the posterior covariance defined in Equation (15.42). The parameters $\boldsymbol{\theta}$ that characterize the surrogate surface $\hat{f}(\mathbf{x}; \boldsymbol{\theta})$ are:

$$\boldsymbol{\theta} = \{\boldsymbol{\psi}, \boldsymbol{\omega}\}, \quad (15.76)$$

with

$$\boldsymbol{\omega} = (\omega_1, \dots, \omega_{d_\omega}), \quad (15.77)$$

being distributed as a standard normal random vector, i.e.,

$$p(\boldsymbol{\omega}) = \mathcal{N}_{d_\omega}(\boldsymbol{\omega} | \mathbf{0}_{d_\omega}, \mathbf{I}_{d_\omega}). \quad (15.78)$$

The posterior probability density of $\boldsymbol{\theta}$, $p(\boldsymbol{\theta} | \mathcal{D})$, is given by:

$$p(\boldsymbol{\theta} | \mathcal{D}) = p(\boldsymbol{\psi} | \mathcal{D}) p(\boldsymbol{\omega}), \quad (15.79)$$

with $p(\boldsymbol{\psi} | \mathcal{D})$ being the posterior of the hyper-parameters (see Equation (15.43)). The matrix

$$\mathbf{X}_d = (\mathbf{x}_{d,1}^T \dots \mathbf{x}_{d,n_d}^T)^T, \quad (15.80)$$

contains n_d *design* points in \mathcal{X} , and $\mathbf{C}(\boldsymbol{\psi}) \in \mathbb{R}^{n_d \times d_\omega}$ is a matrix that corresponds to a factorization of the posterior covariance function of Equation (15.43) over the design points \mathbf{X}_d . The optimal choice of the design points, \mathbf{X}_d , is an open research problem. Below, some heuristics are provided. These depend on how one actually constructs the various quantities of Equation (15.74).

2.8.1 The Karhunen-Loève Approach for Constructing $\hat{f}(\cdot; \theta)$

Let $\omega_\ell, \ell = 1, \dots$ be standard normal random variables. Consider the eigenvalues $\lambda_i(\psi)$ and eigenfunctions $\phi_\ell(\cdot; \psi)$ of the posterior covariance function $k^*(\cdot, \cdot; \psi)$ of Equation (15.42). That is:

$$\int k^*(\mathbf{x}, \mathbf{x}'; \psi) \phi_\ell(\mathbf{x}; \psi) d\mathbf{x} = \lambda_\ell(\psi) \phi_\ell(\mathbf{x}; \psi), \quad (15.81)$$

for $\ell = 1, \dots$. Then, the posterior Gaussian process defined by Equation (15.40) can be written as:

$$\hat{f}(\mathbf{x}; \psi, \omega_1, \dots) = m^*(\mathbf{x}; \psi) + \sum_{\ell=1}^{\infty} \omega_\ell \sqrt{\lambda_\ell(\psi)} \phi_\ell(\mathbf{x}; \psi). \quad (15.82)$$

Typically, one truncates the series to a finite-order d_ω and writes

$$\hat{f}(\mathbf{x}; \theta) = m^*(\mathbf{x}; \psi) + \sum_{\ell=1}^{d_\omega} \omega_\ell \sqrt{\lambda_\ell(\psi)} \phi_\ell(\mathbf{x}; \psi), \quad (15.83)$$

where θ and ω are as in Equations (15.76) and (15.77), respectively. The probability density of θ , $p(\theta | \mathcal{D})$, is defined via Equations (15.79) and (15.78).

Equation (15.81) is a Fredholm integral eigenvalue problem. In general, this equation cannot be solved analytically. A very recent study of the numerical techniques that can be used for the solution of this problem can be found in Betz et al. [5]. This work relies on the Nyström approximation [20, 40] and follows Betz et al. [5] closely in its development.

Start by approximating the integral on the left-hand side of Equation (15.81) by

$$\sum_{j=1}^{n_d} w_j k^*(\mathbf{x}, \mathbf{x}_{d,j}; \psi) \phi_\ell(\mathbf{x}_{d,j}; \psi) \approx \lambda_\ell(\psi) \phi_\ell(\mathbf{x}; \psi), \quad (15.84)$$

where $\{\mathbf{x}_{d,j}, w_j\}_{j=1}^{n_d}$ is a suitable quadrature rule. Notice that in this approximation the design points of Equation (15.80) correspond to the quadrature points. The simplest quadrature rule would be a Monte Carlo type of rule, in which the points $\mathbf{x}_{d,j}$ are randomly picked in \mathcal{X} and $w_j = \frac{1}{n_d}$. Other choices could be based on tensor products of one-dimensional rules or a sparse grid quadrature rule [44]. As shown later on, for the special – but very common – case of a separable covariance function, the difficulty of the problem can be reduced dramatically.

The next step in the Nyström approximation is to solve Equation (15.84) at the quadrature points:

$$\sum_{j=1}^{n_d} w_j k^*(\mathbf{x}_{d,i}, \mathbf{x}_{d,j}; \psi) \phi_\ell(\mathbf{x}_{d,j}; \psi) \approx \lambda_\ell(\psi) \phi_\ell(\mathbf{x}_{d,i}; \psi), \quad (15.85)$$

for $i = 1, \dots, n_d$. Therefore, one needs to solve the generalized eigenvalue problem:

$$\mathbf{k}^*(\mathbf{X}_d, \mathbf{X}_d; \boldsymbol{\psi}) \mathbf{W} \mathbf{v}_\ell = \lambda_\ell \mathbf{v}_\ell, \quad (15.86)$$

where $k^*(\mathbf{X}_d, \mathbf{X}_d; \boldsymbol{\psi})$ is the posterior covariance matrix on the integration points \mathbf{X}_d (see Equation (15.75)), and $\mathbf{W} = \text{diag}(w_1, \dots, w_{n_d})$. It is easy to see that the solution of Equation (15.86) can be obtained by first solving the regular eigenvalue problem

$$\mathbf{B} \tilde{\mathbf{v}}_\ell = \lambda_\ell \tilde{\mathbf{v}}_\ell, \quad (15.87)$$

where

$$\mathbf{B} = \mathbf{W}^{\frac{1}{2}} \mathbf{k}^*(\mathbf{X}_d, \mathbf{X}_d; \boldsymbol{\psi}) \mathbf{W}^{\frac{1}{2}}, \quad (15.88)$$

and noticing that

$$\mathbf{v}_\ell = \frac{1}{\sqrt{w_\ell}} \tilde{\mathbf{v}}_\ell, \quad (15.89)$$

or

$$\phi_\ell(\mathbf{x}_{d,j}; \boldsymbol{\psi}) \approx \frac{1}{\sqrt{w_\ell}} \tilde{\mathbf{v}}_\ell. \quad (15.90)$$

Plugging this into Equation (15.84) and solving for $\phi_\ell(\mathbf{x})$, it is seen that

$$\phi_\ell(\mathbf{x}; \boldsymbol{\psi}) \approx \frac{1}{\lambda_\ell} \sum_{j=1}^{n_d} \sqrt{w_j} \tilde{\mathbf{v}}_{\ell,j} k^*(\mathbf{x}_{d,j}, \mathbf{x}). \quad (15.91)$$

Typically, the KLE is truncated at some $d_\omega \leq n_d$ such that the $\alpha\%$ of the energy of the field is captured, e.g., $\alpha = 90\%$. That is, one may pick d_ω so that:

$$\sum_{\ell=1}^{d_\omega} \lambda_\ell = \alpha \sum_{\ell=1}^{n_d} \lambda_\ell. \quad (15.92)$$

With this choice, the matrix $\mathbf{C}(\boldsymbol{\psi})$, Equation (15.74), is given by:

$$\mathbf{C}(\boldsymbol{\psi}) = \mathbf{W}^{\frac{1}{2}} \tilde{\mathbf{V}} \mathbf{A}^{-\frac{1}{2}}, \quad (15.93)$$

where $\mathbf{A} = \text{diag}(\lambda_1, \dots, \lambda_{d_\omega})$ and $\tilde{\mathbf{V}}$ is the first d_ω eigenvectors of \mathbf{B} of Equation (15.88), i.e.,

$$\tilde{\mathbf{V}} = (\tilde{\mathbf{v}}_1 \dots \tilde{\mathbf{v}}_{d_\omega}), \quad (15.94)$$

is the matrix of the first d_ω eigenvectors as columns.

2.8.2 The O'Hagan Approach for Constructing $\hat{f}(\cdot; \theta)$

Consider the \mathbf{X}_d design points defined in Equation (15.80). Let $\mathbf{Y}_d \in \mathbb{R}^{nd \times 1}$ be the random variable corresponding to the unobserved output of the simulation on the design points \mathbf{X}_d . That is,

$$\mathbf{Y}_d | \mathcal{D}, \psi, \mathbf{X}_d \sim \mathcal{N}_{nd} (\mathbf{Y}_d | \mathbf{m}^*(\mathbf{X}_d; \psi), \mathbf{k}^*(\mathbf{X}_d, \mathbf{X}_d; \psi)), \quad (15.95)$$

where

$$\mathbf{m}^*(\mathbf{X}_d; \psi) = (m^*(\mathbf{x}_{d,1}; \psi) \dots m^*(\mathbf{x}_{d,n_d}; \psi)), \quad (15.96)$$

with $m^*(\cdot; \psi)$ being the posterior mean given defined in Equation (15.41), and

$$\mathbf{k}^*(\mathbf{X}_d, \mathbf{X}_d; \psi) = \begin{pmatrix} k^*(\mathbf{x}_{d,1}, \mathbf{x}_{d,1}; \psi) & \dots & k^*(\mathbf{x}_{d,1}, \mathbf{x}_{d,n_d}; \psi) \\ \vdots & \ddots & \vdots \\ k^*(\mathbf{x}_{d,n}, \mathbf{x}_{d,1}; \psi) & \dots & k^*(\mathbf{x}_{d,n}, \mathbf{x}_{d,n}; \psi) \end{pmatrix}, \quad (15.97)$$

with $k^*(\cdot, \cdot; \psi)$ being the posterior covariance defined in Equation (15.42). Finally, let us condition the posterior Gaussian process of Equation (15.40) on the hypothetical observations $\{\mathbf{X}_d, \mathbf{Y}_d\}$. One has:

$$f(\cdot) | \mathcal{D}, \psi, \mathbf{X}_d, \mathbf{Y}_d \sim \text{GP}(f(\cdot) | \mathbf{m}^{**}(\cdot; \psi, \mathbf{Y}_d), k^{**}(\cdot, \cdot; \psi, \mathbf{Y}_d)), \quad (15.98)$$

where the mean is given by:

$$\mathbf{m}^{**}(\mathbf{x}; \psi, \mathbf{Y}_d) = m^*(\mathbf{x}; \psi) + \mathbf{k}^*(\mathbf{x}, \mathbf{X}_d; \psi) \mathbf{k}^*(\mathbf{X}_d, \mathbf{X}_d; \psi)^{-1} (\mathbf{Y}_d - \mathbf{m}^*(\mathbf{X}_d; \psi)), \quad (15.99)$$

and the covariance is given by:

$$k^{**}(\mathbf{x}, \mathbf{x}'; \psi) = k^*(\mathbf{x}, \mathbf{x}'; \psi) - \mathbf{k}^*(\mathbf{x}, \mathbf{X}_d) \mathbf{k}^*(\mathbf{X}_d, \mathbf{X}_d; \psi)^{-1} \mathbf{k}^*(\mathbf{X}_d, \mathbf{x}). \quad (15.100)$$

The idea of [38] was that if n_d is sufficiently large, then $k^{**}(\mathbf{x}, \mathbf{x}')$ is very small and, thus, negligible. In other words, if \mathbf{X}_d is dense enough, then all the probability mass of Equation (15.98) is accumulated around the mean $\mathbf{m}^{**}(\cdot; \psi, \mathbf{Y}_d)$. Therefore, one may think of the mean $\mathbf{m}^{**}(\cdot; \psi, \mathbf{Y}_d)$ as a sample surface from Equation (15.40).

To make the connection with Equation (15.74), let $\mathbf{L}^*(\psi)$ be the Cholesky decomposition of the covariance $\mathbf{k}^*(\mathbf{X}_d, \mathbf{X}_d; \psi)$, Equation (15.100),

$$\mathbf{k}^*(\mathbf{X}_d, \mathbf{X}_d; \psi) = \mathbf{L}^*(\psi) (\mathbf{L}^*(\psi))^T.$$

From Equation (15.95), one may express \mathbf{Y}_d as

$$\mathbf{Y}_d = \mathbf{m}^*(\mathbf{X}_d; \psi) + \mathbf{L}^*(\psi) \boldsymbol{\omega},$$

for a $\boldsymbol{\omega} \sim \mathcal{N}_{d_\omega}(\boldsymbol{\omega} | \mathbf{0}_{n_d}, \mathbf{I}_{n_d})$. Therefore, one may rewrite Equation (15.99) as:

$$m^{**}(\mathbf{x}; \boldsymbol{\psi}; \boldsymbol{\omega}) = m^*(\mathbf{x}; \boldsymbol{\psi}) + \mathbf{k}^*(\mathbf{x}, \mathbf{X}_d; \boldsymbol{\psi}) (\mathbf{L}^*(\boldsymbol{\psi}))^{T,-1} \boldsymbol{\omega}.$$

From this, the matrix $\mathbf{C}(\boldsymbol{\psi})$ of Equation (15.74) should be:

$$\mathbf{C}(\boldsymbol{\psi}) = (\mathbf{L}^*(\boldsymbol{\psi}))^{T,-1}. \quad (15.101)$$

However, since n_d is expected to be quite large, it is not a good idea to use all n_d design points in \mathbf{X}_d to build a functional sample. Apart from the increased computational complexity, the Cholesky of the large covariance matrix of Equation (15.100) introduces numerical instabilities. A heuristic that can be used to construct a subset of design points, $\mathbf{X}_{d,s}$, from the original, dense, set of design points, \mathbf{X}_d , without sacrificing accuracy, is discussed. The idea is to iteratively select the points of \mathbf{X}_d with maximum variance, until the maximum variance falls below a threshold $\epsilon > 0$. The algorithm is as follows:

1. Start with

$$\mathbf{X}_{d,s} = \{\}.$$

2. If

$$|\mathbf{X}_{d,s}| = n_d,$$

then STOP. Otherwise, CONTINUE.

3. Find

$$i^* = \arg \max_{1 \leq j \leq n_d} k^{**}(\mathbf{x}_{d,i}, \mathbf{x}_{d,i}; \boldsymbol{\psi}, \mathbf{X}_{d,s}),$$

where $k^{**}(\mathbf{x}, \mathbf{x}'; \boldsymbol{\psi}, \mathbf{X}_{d,s})$ is the covariance function defined in Equation (15.100) if $\mathbf{X}_{d,s}$ is used instead of \mathbf{X}_d .

4. If

$$k^{**}(\mathbf{x}_{d,i^*}, \mathbf{x}_{d,i^*}; \boldsymbol{\psi}, \mathbf{X}_{d,s}) > \epsilon,$$

then

$$\mathbf{X}_{d,s} \leftarrow \mathbf{X}_{d,s} \cup \{\mathbf{x}_{d,i^*}\},$$

and GO TO 2. Otherwise, STOP.

Notice that when one includes a new point \mathbf{x}_{d,i^*} , he has to compute the Cholesky decomposition of the covariance matrix $\mathbf{k}^*(\mathbf{X}_{d,s} \cup \{\mathbf{x}_{d,i^*}\}, \mathbf{X}_{d,s} \cup \{\mathbf{x}_{d,i^*}\}; \boldsymbol{\psi})$. This can be done efficiently using rank-one updates of the covariance matrix (see Seeger [43]).

2.9 Semi-analytic Formulas for the Mean and the Variance

It is quite obvious how Equation (15.74) can be used to obtain samples from the predictive distribution, $p(\mathcal{Q}|\mathcal{D})$, of a statistic of interest $\mathcal{Q}[\cdot]$. Thus, using a Monte Carlo procedure, one can characterize one's uncertainty about any statistic of the response surface. This could become computationally expensive in the case of high dimensions and many observations, albeit less expensive than evaluating these statistics using the simulator itself. Fortunately, as shown in this section, it is actually possible to evaluate exactly the predictive distribution for the mean statistic, Equation (15.11), since it turns out to be Gaussian. Furthermore, it is possible to derive the predictive mean and variance of the covariance statistic Equation (15.12). In this subsection, it is shown that the predictive distribution for the mean statistic Equation (15.11) is actually Gaussian.

2.9.1 One-Dimensional Output with No Spatial or Time Inputs

Assume a one-dimensional output $d_y = 1$ and that there are no spatial or time inputs, i.e., $d_s = d_t = 0$. In this case, one has $\mathbf{x} = \xi$, $\mathbf{X}_d = \Xi_d$, and he may simply rewrite Equation (15.74) as:

$$\hat{f}(\xi; \theta) = m^*(\xi; \psi) + \mathbf{k}^*(\xi, \Xi_d; \psi) \mathbf{C}(\psi) \omega, \quad (15.102)$$

where θ , ψ , and ω are as before. Taking the expectation of this over $p(\xi)$, one obtains:

$$\mathbb{E}_{\xi}[\hat{f}(\cdot; \theta)] = \mathbb{E}_{\xi}[m^*(\cdot; \psi)] + \mathbb{E}_{\xi}[\mathbf{k}^*(\xi, \Xi_d; \psi)] \mathbf{C}(\psi) \omega. \quad (15.103)$$

Since ω is a standard normal random variable (see Equation (15.78)), it can be integrated out from Equation (15.103) to give:

$$\mathbb{E}_{\xi}[f(\cdot)|\mathcal{D}, \psi] \sim \mathcal{N}\left(\mathbb{E}_{\xi}[f(\cdot)|\mu_{\mu_f}(\psi), \sigma_{\mu_f}^2(\psi)], \right) \quad (15.104)$$

where

$$\mu_{\mu_f}(\psi) := \mathbb{E}_{\xi}[m^*(\cdot; \psi)], \quad (15.105)$$

and

$$\sigma_{\mu_f}^2(\psi) := \| \mathbf{C}^T(\psi) \epsilon^*(\Xi_d; \psi) \|^2, \quad (15.106)$$

with

$$\epsilon^*(\Xi_d; \psi) := \mathbb{E}_{\xi}[\mathbf{k}^*(\Xi_d, \cdot; \psi)]. \quad (15.107)$$

All these quantities are expressible in terms of expectations of the covariance function with respect to $p(\xi)$:

$$\epsilon(\Xi'; \psi_k) := \mathbb{E}_\xi [\mathbf{k}(\Xi', \cdot; \psi_k)]. \quad (15.108)$$

Indeed, from Equation (15.41) one gets:

$$\mu_{\mu_f}(\psi) = \mathbb{E}_\xi [m(\cdot; \psi_m)] + \epsilon(\Xi; \psi_k)^T \mathbf{k}(\Xi, \Xi; \psi_k)^{-1} (\mathbf{Y} - \mathbf{m}(\Xi; \psi_m)), \quad (15.109)$$

and from Equation (15.42)

$$\epsilon^*(\Xi_d; \psi) = \epsilon(\Xi_d; \psi_k) - \mathbf{k}(\Xi_d, \Xi; \psi_k) \mathbf{k}(\Xi, \Xi; \psi_k)^{-1} \epsilon(\Xi; \psi_k). \quad (15.110)$$

For the case of a SE covariance (see Equation (15.37)) combined with a Gaussian or uniform distribution $p(\xi)$, [34] and [7], respectively, show that Equation (15.108) can be computed analytically. As shown in [8], for the case of an arbitrary separable covariance as well as arbitrary independent random variables ξ , Equation (15.108) can be computed efficiently by doing d_y one-dimensional integrals.

2.9.2 One-Dimensional Output with Spatial and/or Time Inputs

Consider the case of one-dimensional output, i.e., $d_y = 1$, with possible spatial and/or time inputs, i.e., $d_s, d_t \geq 0$. In this generic case, $\mathbf{x} = (\mathbf{x}_s, t, \xi)$.

It is possible to use the particular form of Equation (15.74) to derive semi-analytic formulas for some of the statistics. Let us start by considering the mean statistic. One has

$$\mathbb{E}_\xi [\hat{f}(\cdot; \theta)](\mathbf{x}_s, t) = \mathbb{E}_\xi [m^*(\mathbf{x}_s, t, \xi; \psi)] + \mathbb{E}_\xi [\mathbf{k}^*((\mathbf{x}_s, t, \xi), \mathbf{X}_d; \psi)] \mathbf{C}(\psi) \boldsymbol{\omega}. \quad (15.111)$$

In other words, it has been shown that if $f(\cdot)$ is a Gaussian process, then its mean $\mathbb{E}_\xi [f(\cdot)](\cdot)$ is a Gaussian process:

$$\mathbb{E}_\xi [f(\cdot)](\cdot) | \mathcal{D}, \psi \sim \text{GP}(\mathbb{E}_\xi [f(\cdot)](\cdot) | m_{\text{mean}}(\cdot; \psi), k_{\text{mean}}(\cdot, \cdot; \psi)), \quad (15.112)$$

with mean function:

$$m_{\text{mean}}(\mathbf{x}_s, t) = \mathbb{E}_\xi [m^*(\mathbf{x}_s, t, \xi; \psi)], \quad (15.113)$$

and covariance function:

$$\begin{aligned} k_{\text{mean}}((\mathbf{x}_s, t), (\mathbf{x}'_s, t')) \\ = \mathbb{E}_\xi [\mathbf{k}^*((\mathbf{x}_s, t, \xi), \mathbf{X}_d; \psi)] \mathbf{C}(\psi) \mathbf{C}(\psi)^T \mathbb{E}_\xi [\mathbf{k}^*((\mathbf{x}'_s, t', \xi), \mathbf{X}_d; \psi)]^T. \end{aligned} \quad (15.114)$$

Note, that if the stochastic variables in ξ are independent and the covariance function $k(\mathbf{x}, \mathbf{x}'; \psi)$ is separable with respect to the ξ_i 's, then all these quantities can be computed efficiently with numerical integration.

Equations similar to Equation (15.111) can be derived without difficulty for the covariance statistic of Equation (15.12) as well as for the variance statistic of Equation (15.13) [10, 14]. In contrast to the mean statistic, however, the resulting random field is not Gaussian. That is, an equation similar to Equation (15.112) does not hold.

3 Numerical Examples

3.1 Synthetic One-Dimensional Example

In this synthetic example, the ability of the Bayesian approach to characterize one's state of knowledge about the statistics with a very limited number of observations is demonstrated. To keep things simple, start with no space/time inputs ($d_s = d_t = 0$), one stochastic variable $d_\xi = 0$, and one output $d_y = 0$. That is, the input is just $x = \xi$. Consider $n = 7$ arbitrary observations, $\mathcal{D} = \{(x^{(i)}, y^{(i)})\}_{i=1}^n$, which are shown as crosses in Fig. 15.1a. The goal is to use these seven observations to learn the underlying response function $y = f(x)$ and characterize one's state of knowledge about the mean $\mathbb{E}[f(\cdot)]$ (Equation (15.11)), the variance $\mathbb{V}[f(\cdot)]$ (Equation (15.13)), and the induced probability density function in the response y :

$$p(y) = \int \delta(y - f(x)) p(x) dx,$$

where $p(x)$ is the input probability density, taken to be a Beta(10, 2) and shown in Fig. 15.1b.

The first step is to assign a prior Gaussian process to the response (Equation (15.18)). This is done by picking a zero mean and an SE covariance function (Equation (15.37)) with no nugget, $\sigma^2 = 0$ in Equation (15.35), and fixed signal and length-scale parameters to $s = 1$ and $\ell = 0.1$, respectively. These choices represent one's prior beliefs about the underlying response function $y = f(x)$.

Given the observations in \mathcal{D} , the updated state of knowledge is characterized by the posterior GP of Equation (15.40). The posterior mean function, $m^*(\cdot)$ of Equation (15.41), is the dashed blue line of Fig. 15.1a. The shaded gray area of the same figure corresponds to a 95% predictive interval about the mean. This interval is computed using the posterior covariance function, $k^*(\cdot, \cdot)$ of Equation (15.42). Specifically, the point predictive distribution at x is

$$p(y|x, \mathcal{D}) \sim \mathcal{N}\left(m^*(x), (\sigma^*(x))^2\right),$$

where $\sigma^*(x) = \sqrt{k^*(x, x)}$ and, thus, the 95% predictive interval at x is given, approximately, by $(m^*(x) - 1.96\sigma^*(x), m^*(x) + 1.96\sigma^*(x))$. The posterior mean can be thought of as a point estimation of the underlying response surface.

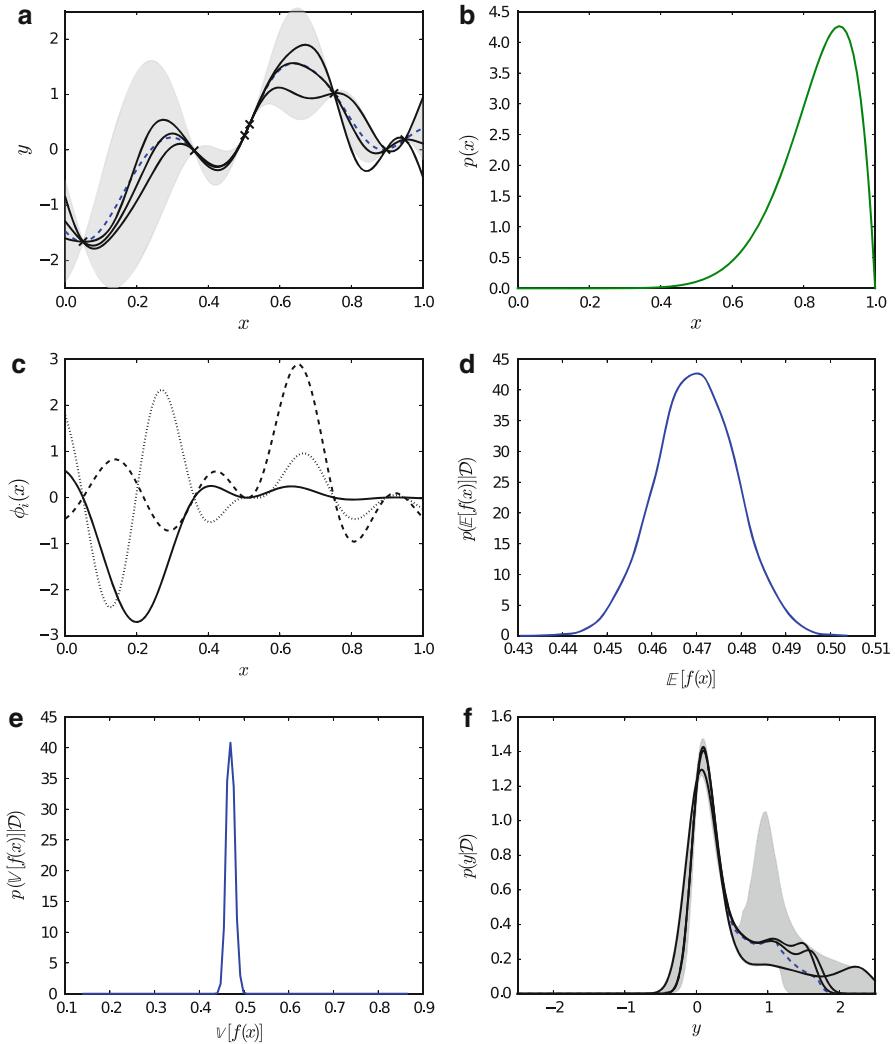

Fig. 15.1 Synthetic: Subfigure (a) shows the observed data (cross symbols), the mean (dashed blue line), the 95% predictive intervals (shaded gray area), and three samples (solid black lines) from the posterior Gaussian process conditioned on the observed data. The green line of subfigure (b) shows the probability density function imposed on the input x . The three lines in subfigure (c) correspond to the first three eigenfunctions used in the KLE of the posterior GP. Subfigures (d) and (e) depict the predictive distribution conditioned on the observations of the mean and the variance statistic of $f(x)$, respectively. Subfigure (f) shows the mean predicted probability density of $y = f(x)$ (blue dashed line) with 95% predictive intervals (shaded gray area), and three samples (solid black lines) from the posterior predictive probability measure on the space of probability densities

In order to sample possible surrogates from Equation (15.40), the Karhunen-Loëve approach for constructing $\hat{f}(\cdot; \theta)$ is followed (see Equations (15.74) and (15.83)), retaining $d_\omega = 3$ eigenfunctions (see Equations (15.81) and (15.91)) of the posterior covariance which account for more than $\alpha = 90\%$ of the energy of the posterior GP (see Equation (15.92)). These eigenfunctions are shown in Fig. 15.1c. Using the constructed $\hat{f}(\cdot; \theta)$, one can sample candidate surrogates. Three such samples are shown as solid black lines in Fig. 15.1a.

Having constructed a finite dimensional representation of the posterior GP, one is in a position to characterize one's state of knowledge about arbitrary statistics of the response, which is captured by Equation (15.17). Here the suggested two-step procedure is followed. That is, candidate surrogates are repeatedly sampled and then the statistic of interest are computed for each sample. In the results presented, 1,000 sampled candidate surrogates are used. Figure 15.1d shows the predictive probability density for the mean of the response $p(\mathbb{E}[f(\cdot)]|\mathcal{D})$. Note that this result can also be obtained semi-analytically using Equation (15.104). Figure 15.1e shows the predictive probability density for the variance of the response $p(\mathbb{V}[f(\cdot)]|\mathcal{D})$, which cannot be approximated analytically. Finally, subfigure (f) of the same figure characterizes the predictive distribution of the PDF of the response $p(y)$. Specifically, the blue dashed line corresponds to the median of the PDFs of each one of the 1,000 sampled candidate surrogates, while the gray shaded area corresponds to a 95% predictive interval around the median. The solid black lines of the same figure are the PDFs of three arbitrary sampled candidate surrogates.

3.2 Dynamical System Example

In this example, the Bayesian approach to uncertainty propagation is applied to a dynamical system with random initial conditions. In particular, the dynamical system [49]:

$$\begin{aligned}\frac{dy_1}{dt} &= y_1 y_3, \\ \frac{dy_2}{dt} &= -y_2 y_3, \\ \frac{dy_3}{dt} &= -y_1^2 + y_2^2,\end{aligned}$$

subject to random uncertain conditions at $t = 0$:

$$y_1(0) = 1, \quad y_2(0) = 0.1\xi_1, \quad y_3(0) = \xi_2,$$

where

$$\xi_i \sim \mathcal{U}([-1, 1]), \quad i = 1, 2,$$

is considered. To make the connection with the notation of this chapter, note that $d_s = 0$, $d_t = 1$, $d_\xi = 2$, and $d_y = 3$. For each choice of ξ , the computer

emulator, $\mathbf{f}_c(\xi)$ of Equation (15.7), reports the response at $n_t = 20$ equidistant time steps in $[0, 10]$, \mathbf{X}_t of Equation (15.5). The result of n_ξ randomly picked simulations is observed, and one wants to characterize his state of knowledge about the statistics of the response. Consider the case of $n_\xi = 70, 100$, and 150 . Note that propagating uncertainty through this dynamical system is not trivial since there exists a discontinuity in the response surface as ξ_1 crosses zero.

The prior GP is picked to be a multi-output GP with linearly correlated outputs, Equation (15.67), with a constant mean function, $h(t, \xi) = 1$, and a separable covariance function, Equation (15.46), with both the time and stochastic covariance functions being SE, Equation (15.37), with nuggets, Equation (15.35). Denote the hyper-parameters of the time and stochastic part of the covariance by $\psi_t = \{\ell_t, \sigma_t\}$ and $\psi_\xi = \{\ell_{\xi,1}, \ell_{\xi,2}, \sigma_\xi\}$, respectively. An exponential prior is assigned to all of them, albeit with different rate parameters. Specifically, the rate of ℓ_t is 2, the rate of $\ell_{\xi,i}, i = 1, 2$ is 20, and the rate of the nuggets σ_t and σ_ξ is 10^6 . This assignment corresponds to the vague prior knowledge that the a priori mean of the time scale is about 0.5 of the time unit, the scale of ξ is about 0.05 of its unit, and the nuggets expected to be around 10^{-6} . According to the comment below Equation (15.70), the signal strength can be picked to be identically equal to one since it is absorbed by the covariance matrix Σ . For the hyper-parameters of the mean function, i.e., the constant number, a flat uninformative prior is assigned. As already discussed, with this choice it is possible to integrate it out of the model analytically.

The model is trained by sampling the posterior of $\psi = \{\psi_t, \psi_\xi\}$ (see Equation (15.43)) using a mixed MCMC-Gibbs scheme (see [10] for a discussion on the scheme and evidence of convergence). After the MCMC chain sufficiently mixed (it takes about 500 iterations), a particle approximation of the posterior state of knowledge about the response surface is constructed. This is done this as follows. For every 100-th step of the MCMC chain (the intermediate 99 steps are dropped to reduce the correlations), 100 candidate surrogates are drawn using the O'Hagan procedure with a tolerance of $\epsilon = 10^{-2}$.

In all plots, the blue solid lines and the shaded gray areas depict the predictive mean and 95% intervals of the corresponding statistics, respectively. The prediction about the time evolution of the mean response, $p(\mathbb{E}[y_i(t)] | \mathcal{D}), i = 1, 3$ for the case of $n_\xi = 100$ observations is shown in the first row of Fig. 15.2. Note that there is very little residual epistemic uncertainty for this prediction. The time evolution of the variance of the response, $p(\mathbb{V}[y_i(t)] | \mathcal{D})$, is shown on the second and third rows of the same figure for $n_\xi = 100$ and $n_\xi = 150$, respectively. Notice how the width of the predictive interval decreases with increasing n_ξ . In Fig. 15.3, the time evolution of the probability density of $y_2(t)$ is summarized. Specifically, the four rows correspond to four different time instants, $t = 4, 6, 8$, and 10 , and the columns refer to different sample sizes of $n_\xi = 70, 100$, and 150 , counting from the left.

3.3 Partial Differential Equation Example

In this example, it is shown how the Bayesian approach to uncertainty propagation can be applied to a partial differential equation. In particular, a two-dimensional

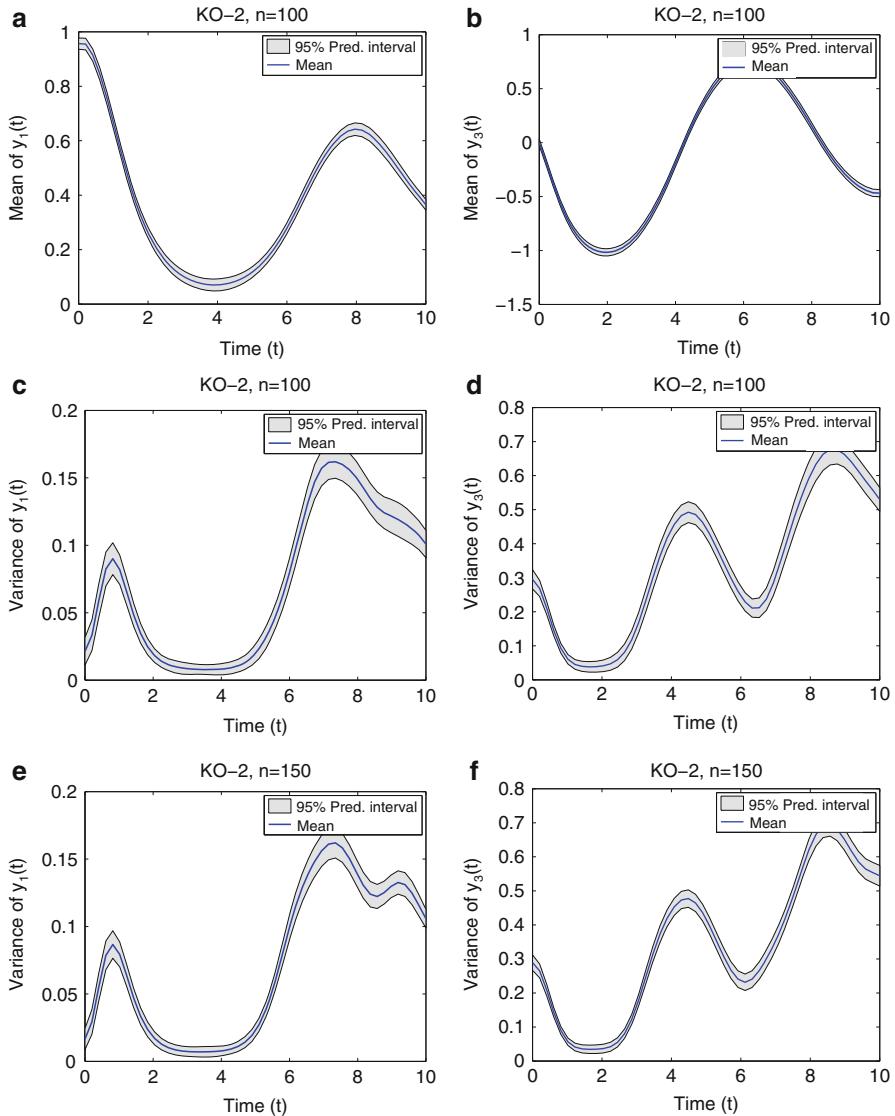

Fig. 15.2 Dynamical system: Subfigures (a) and (b) correspond to the predictions about the mean of $y_1(t)$ and $y_3(t)$, respectively, using $n_\xi = 100$ simulations. Subfigures (c) and (d) (e) and (f) show the predictions about the variance of the same quantities for $n_\xi = 100$ ($n_\xi = 150$) simulations (Reproduced with permission from [10])

($\mathcal{X}_s = [0, 1]^2$ and $d_s = 2$), single-phase, steady-state ($d_t = 0$) flow through an uncertain permeability field is studied; see Aarnes et al. [1] for a review of the underlying physics and solution methodologies. The uncertainty in the permeability is represented by a truncated KLE of an exponentiated Gaussian random field with

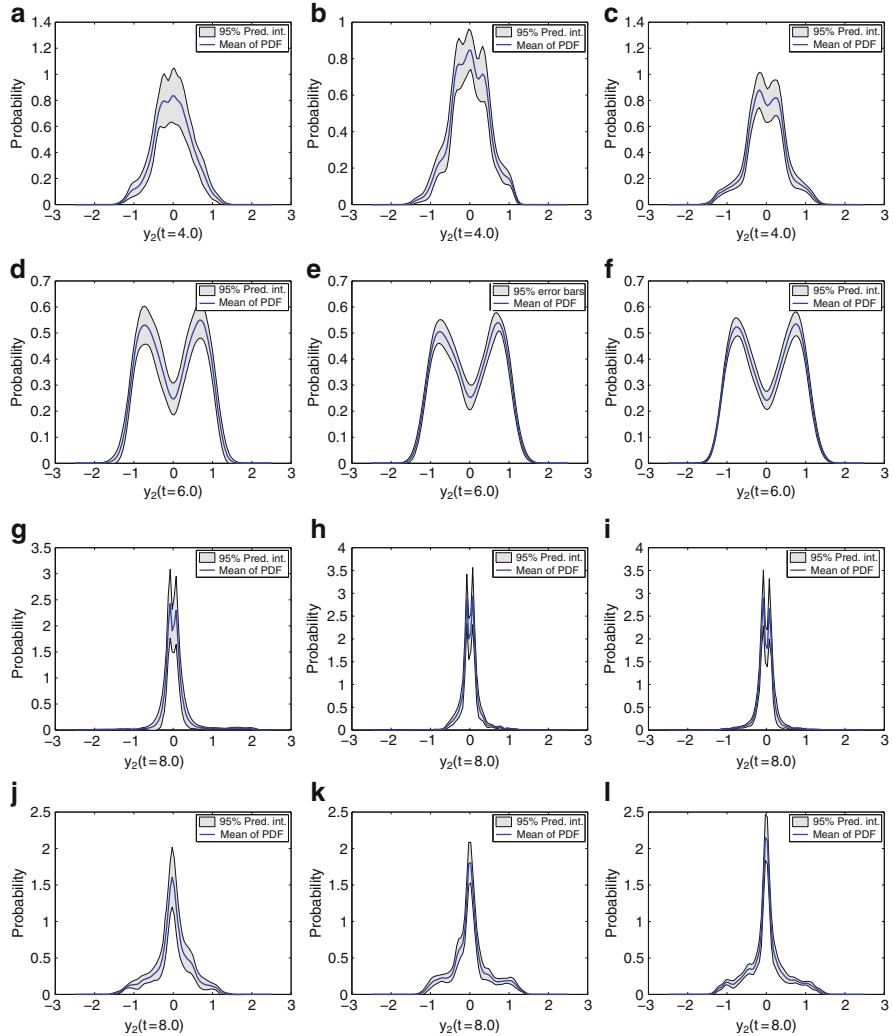

Fig. 15.3 Dynamical system: Columns correspond to results using $n_\xi = 70, 100$, and 150 simulations counting from the left. Counting from the top, rows one, two, three, and four show the predictions about the PDF of $y_2(t)$ at times $t = 4, 6, 8, 10$, respectively (Reproduced with permission from [10])

exponential covariance function of signal strength equal to one and correlation length equal to 0.1 and a zero mean. The total number of stochastic variables corresponds to the truncation order of the KLE, and it is chosen to be $n_\xi = 50$. Three outputs, $d_y = 3$, are considered: the pressure, $p(\mathbf{x}_s; \xi)$, and the horizontal and vertical components of the velocity field, $u(\mathbf{x}_s; \xi)$ and $v(\mathbf{x}_s; \xi)$, respectively. The emulator, $\mathbf{f}_c(\xi)$ of Equation (15.7), is based on the finite element method and is

described in detail in [10], and it reports the response on a regular 32×32 spatial grid, i.e., $n_s = 32^2 = 1,024$. The objective is to quantify the statistics of the response using a limited number of $n_\xi = 24, 64$, and 120 simulations. The results are validated by comparing against a plain vanilla MC estimate of the statistics using 108,000 samples.

As in the previous example, the prior state of knowledge is represented using a multi-output GP with linearly correlated outputs, Equation (15.67); a constant mean function, $h(t, \xi) = 1$; and a separable covariance function, Equation (15.46), with both the space and stochastic covariance functions being SE, Equation (15.37), with nuggets, Equation (15.35). Denote the hyper-parameters of the spatial and stochastic part of the covariance by $\psi_s = \{\ell_{s,1}, \ell_{s,2}, \sigma_s\}$ and $\psi_\xi = \{\ell_{\xi,1}, \dots, \ell_{\xi,50}, \sigma_\xi\}$, respectively. Note that the fact that the spatial component is also separable is exploited to significantly reduce the computational cost of the calculations. Again, exponential priors are assigned. The rate parameters of the spatial length scales are 100 corresponding to an a priori expectation of 0.01 spatial units. The rates of $\ell_{xi,i}, \sigma_s$, and σ_ξ are 3, 100, and 100, respectively.

The posterior of the hyper-parameters, Equation (15.43), is sampled using 100,000 iterations of the same MCMC-Gibbs procedure as in the previous example. However, in order to reduce the computational burden, a single-particle MAP approximation to the posterior, Equation (15.59), is constructed, by searching for the MAP over the 100,000 MCMC-Gibbs samples collected. Then, 100 candidate surrogate surfaces are sampled following the O'Hagan procedure with a tolerance of $\epsilon = 10^{-2}$. For each sampled surrogate, the statistics of interest are calculated and compared to MC estimates.

In Fig. 15.4 the mean prediction is compared to the mean of the horizontal component of the velocity, $u(\mathbf{x}_s; \xi)$ as a function of the spatial coordinates, $\mathbb{E}_\xi[u(\mathbf{x}_s; \xi)]$, conditioned on $n_\xi = 24, 64$, and 120 simulations, subfigures (a), (b), and (c), respectively, to the MC estimate, subfigure (e). The error bars shown in subfigure (d) of the same figure correspond to two standard deviations of the predictive $p(\mathbb{E}_\xi[u(\mathbf{x}_s; \xi)] | \mathcal{D})$ for the case of $n_\xi = 120$ simulations. Figures 15.5 and 15.6 report the same statistic for the y-component of the velocity, $v(\mathbf{x}_s; \xi)$, and the pressure, $p(\mathbf{x}_s; \xi)$, respectively. Similarly, in Figs. 15.7, 15.8, and 15.9, the predictive distributions of the variances of the horizontal component of the velocity, $p(\mathbb{V}[u(\mathbf{x}_s; \xi_s)] | \mathcal{D})$; the vertical component of the velocity, $p(\mathbb{V}[v(\mathbf{x}_s; \xi_s)] | \mathcal{D})$; and the pressure, $p(\mathbb{V}[p(\mathbf{x}_s; \xi_s)] | \mathcal{D})$, respectively, are characterized. Even though one observes an underestimation of the variance, which is more pronounced for the limited simulation cases, the truth is well covered by the predicted error bars.

In Fig. 15.10 the solid blue line and the shaded gray area correspond to the mean of the predictive probability density of the PDF of the horizontal component of the velocity $u(\mathbf{x}_s = (0.5, 0.5); \xi)$, respectively, conditioned on 24 (a), 64 (b), and 120 (c) simulations, and compares it to an MC estimate (d). Notice that the ground truth, i.e., the MC estimate, always falls within the shaded areas. Finally, Figs. 15.11, 15.12, and 15.13 show the predictive distribution of the PDF of $u(\mathbf{x}_s = (0.25, 0.25); \xi)$ and $p(\mathbf{x}_s = (0.25, 0.25); \xi)$, respectively.

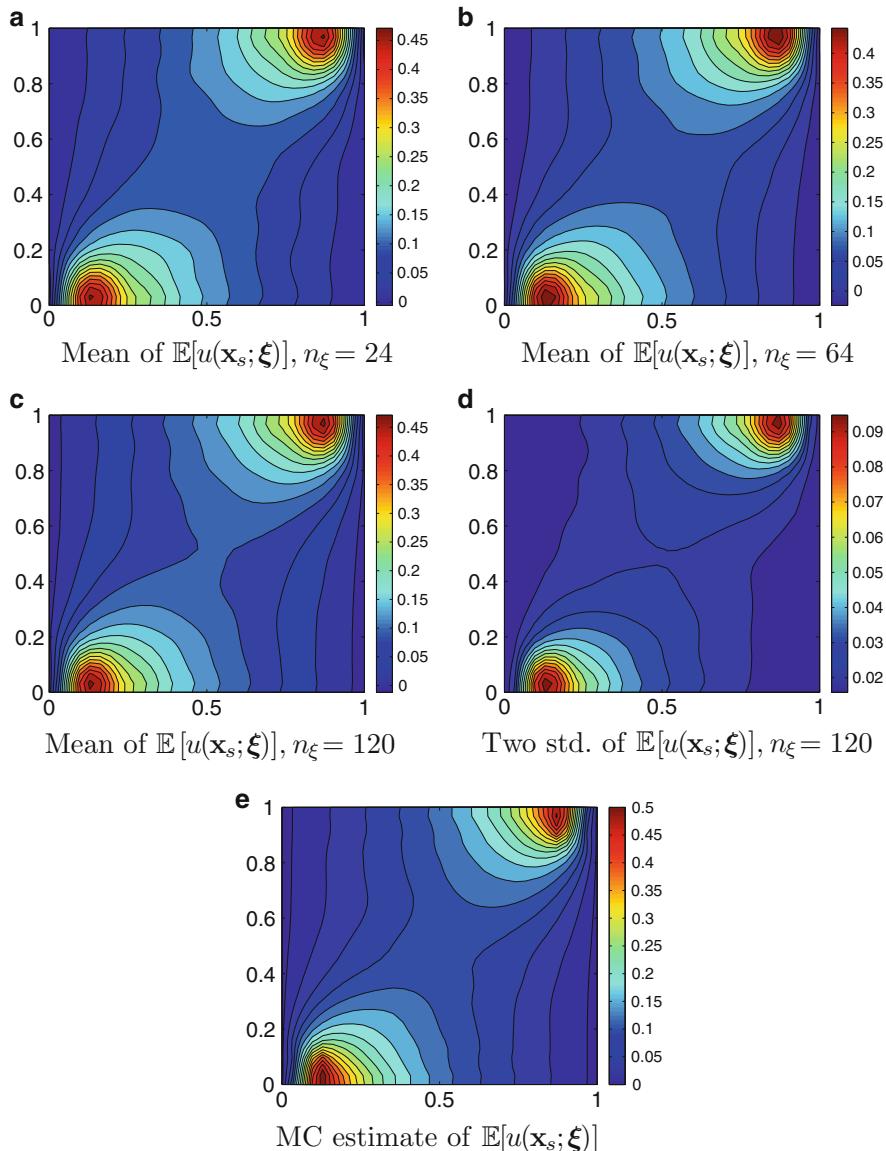

Fig. 15.4 Partial differential equation: Mean of $\mathbb{E}[u(\mathbf{x}_s; \xi)]$. Subfigures (a), (b), and (c) show the predictive mean of $\mathbb{E}[u(\mathbf{x}_s; \xi)]$ as a function of \mathbf{x}_s conditioned on 24, 64, and 120 simulations, respectively. Subfigure (d) plots two standard deviations $\mathbb{E}[u(\mathbf{x}_s; \xi)]$ conditioned on 120 observations. 4 Conclusions

In this chapter we presented a comprehensive review of the Bayesian approach to the UP problem that is able to quantify the epistemic uncertainty induced by limited number of simulations. The core idea was to interpret a GP as a probability measure on the space of surrogates which characterizes our prior state of knowledge about the response surface. We focused on practical aspects of GPs such as the treatment of spatiotemporal variation and multi-output responses. We showed how the prior GP can be conditioned on the observed simulations to obtain a posterior GP, whose probability mass corresponds to the epistemic uncertainty introduced by the limited number of simulations, and we introduced sampling-based techniques that allow for its quantification.

Despite the successes of the current state of the Bayesian approach to the UP problem, there is still a wealth of open research questions. First, carrying out GP regression in high dimensions is not a trivial problem since it requires the development of application-specific covariance functions. The study of covariance functions that automatically perform some kind of internal dimensionality reduction seems to be a promising step forward. Second, in order to capture sharp variations in the response surface, such as localized bumps or even discontinuities, there is a need for flexible nonstationary covariance functions or alternative approaches based on mixtures of GPs, e.g., see [14]. Third, there is a need for computationally efficient ways of treating nonlinear correlations between distinct model outputs, since this is expected to squeeze more information out of the simulations. Fourth, as a semi-

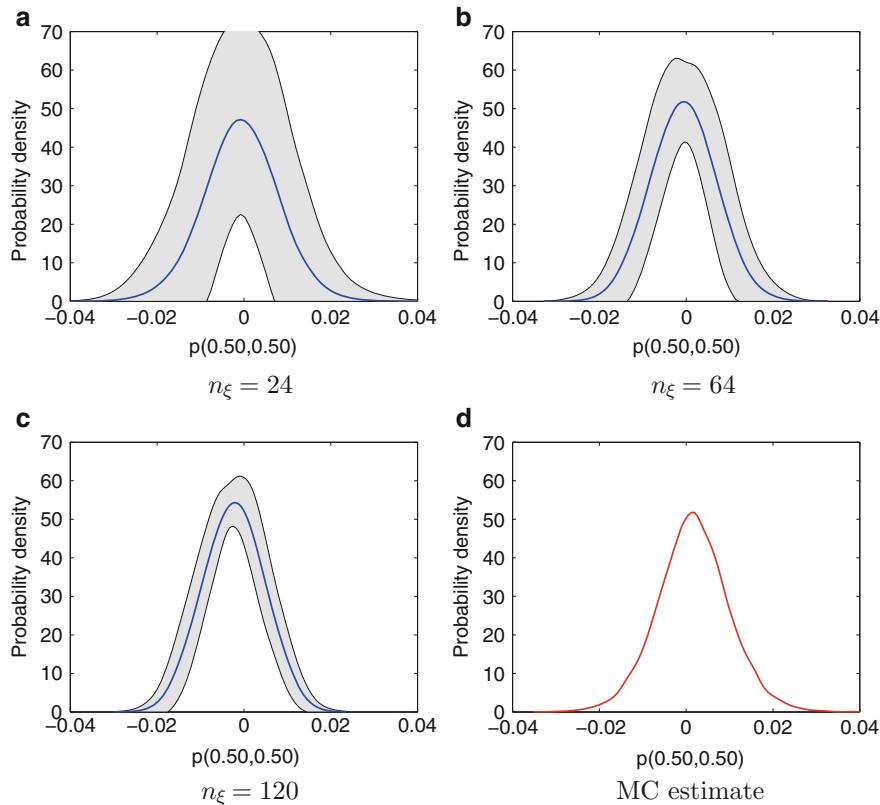

Fig. 15.12 Partial differential equation: The prediction for the PDF of $p(\mathbf{x}_s = (0.5, 0.5); \xi)$. intrusive approach, the mathematical models describing the physics of the problem could be used to derive physics-constrained covariance functions that would, presumably, force the prior GP probability measure to be compatible with known response properties, such as mass conservation. That is, such an approach would put more effort on better representing our prior state of knowledge about the response. Fifth, there is an evident need for developing simulation selection policies which are specifically designed to gather information about the uncertainty propagation task. Finally, note that the Bayesian approach can also be applied to other important contexts such as model calibration and design optimization under uncertainty. As a result, all the open research questions have the potential to also revolutionize these fields.

Solution Algorithms for Stochastic Galerkin Discretizations of Differential Equations with Random Data

16

Howard Elman

Abstract

This chapter discusses algorithms for solving systems of algebraic equations arising from stochastic Galerkin discretization of partial differential equations with random data, using the stochastic diffusion equation as a model problem. For problems in which uncertain coefficients in the differential operator are linear functions of random parameters, a variety of efficient algorithms of multigrid and multilevel type are presented, and, where possible, analytic bounds on convergence of these methods are derived. Some limitations of these approaches for problems that have nonlinear dependence on parameters are outlined, but for one example of such a problem, the diffusion equation with a diffusion coefficient that has exponential structure, a strategy is described for which the reformulated problem is also amenable to efficient solution by multigrid methods.

1 Introduction: The Stochastic Finite Element Method

This chapter is concerned with algorithms for solving the systems of algebraic equations arising from stochastic Galerkin discretization of partial differential equations (PDEs) with random data. Consider a PDE of generic form $\mathcal{L}u = f$ on a spatial domain \mathcal{D} , subject to boundary conditions $\mathcal{B}u = g$ on $\partial\mathcal{D}$, where one or more of the operators \mathcal{L} , \mathcal{B} , or functions f , g depend on random data. The most challenging scenario is when the dependence is in the differential operator \mathcal{L} and the discussion will be concentrated on this case. An example is the diffusion equation, where $\mathcal{L}u \equiv -\nabla \cdot (a\nabla u)$, subject to boundary conditions $u = g_D$ on $\partial\mathcal{D}_D$, $a \frac{\partial u}{\partial n} = 0$ on $\partial\mathcal{D}_N$. The diffusion coefficient $a = a(\mathbf{x}, \omega)$ is a random field: given a probability space (Ω, \mathcal{F}, P) , for each $\omega \in \Omega$, the realization $a(\cdot, \omega)$ is a function defined on \mathcal{D} , and for each $\mathbf{x} \in \mathcal{D}$, $a(\mathbf{x}, \cdot)$ is a random variable. Although the focus will be on the diffusion equation, the solution algorithms described are easily generalized to other problems with random coefficients. (See, e.g., [22] for a study of the Navier-Stokes equations.) In discussion of the diffusion problem, it will be assumed that $a(\mathbf{x}, \omega)$ is uniformly bounded, i.e., $0 < \alpha_1 \leq a(\mathbf{x}, \omega) \leq \alpha_2 < \infty$ a.e., which ensures well posedness. The Galerkin formulation of the stochastic diffusion problem augments the standard (spatial) Galerkin methodology using averaging with respect to expected value in the probability measure.

To begin, this section contains a concise introduction to the stochastic Galerkin methodology. Comprehensive treatments of this approach can be found in [10, 17, 18, 33]. The next section contains a description and analysis of two efficient solution algorithms that use a multigrid structure in the spatial component of the problem, together with a description of an algorithm that can be viewed as having a multilevel structure in the stochastic component. These methods are designed for problems that depend linearly on a set of random parameters. This is followed by a section discussing some limitations of these ideas for problems with nonlinear dependence on random parameters, coupled with the presentation of an effective strategy to handle one specific version of such problems, where the diffusion coefficient is of exponential form. The final section contains a brief recapitulation of the chapter.

Let $H^1(\mathcal{D})$ denote the Sobolev space of functions on \mathcal{D} with square integrable first derivatives, let $H_E^1(\mathcal{D}) \equiv \{u \in H^1(\mathcal{D}) \mid u = g_D \text{ on } \partial\mathcal{D}_D\}$, let $H_0^1(\mathcal{D}) \equiv \{u \in H^1(\mathcal{D}) \mid u = 0 \text{ on } \partial\mathcal{D}_D\}$, and let $L^2(\Omega)$ denote the Hilbert space with inner product defined by expected value on Ω ,

$$\langle v, w \rangle \equiv \int_{\Omega} v(\omega)w(\omega)dP(\Omega).$$

The weak formulation of the stochastic diffusion problem is then to find $u \in H_E^1(\mathcal{D}) \otimes L^2(\Omega)$ such that

$$\int_{\Omega} \int_{\mathcal{D}} a \nabla u \cdot \nabla v d\mathbf{x} dP(\Omega) = \int_{\Omega} \int_{\mathcal{D}} f v d\mathbf{x} dP(\Omega) \quad (16.1)$$

for all $v \in H_0^1(\mathcal{D}) \otimes L^2(\Omega)$.

For the abstract formulation (16.1) to be suitable for computation, the random field $a(\cdot, \cdot)$ must be expressed in terms of a finite number of random variables. Galerkin methods are most useful when this dependence is *linear*:

$$a(\mathbf{x}, \omega) = a_0(\mathbf{x}) + \sum_{r=1}^m a_r(\mathbf{x}) \xi_r(\omega), \quad (16.2)$$

where $\{\xi_r\}_{r=1}^m$ is a set of m random variables. A typical example comes from a Karhunen-Loëve (KL) expansion derived from a covariance function. In this case, $\{a_r\}_{r=1}^m$ correspond to discrete versions of the m eigenfunctions of the covariance operator associated with the m largest eigenvalues, and $\{\xi_r\}$ are uncorrelated zero-mean random variables defined on Ω . (It is assumed for (16.2) that the associated eigenvalues are incorporated into $\{a_r\}$ as factors.) The covariance function is positive semi-definite and $\{a_r\}_{r=1}^m$ can be listed in nonincreasing order of magnitude, according to the nonincreasing sizes of the eigenvalues.

Let $\boldsymbol{\xi} \equiv (\xi_1, \dots, \xi_m)^T$. For fixed \mathbf{x} , the diffusion coefficient can be viewed as a function of $\boldsymbol{\xi}$, and it will be written using the same symbol, as $a(\mathbf{x}, \boldsymbol{\xi})$. It can then be shown that the solution $u(\mathbf{x}, \cdot)$ is also a function of $\boldsymbol{\xi}$ [18, Ch. 9], and if the joint density $\rho(\boldsymbol{\xi})$ is known, then (16.1) can be rewritten as

$$\int_{\Gamma} \int_{\mathcal{D}} a(\mathbf{x}, \boldsymbol{\xi}) \nabla u(\mathbf{x}, \boldsymbol{\xi}) \cdot \nabla v(\mathbf{x}, \boldsymbol{\xi}) d\mathbf{x} \rho(\boldsymbol{\xi}) d\boldsymbol{\xi} = \int_{\Gamma} \int_{\mathcal{D}} f(\mathbf{x}, \boldsymbol{\xi}) v(\mathbf{x}, \boldsymbol{\xi}) d\mathbf{x} \rho(\boldsymbol{\xi}) d\boldsymbol{\xi}, \quad (16.3)$$

where $\Gamma = \boldsymbol{\xi}(\Omega)$. Note that in (16.3), the vector of random variables is playing a role analogous to spatial Cartesian coordinates in the physical domain. For a d -dimensional physical domain, (16.3) is similar in form to the weak formulation of a $(d+m)$ -dimensional continuous deterministic problem.

Numerical approximation is done on a finite-dimensional subset of $H_E^1(\mathcal{D}) \otimes L^2(\Omega)$. For this, let $\mathcal{S}^{(h)}$ denote a finite-dimensional subspace of $H_0^1(\mathcal{D})$ with basis $\{\phi_j\}_{j=1}^{N_x}$, let $\mathcal{S}_E^{(h)}$ be an extended version of this space with additional functions $\{\phi_j\}_{j=N_x+1}^{N_x+N_\partial}$, so that $\sum_{j=N_x+1}^{N_x+N_\partial} u_j \phi_j$ interpolates the boundary data g_D on $\partial\mathcal{D}$, and let $\mathcal{T}^{(p)}$ denote a finite-dimensional subspace of $L^2(\Gamma)$ with basis $\{\psi_q\}_{q=1}^{N_\xi}$. The discrete weak problem is then to find $u^{(hp)} \in \mathcal{S}_E^{(h)} \otimes \mathcal{T}^{(p)}$ such that

$$\int_{\Gamma} \int_{\mathcal{D}} a \nabla u^{(hp)} \cdot \nabla v^{(hp)} d\mathbf{x} \rho(\boldsymbol{\xi}) d\boldsymbol{\xi} = \int_{\Gamma} \int_{\mathcal{D}} f v^{(hp)} d\mathbf{x} \rho(\boldsymbol{\xi}) d\boldsymbol{\xi},$$

for all $v^{(hp)} \in \mathcal{S}^{(h)} \otimes \mathcal{T}^{(p)}$. The discrete solution has the form

$$u^{(hp)}(\mathbf{x}, \boldsymbol{\xi}) = \sum_{q=1}^{N_\xi} \sum_{j=1}^{N_x} u_{jq} \phi_j(\mathbf{x}) \psi_q(\boldsymbol{\xi}) + \sum_{j=N_x+1}^{N_x+N_\partial} u_j \phi_j(\mathbf{x}). \quad (16.4)$$

Computing the solution entails solving a linear system of equations

$$A^{(hp)} \mathbf{u}^{(hp)} = \mathbf{f}^{(hp)} \quad (16.5)$$

for the coefficients $\{u_{jq}\}_{j=1:N_x, q=1:N_\xi}$. (From the assumption of deterministic boundary data, the known coefficients of the spatial basis functions on the Dirichlet boundary $\partial\Omega_D$ can be incorporated into the right-hand side of (16.4).) If the vector $\mathbf{u}^{(hp)}$ of these coefficients is ordered by grouping the spatial indices together, as

$$u_{11}, u_{21}, \dots, u_{N_x 1}, u_{12}, u_{22}, \dots, u_{N_x 2}, u_{1N_\xi}, u_{2N_\xi}, \dots, u_{N_x N_\xi},$$

and the equations are ordered in an analogous way, then the coefficient matrix is a sum of matrices of Kronecker-product structure,

$$A^{(hp)} = G_0^{(p)} \otimes A_0^{(h)} + \sum_{r=1}^m G_r^{(p)} \otimes A_r^{(h)}, \quad (16.6)$$

where

$$\begin{aligned} [A_r^{(h)}]_{jk} &= \int_{\mathcal{D}} a_r(\mathbf{x}) \nabla \phi_k(\mathbf{x}) \cdot \nabla \phi_j(\mathbf{x}) d\mathbf{x}, \\ [G_0^{(p)}]_{lq} &= \int_{\Gamma} \psi_q(\boldsymbol{\xi}) \psi_l(\boldsymbol{\xi}) \rho(\boldsymbol{\xi}) d\boldsymbol{\xi}, \quad [G_r^{(p)}]_{lq} = \int_{\Gamma} \xi_r \psi_q(\boldsymbol{\xi}) \psi_l(\boldsymbol{\xi}) \rho(\boldsymbol{\xi}) d\boldsymbol{\xi}, \end{aligned} \quad (16.7)$$

and the Kronecker product of matrices G (of order N_ξ) and A (of order N_x) is the matrix of order $N_x N_\xi$ given by

$$G \otimes A = \begin{bmatrix} g_{11}A & g_{12}A & \cdots & g_{1N_\xi}A \\ g_{21}A & g_{22}A & \cdots & g_{2N_\xi}A \\ \vdots & \vdots & \ddots & \vdots \\ g_{N_\xi 1}A & g_{N_\xi 2}A & \cdots & g_{N_\xi N_\xi}A \end{bmatrix}.$$

The joint density function $\rho(\boldsymbol{\xi})$ may not be known, and an additional assumption typically made is that the random variables $\{\xi_r\}$ are *independent* with known marginal density functions $\{\rho_r\}$ [34] (cf. [12] for an analysis of this assumption). The joint density function is then the product of marginal density functions, $\rho(\boldsymbol{\xi}) = \rho_1(\xi_1)\rho_2(\xi_2)\cdots\rho_m(\xi_m)$. This also enables a simple choice of basis functions for $\mathcal{T}^{(p)}$. Let $\{p_j^{(r)}\}_{j \geq 0}$ be the set of polynomials orthogonal with respect to the density function ρ_r , normalized so that $\langle p_j^{(r)}, p_j^{(r)} \rangle = 1$. Then, each basis function ψ_q can be taken to be a product of univariate polynomials [10, 34]

$$\psi_q(\boldsymbol{\xi}) = p_{j_1}^{(1)}(\xi_1) p_{j_2}^{(2)}(\xi_2) \cdots p_{j_m}^{(m)}(\xi_m) \quad (16.8)$$

where the index q is determined by a mapping between multi-indices $\{j_1 j_2 \cdots j_m\}$ of polynomial degrees and integers in $\{1, 2, \dots, N_\xi\}$. This construction is known as the *generalized polynomial chaos*. A common choice of basis is the set of m -variate

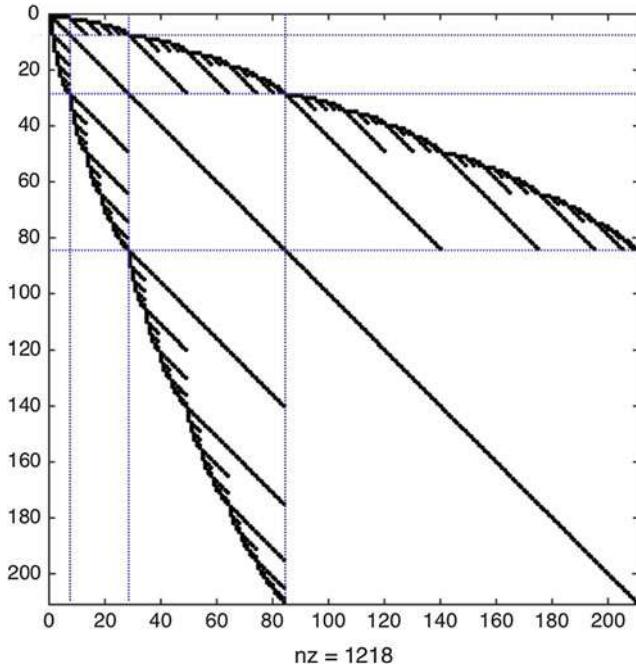

Fig. 16.1 Representative sparsity pattern of coefficient matrix obtained from stochastic Galerkin discretization with $m = 6$, $p = 4$, giving block order 210

polynomials of total degree at most p , i.e., $j_1 + \dots + j_m \leq p$. Then, $N_\xi = \binom{m+p}{p}$, and it follows from properties of orthogonal polynomials that the matrices $\{G_r^{(p)}\}$ are sparse, with at most two nonzeros per row. $A^{(hp)}$ is also sparse; a representative example of its sparsity pattern, for $m = 4$ and $p = 6$, is shown in Fig. 16.1. Each pixel in the figure corresponds to a matrix of order N_x with nonzero structure like that obtained from discretization of a deterministic PDE. The blocking of the matrix will be explained below.

The following lemma will be of use for analyzing the convergence properties of iterative solution algorithms for the linear system.

Lemma 1. *If $\mathcal{T}^{(p)}$ consists of polynomials of total degree p specified above and each density function ρ_r is an even function of ξ_r , then for $r \geq 1$, the eigenvalues of $G_r^{(p)}$ are contained in the symmetric interval $[-\eta_p, +\eta_p]$ where η_p is the maximal positive root of the polynomial $p_{p+1}^{(r)}$ of degree $p+1$.*

See [8] or [21] for a proof. It is shown in the latter reference that η_p is bounded by $\sqrt{p} + \sqrt{p-1}$ in the case of standard Gaussian random variables and by $\sqrt{3}$ for uniform variables with mean 0 and variance 1. The assumption concerning normalized polynomials implies that $G_0^{(p)} = I$, the identity matrix of order N_ξ .

2 Solution Algorithms

This section presents a collection of efficient iterative solution algorithms for the coupled linear system (16.5) that arises from stochastic finite element methods. The emphasis is on approaches whose convergence behavior has been shown to be insensitive to the parameters such as spatial mesh size or polynomial order that determine the discretization; they include multigrid and multilevel approaches and techniques that take advantage of the hierarchical structure of the problem. Other methods, mostly developed earlier than the ones described here, can be viewed as progenitors of these techniques; they include methods based on incomplete factorization [11, 20] or block splitting methods [15, 24]. The discussion will be limited to primal formulations of the problem; see [5, 9] for treatment of the stochastic diffusion equation using mixed finite elements in space.

2.1 Multigrid Methods I

One way to apply multigrid to the stochastic Galerkin system (16.5) is by generalizing methods devised for deterministic problems. This idea was developed in [16], and convergence analysis was presented in [4]; see also [26]. Assume there is a set of spatial grids of mesh width $h, 2h, 4h$, etc., and let the discrete space $\mathcal{T}^{(p)}$ associated with the stochastic component of the problem be fixed. The coefficient matrices for fine-grid and coarse-grid spatial discretizations are

$$A^{(hp)} = G_0^{(p)} \otimes A_0^{(h)} + \sum_{r=1}^m G_r^{(p)} \otimes A_r^{(h)}, \quad A^{(2h,p)} = G_0^{(p)} \otimes A_0^{(2h)} + \sum_{r=1}^m G_r^{(p)} \otimes A_r^{(2h)}.$$

Let P_{2h}^h denote a prolongation operator mapping (spatial) coarse-grid vectors to fine-grid vectors, and let R_h^{2h} denote a restriction operator mapping fine to coarse. Typically P_{2h}^h is specified using interpolation and $R_h^{2h} = [P_{2h}^h]^T$ [7]. Then, $\mathcal{P} = I \otimes R_h^{2h}$ is a restriction operator on the tensor product space that leaves the discrete stochastic space intact, and $\mathcal{P} = I \otimes P_{2h}^h$ is an analogous prolongation operator. In addition, let Q represent a smoothing operator on the fine grid; a more precise specification of Q is given below. One step of a *two-grid algorithm* for (16.5) to update an approximate solution $\mathbf{u}^{(hp)}$ is defined as follows:

Recall that any positive-definite matrix M induces a norm $\|\mathbf{v}\|_M \equiv (\mathbf{v}, M\mathbf{v})^{1/2}$. Convergence of Algorithm 1 is established by the following result [4]. It is stated in terms of generic constants c_1 and c_2 whose properties will be discussed below.

Theorem 1. *Let $\mathbf{u}_i^{(hp)}$ denote the approximate solution to (16.5) obtained after i steps of Algorithm 1, with error $\mathbf{e}_i = \mathbf{u}^{(hp)} - \mathbf{u}_i^{(hp)}$. If the smoothing property*

$$\|A^{(hp)}(I - Q^{-1}A^{(hp)})^k \mathbf{y}\|_2 \leq \eta(k) \|\mathbf{y}\|_{A^{(hp)}} \quad \text{for all } \mathbf{y} \in \mathbb{R}^{N_x N_\xi} \quad (16.9)$$

Algorithm 1 One step of a two-grid method for the stochastic Galerkin system, given an estimate $\mathbf{u}^{(hp)}$ for the solution.

```

for  $j = 1 : k$ 
     $\mathbf{u}^{(hp)} \leftarrow \mathbf{u}^{(hp)} + Q^{-1}(\mathbf{f}^{(hp)} - A^{(hp)}\mathbf{u}^{(hp)})$        $k$  smoothing steps
end
 $\mathbf{r}^{(2h,p)} = \mathcal{R}(\mathbf{f}^{(hp)} - A^{(hp)}\mathbf{u}^{(hp)})$           Restriction,  $\mathcal{R} = I \otimes R_h^{2h}$ 
Solve  $A^{(2h,p)}\mathbf{c}^{(2h,p)} = \mathbf{r}^{(2h,p)}$           Compute coarse-grid correction
 $\mathbf{u}^{(hp)} \leftarrow \mathbf{u}^{(hp)} + \mathcal{P}\mathbf{c}^{(2h,p)}$           Prolongation,  $\mathcal{P} = I \otimes P_{2h}^h$ 

```

holds with $\eta(k) \rightarrow 0$ as $k \rightarrow \infty$, and the approximation property,

$$\|[(A^{(hp)})^{-1} - \mathcal{P}(A^{(2h,p)})^{-1}\mathcal{R}]\mathbf{y}\|_{A^{(hp)}} \leq c_1 \|\mathbf{y}\|_2 \quad \text{for all } \mathbf{y} \in \mathbb{R}^{N_x N_\xi}, \quad (16.10)$$

holds, then the error satisfies $\|\mathbf{e}_i\|_A \leq c_2 \|\mathbf{e}_{i-1}\|_{A^{(hp)}}$.

Proof. The errors associated with Algorithm 1 satisfy the recursive relationship

$$\mathbf{e}_i = [(A^{(hp)})^{-1} - \mathcal{P}(A^{(2h,p)})^{-1}\mathcal{R}][A^{(hp)}(I - Q^{-1}A^{(hp)})^k]\mathbf{e}_{i-1}.$$

Application of the approximation property (16.10) and smoothing property (16.9) gives

$$\begin{aligned} \|\mathbf{e}_i\|_{A^{(hp)}} &= \|[(A^{(hp)})^{-1} - \mathcal{P}(A^{(2h,p)})^{-1}\mathcal{R}][A^{(hp)}(I - Q^{-1}A^{(hp)})^k]\mathbf{e}_{i-1}\|_{A^{(hp)}} \\ &\leq c_1 \|[A^{(hp)}(I - Q^{-1}A^{(hp)})^k]\mathbf{e}_{i-1}\|_2 \\ &\leq c_1 \eta(k) \|\mathbf{e}_{i-1}\|_{A^{(hp)}} \leq c_2 \|\mathbf{e}_{i-1}\|_{A^{(hp)}} \end{aligned}$$

for all large enough k .

An outline of what is required to establish (16.9)–(16.10) is as follows. For the smoothing property (16.9), a simple splitting operator is $Q = \theta I$ for constant θ . With this choice, each smoothing step in Algorithm 1 consists of a damped Richardson iteration with damping parameter $1/\theta$. A standard analysis of multigrid [2, Ch. V] [7, Ch. 2] shows that the smoothing property holds for $\theta \geq \lambda_{\max}(A^{(hp)})$. Thus, it suffices to have an upper bound for the maximal eigenvalue of the symmetric positive-definite matrix $A^{(hp)}$, which can be obtained using properties of Kronecker products [14] and sums of symmetric matrices [13]:

$$\lambda_{\max}(A^{(hp)}) \leq \sum_{r=0}^m \lambda_{\max}(G_r^{(p)} \otimes A_r^{(h)}) = \sum_{r=0}^m \lambda_{\max}(G_r^{(p)}) |\lambda_{\max}(A_r^{(h)})|. \quad (16.11)$$

Bounds on the eigenvalues of $G_r^{(p)}$ come from Lemma 1. The eigenvalues of $A_r^{(h)}$ can be bounded using Rayleigh quotients; see (16.15) below.

To see what is needed to establish the approximation property (16.10), first recall some results for deterministic problems. Let $\mathcal{S}^{(h)}$ and $\mathcal{S}_E^{(h)}$ be above. Given $\mathbf{y} \in \mathbb{R}^{N_x}$, let $y = y^{(h)} = \sum_{j=1}^{N_x} y_j \phi_j \in \mathcal{S}^{(h)}$, and consider the deterministic diffusion equation $-\nabla \cdot (a \nabla u) = y$ on \mathcal{D} , for which no components of the problem depend on random data. Let $u \in H_E^1(\mathcal{D})$ denote the (weak) solution. Then, $\mathbf{u} = (A^{(h)})^{-1} \mathbf{y}$ corresponds to a discrete weak solution $u^{(h)} \in \mathcal{S}^{(h)}$ (which can be extended to $\mathcal{S}_E^{(h)}$ as in (16.4)). Similarly, $\mathbf{u} = (A^{(2h)})^{-1} R_h^{2h} \mathbf{y}$ corresponds to a coarse-grid solution $u^{(2h)}$. The approximation property follows from the relations

$$\begin{aligned} \|[(A^{(h)})^{-1} - P_{2h}^h (A^{(2h)})^{-1} R_h^{2h}] \mathbf{y}\|_{A^{(h)}} &= \|\nabla(u^{(h)} - u^{(2h)})\|_0 \\ &\leq \|\nabla(u^{(h)} - u)\|_0 + \|\nabla(u - u^{(2h)})\|_0 \\ &\leq c_1 \|\mathbf{y}\|_2. \end{aligned} \quad (16.12)$$

The last inequality depends on an assumption of regularity of the solution that $u \in H^2(\mathcal{D})$.

The key to this analysis is that the difference between the fine-grid and coarse-grid solutions is bounded by the sum of the fine-grid and coarse-grid errors. Generalization to the stochastic problem requires an analogue of the deterministic solution u . This is obtained using a semi-discrete space $H^1(\mathcal{D}) \otimes \mathcal{T}^{(p)}$. The weak solution in this semi-discrete setting is $u^{(p)} \in H_E^1(\mathcal{D}) \otimes \mathcal{T}^{(p)}$ for which (16.1) holds for all $v^{(p)} \in H_0^1(\mathcal{D}) \otimes \mathcal{T}^{(p)}$. The analysis then proceeds as in (16.12) using $u^{(hp)}$, $u^{(2h,p)}$ and $u^{(p)}$ in place of the deterministic quantities. Complete details can be found in [4]. Extension from two grid to multigrid follows arguments for deterministic problems.

Theorem 1 establishes “textbook” multigrid convergence, i.e., it shows that the convergence factor is independent of the discretization parameter h . The constant c_1 in the approximation property does not depend on the number of terms m in the representation of the diffusion coefficient (16.2) or the polynomial degree p used to discretize the probability space. The smoothing property and constant c_2 depend on bounds on $\lambda_{\max}(A^{(hp)})$ from (16.11); these bounds may depend on m . (They are independent of p if the support of the density function ρ is bounded.) Computational results in [4] and [16] showed no dependence on this parameter. The number of nonzero entries in $A^{(hp)}$ is $O(N_x N_\xi)$, so that the cost of the matrix-vector product is linear in the problem size. The coarse-grid solves require solutions of systems of equations of order proportional to $|\mathcal{T}^{(p)}|$, the dimension of $\mathcal{T}^{(p)}$. If this is not too large, then direct methods can be used for these computations. Modulo this computation, the cost per step of the multigrid algorithm is also of order $N_x N_\xi$.

2.2 Multigrid Methods II: Mean-Based Preconditioning

A different way to apply multigrid to the system (16.5) comes from use of $\mathcal{Q}_0^{(hp)} \equiv G_0^{(p)} \otimes A_0^{(h)}$ as a preconditioner for the coefficient matrix $A^{(hp)}$ [21]. The preconditioning operator derives from the mean a_0 of the diffusion coefficient.

If $a(\cdot, \cdot)$ is not too large a perturbation of a_0 , then $Q_0^{(hp)}$ will be a reasonable approximation of $A^{(hp)}$ and can be used as a preconditioner in combination with Krylov subspace methods such as the conjugate gradient method (CG). Moreover, since $G_0^{(p)} = I_{N_\xi}$, the identity matrix, $Q_0^{(hp)}$, is a block-diagonal matrix consisting of N_ξ decoupled copies of $A_0^{(h)}$. Thus, the overhead of using it with CG entails applying the action of the inverse of N_ξ decoupled copies of $A^{(h)}$ at each step.

Assume that $a_0(\mathbf{x})$ is uniformly bounded below by $\alpha_1 > 0$. The following result establishes the effectiveness of $Q_0^{(hp)}$ as a preconditioner.

Theorem 2. *The eigenvalues of the generalized eigenvalue problem $A^{(hp)}\mathbf{v} = \mu Q_0^{(hp)}\mathbf{v}$ are contained in an interval $[1 - \tau, 1 + \tau]$, where*

$$\tau \leq \sum_{r=1}^m |\eta_{\max}(G_r^{(p)})| \left(\frac{\|a_r\|_\infty}{\alpha_1} \right), \quad (16.13)$$

and $|\eta_{\max}(G_r^{(p)})|$ is the modulus of the eigenvalue of $G_r^{(p)}$ of maximal modulus.

If $\tau < 1$, the condition number of the preconditioned operator $(Q_0^{(hp)})^{-1}A^{(hp)}$ is bounded by $\frac{1+\tau}{1-\tau}$.

Proof. The proof is done by establishing bounds on the Rayleigh quotient

$$\frac{(\mathbf{v}, A^{(hp)}\mathbf{v})}{(\mathbf{v}, Q_0^{(hp)}\mathbf{v})} = 1 + \sum_{r=1}^m \frac{\left(\mathbf{v}, \left(G_r^{(p)} \otimes A_r^{(h)} \right) \mathbf{v} \right)}{\left(\mathbf{v}, \left(G_0^{(p)} \otimes A_0^{(h)} \right) \mathbf{v} \right)}.$$

Each of the fractions in the sum is bounded by the product of the maximal eigenvalue of $G_r^{(p)}$ times the modulus of the maximal eigenvalue of $(A_0^{(h)})^{-1}A_r^{(h)}$. The latter quantities are the extrema of the Rayleigh quotient

$$\frac{|(\mathbf{v}^{(h)}, A_r^{(h)}\mathbf{v}^{(h)})|}{(\mathbf{v}^{(h)}, A_0^{(h)}\mathbf{v}^{(h)})}, \quad (16.14)$$

where $\mathbf{v}^{(h)}$ is a vector of length N_x that corresponds to $v_h \in \mathcal{S}^{(h)}$. The terms in (16.14) are bounded as

$$\begin{aligned} |(\mathbf{v}^{(h)}, A_r^{(h)}\mathbf{v}^{(h)})| &= \left| \int_{\mathcal{D}} a_r(\mathbf{x}) \nabla v_h(\mathbf{x}) \cdot \nabla v_h(\mathbf{x}) d\mathbf{x} \right| \leq \|a_r\|_\infty \int_{\mathcal{D}} |\nabla v_h(\mathbf{x})| |\nabla v_h(\mathbf{x})| d\mathbf{x}, \\ (\mathbf{v}^{(h)}, A_0^{(h)}\mathbf{v}^{(h)}) &= \int_{\mathcal{D}} a_0(\mathbf{x}) \nabla v_h(\mathbf{x}) \cdot \nabla v_h(\mathbf{x}) d\mathbf{x} \geq \alpha_1 \int_{\mathcal{D}} |\nabla v_h(\mathbf{x})| |\nabla v_h(\mathbf{x})| d\mathbf{x}. \end{aligned} \quad (16.15)$$

The assertion follows. Bounds on the eigenvalues of $G_r^{(p)}$ again come from Lemma 1.

It is generally preferable to *approximate* the action of $(A_0^{(h)})^{-1}$, which can be done using multigrid. In particular, suppose $(Q_{0,MG}^{(h)})^{-1}$ represents a spectrally equivalent approximation to $(A_0^{(h)})^{-1}$ resulting from a fixed number of multigrid steps. That is,

$$\beta_1 \leq \frac{(\mathbf{v}^{(h)}, A_0^{(h)} \mathbf{v}^{(h)})}{(\mathbf{v}^{(h)}, Q_{0,MG}^{(h)} \mathbf{v}^{(h)})} \leq \beta_2$$

for constants β_1, β_2 independent of the spatial discretization parameter h . With $Q_{0,MG}^{(hp)} \equiv G_0^{(p)} \otimes Q_{0,MG}^{(h)}$, this leads to the following result.

Corollary 1. *The condition number of the multigrid preconditioned operator $(Q_{0,MG}^{(hp)})^{-1} A^{(hp)}$ is bounded by $(\frac{1+\tau}{1-\tau}) (\frac{\beta_2}{\beta_1})$.*

As is well known, the number of steps required for convergence of the conjugate gradient method is bounded in terms of the condition number of the coefficient matrix [7]. Thus, Corollary 1 establishes the optimality of this method. The requirement $\tau < 1$ implies that the method is useful only if $A^{(hp)}$ is not too large, a perturbation of $Q_{0,MG}^{(hp)}$. However, this method is significantly simpler to implement than Algorithm 1. In particular, it is straightforward to use algebraic multigrid (e.g., [25]) to handle the approximate action of $(A_0^{(h)})^{-1}$, and there are no coarse-grid operations with matrices of order $|\mathcal{T}^{(p)}|$. A comparison of these two versions of multigrid, showing some advantages of each, is given in [24]. It is also possible to improve performance of the mean-based approach using a variant of the form $\widehat{Q}_p^{(hp)} \equiv \widehat{G}^{(p)} \otimes A_0^{(h)}$, where some $\widehat{G}^{(p)}$ replaces the identity in the Kronecker product [29]; a good choice of $\widehat{G}^{(p)}$ is determined by minimizing the Frobenius norm $\|A^{(hp)} - \widehat{G}^{(p)} \otimes A_0^{(h)}\|_F$ [31].

2.3 Hierarchical Methods

The blocking of the matrix shown in Fig. 16.1 reflects the hierarchical structure of the discrete problem. The coefficient matrix arising from the subspace $\mathcal{T}^{(p)} \subset L^2(\Gamma)$, consisting of polynomials of total degree p , has the form

$$A^{(hp)} = \begin{bmatrix} A^{(h,p-1)} & B^{(hp)} \\ C^{(hp)} & D^{(hp)} \end{bmatrix}$$

where the $(1, 1)$ -subblock comes from $\mathcal{S}^{(h)} \otimes \mathcal{T}^{(p-1)}$. In the figure, $p = 4$ and (with $m = 6$), the block corresponding to $\mathcal{T}^{(3)}$ has order $\binom{6+3}{3} = 84$. It follows from the orthogonality of the basis for $\mathcal{T}^{(p)}$ that the $(2, 2)$ -block $D^{(hp)}$ is a block-diagonal

matrix, each of whose blocks is A_0^h (see, e.g., [24]). The number of such blocks is the number of basis functions of total degree exactly p .

This structure has been used in [28], building on ideas in [11], to develop a hierarchical preconditioning strategy. The approach can also be viewed as a multilevel method in the stochastic dimension, and it bears some resemblance to iterative substructuring methods as described, for example, in [27]. To make the description more readable, the dependence on the spatial mesh size h will be suppressed from the notation. The coefficient matrix then has a block factorization

$$A^{(p)} = \begin{bmatrix} A^{(p-1)} & B^{(p)} \\ C^{(p)} & D^{(p)} \end{bmatrix} = \begin{bmatrix} I & B^{(p)}(D^{(p)})^{-1} \\ 0 & I \end{bmatrix} \begin{bmatrix} S^{(p-1)} & 0 \\ 0 & D^{(p)} \end{bmatrix} \begin{bmatrix} I & 0 \\ (D^{(p)})^{-1}B^{(p)} & I \end{bmatrix},$$

where $S^{(p-1)} \equiv A^{(p-1)} - B^{(p)}(D^{(p)})^{-1}C^{(p)}$ is a Schur complement. Equivalently,

$$(A^{(p)})^{-1} = \begin{bmatrix} I & 0 \\ -(D^{(p)})^{-1}B^{(p)} & I \end{bmatrix} \begin{bmatrix} (S^{(p-1)})^{-1} & 0 \\ 0 & (D^{(p)})^{-1} \end{bmatrix} \begin{bmatrix} I & -B^{(p)}(D^{(p)})^{-1} \\ 0 & I \end{bmatrix}.$$

The Schur complement is expensive to work with, and the idea in [28] is to replace $S^{(p-1)}$ with $A^{(p-1)}$, giving the approximate factorization

$$(A^{(p)})^{-1} \approx \begin{bmatrix} I & 0 \\ -(D^{(p)})^{-1}B^{(p)} & I \end{bmatrix} \begin{bmatrix} (A^{(p-1)})^{-1} & 0 \\ 0 & (D^{(p)})^{-1} \end{bmatrix} \begin{bmatrix} I & -B^{(p)}(D^{(p)})^{-1} \\ 0 & I \end{bmatrix}. \quad (16.16)$$

The preconditioning operator is then defined by applying this strategy recursively to $(A^{(p-1)})^{-1}$; implementation details are given in [28]. A key point is that the only (subsidiary) system solves required entail independent computations of the action of $(A_0^{(h)})^{-1}$. These are analogous to the coarse-grid solves required by Algorithm 1, and they can be replaced by approximate solves.

The following convergence result is given in [28].

Theorem 3. *Let $Q^{(hp)}$ denote the preconditioning operator defined by recursive application of the approximation (16.16). Then, the condition number of the preconditioned operator $(Q^{(hp)})^{-1}A^{(hp)}$ is bounded by $1/\left(\prod_{q=1}^{p-1} \beta_{1q}\right)$, where*

$$\beta_{1q}(\mathbf{u}, A^{(q)}\mathbf{u})^{1/2} \leq (\mathbf{u}, S^{(q)}\mathbf{u})^{1/2} \leq (\mathbf{u}, A^{(q)}\mathbf{u})^{1/2}, \quad 1 \leq q \leq p-1.$$

Bounds on the terms $\{\beta_{1q}\}$ appearing in this expression have not been established. However, experimental results in [28] suggest that for a diffusion equation with coefficient as in (16.2) (with uniformly distributed random variables), the condition number of the preconditioned system $(Q^{(hp)})^{-1}A^{(hp)}$ is very close to 1 and largely insensitive to the problem parameters, i.e., spatial mesh size h , stochastic dimension m , and polynomial degree p .

This hierarchical strategy is more effective than a pure multilevel method. A two-level strategy would have the form of Algorithm 1 with the “lower-level” space $\mathcal{S}^{(h)} \otimes \mathcal{T}^{(p-1)}$ used in place of the coarse physical space $\mathcal{S}^{(2h)} \otimes \mathcal{T}^{(p)}$. The latter steps of the computation, corresponding to the analogous steps in Algorithm 1, are:

$$\begin{array}{ll} \mathbf{r}^{(2,p-1)} = \mathcal{R}_p^{p-1}(\mathbf{f}^{(hp)} - A^{(hp)}\mathbf{u}^{(hp)}) & \text{Restriction} \\ \text{Solve } A^{(h,p-1)}\mathbf{c}^{(h,p-1)} = \mathbf{r}^{(h,p-1)} & \text{Compute coarse-grid correction} \\ \mathbf{u}^{(hp)} \leftarrow \mathbf{u}^{(hp)} + \mathcal{P}_{p-1}^p \mathbf{c}^{(h,p-1)} & \text{Prolongation} \end{array}$$

Results for such a strategy, for restriction and prolongation operators $\mathcal{R}_p^{p-1} = [I, 0]$, $\mathcal{P} = \mathcal{R}^T$ (injection), are discussed in [15, Ch. 4] and [24, Sect. 4], where it is shown that this method *does not* display costs that grow linearly with the number of unknowns.

3 Approaches for Other Formulations

As noted above, the stochastic Galerkin method is most effective when the dependence of the problem on random data is a linear function of parameters, as in (16.2). This section expands on this point, showing what issues arise for problems depending on random fields that are nonlinear functions of the data. In addition, one method is presented that avoids some of these issues for one important class of problems, the particular case of the diffusion equation in which the diffusion coefficient has an exponential structure. A commonly used model of this type is where the diffusion coefficient has a log-normal distribution, see [1, 35].

Suppose now that $a(\mathbf{x}, \xi)$ is a nonlinear function of ξ , where ξ is of length m , and that this function has a series expansion in the polynomial chaos basis

$$a(\mathbf{x}, \xi) = \sum_r a_r(\mathbf{x}) \psi_r(\xi),$$

where, as in (16.8), each index r is associated with a multi-index of m -tuples of nonnegative integers. Assume that this series can be approximated well using a finite-term sum whose length will temporarily be denoted by \hat{m} . Then, the formalism of the stochastic Galerkin discretization giving rise to equation (16.5) carries over essentially unchanged, where

$$A^{(hp)} = \sum_{r=1}^{\hat{m}} G_r^{(p)} \otimes A_r^{(h)}. \quad (16.17)$$

The main difference lies in the definition of the matrices $\{G_r^{(p)}\}$ associated with the stochastic terms, where ξ_r in (16.7) is replaced by $\psi_r(\xi)$:

$$[G_r^{(p)}]_{\ell q} = \int_{\Gamma} \psi_r(\xi) \psi_q(\xi) \psi_\ell(\xi) \rho(\xi) d\xi. \quad (16.18)$$

(There is also a slight difference in indexing conventions, in that the lowest index in (16.17) is $r = 1$.) If the finite-dimensional subspace $\mathcal{T}^{(p)}$ is defined by the generalized polynomial chaos of maximal degree p , then this determines the length of the finite-term approximation to $a(\cdot, \cdot)$. In particular, it follows from properties of orthogonal polynomials that the triple product $\langle \psi_r \psi_q \psi_\ell \rangle = 0$ for all indices r corresponding to polynomials of degree greater than $2p$ [19]. Thus, the number of terms in (16.17) is $\hat{m} = \binom{m+2p}{2p}$.

It is possible to develop preconditioning strategies that are effective with respect to iteration counts to solve the analogue of (16.5) in this setting. In particular, let $a_0(\mathbf{x}) \equiv \langle a(\mathbf{x}, \cdot) \rangle$ denote the mean of $a(\mathbf{x}, \cdot)$, and let $A_0^{(h)}$ denote the matrix obtained from finite element discretization of the diffusion operator with diffusion coefficient a_0 . Then, the analogue of the mean-based preconditioner described above is $Q_0^{(hp)} \equiv I \otimes A_0^{(h)}$, and the analysis of [21] establishes mesh-independent conditioning of the preconditioned operator $(Q_0^{(hp)})^{-1} A^{(hp)}$.

Unfortunately, there are serious drawbacks to this approach. The coefficient matrices of (16.18) are considerably more dense than those of (16.7). Indeed, $A^{(hp)}$ of (16.17) is *block dense*; that is, most blocks of order N_x are nonzero [19]. Although each individual block has sparsity structure like that arising from finite element discretization in space, most blocks are nonzero. Equivalently, the analogue of Fig. 16.1 would be dense. As a result, the cost of a matrix-vector product required by a Krylov subspace method is of order $O(N_x N_\xi^2)$. Even with an optimally small number of iterations, the costs of a preconditioned iterative solver cannot scale linearly with the number of unknowns, $N_x N_\xi$. The mean-based preconditioned operator is also ill conditioned with respect to the polynomial degree p [23]. Thus, the stochastic Galerkin method is less effective for problems whose dependence on ξ is nonlinear than in the linear case.

There is a way around this in the particular setting where the diffusion coefficient is the exponential of a (smooth enough) random field. Our description follows [30]. Consider the equation

$$-\nabla \cdot (\exp(c) \nabla u) = f.$$

Premultiplying by $\exp(-c)$ and applying the product rule to the divergence operator transforms this problem to

$$-\Delta u + \mathbf{w} \cdot \nabla = f \exp(-c) \quad (16.19)$$

where $\mathbf{w} = -\nabla c$. Now suppose that $c = c(\mathbf{x}, \xi)$ is a random field that is well approximated by a finite-term KL expansion, i.e.,

$$c(\mathbf{x}, \xi) = c_0(x) + \sum_{r=1}^m c_r(x) \xi_r. \quad (16.20)$$

A typical example is where c is a finite-term approximation to a normally distributed random field, so that $a = \exp(c(\mathbf{x}, \xi))$ is essentially of log-normal form. Then, (16.19) is a convection-diffusion equation with convection coefficient

$$\mathbf{w} = \nabla c(\mathbf{x}, \xi) = \nabla c_0(\mathbf{x}) + \sum_{r=1}^m \nabla c_r(x) \xi_r, \quad (16.21)$$

a random field that is linear in the parameters $\{\xi_r\}$. The stochastic Galerkin method can be applied in the identical way it was used for the diffusion equation. The coefficient matrix has the form

$$A^{(hp)} = G_0^{(p)} \otimes (L^{(h)} + N_0^{(h)}) + \sum_{r=1}^m G_r^{(p)} \otimes N_r^{(h)},$$

where

$$[L^{(h)}]_{jk} = \int_{\mathcal{D}} \nabla \phi_k(\mathbf{x}) \cdot \nabla \phi_j(\mathbf{x}) d\mathbf{x}, \quad [N_r^{(h)}]_{jk} = - \int_{\mathcal{D}} \phi_j(\mathbf{x}) \nabla c_r \cdot \nabla \phi_k(\mathbf{x}) d\mathbf{x},$$

and, most importantly, $\{G_r^{(p)}\}$ are as in (16.7).

Remark 1. Although this method avoids the difficulties associated with nonlinear dependence on parameters, it is somewhat less general than a more direct approach. In particular, if (16.20) is a truncated approximation to a convergent series, then the series expansion of the gradient ∇c , for which (16.21) is an approximation, must also be convergent. This is true if and only if ∇c_0 and the second derivatives of the covariance function for c are continuous; see, e.g., [3, Sect. 4.3]. It holds, for example, for covariance functions of the form $\exp(-\|x - y\|_2^2)$ but not for those of the form $\exp(-\|x - y\|_2)$.

Any of the solution methods developed for problems that depend linearly on ξ are applicable in this setting, with slight modifications. For example, the mean-based preconditioner is $Q_0^{(hp)} \equiv G_0^{(p)} \otimes (L^{(h)} + N_0^{(h)})$. Since $A^{(hp)}$ is nonsymmetric, this preconditioner must be used with a Krylov subspace method such as GMRES designed for nonsymmetric systems. Moreover, $L^{(h)} + N_0^{(h)}$ is a discrete convection-diffusion operator, so that applying the preconditioner requires the (approximate) solution of N_ξ decoupled such operators. There are robust methods for solving the discrete convection-diffusion equation, using multigrid (see, e.g., [7, 32]), so the presence of this operator is not a significant drawback of this approach.

Convergence analysis of the GMRES method typically takes the form of bounds on the eigenvalues of the preconditioned operator $(Q_0^{(hp)})^{-1} A^{(hp)}$, which determines bounds on the asymptotic convergence factor for GMRES. The proof and additional details can be found in [30].

Theorem 4. *If the matrix N_0 has positive semi-definite symmetric part, then the eigenvalues of the mean-based preconditioned operator $(Q_0^{(hp)})^{-1} A^{(hp)}$ are contained in the circle*

$$\left\{ z \in \mathbb{C} : |z - 1| \leq 2c \eta_p \left(\sum_{r=1}^m \|\nabla a_m\|_\infty, \right) \right\},$$

where η_p is as in Lemma 1 and $c > 0$ is a constant independent of h and p .

4 Conclusion

This chapter contains a description of some of the main approaches for solving the coupled system of equations associated with stochastic Galerkin discretization of parameter-dependent partial differential equations. This “intrusive” discretization strategy gives rise to large algebraic systems of linear equations, but there is a variety of computational algorithms available that, especially for problems that depend linearly on the random parameters, offer the prospect of rapid solution. Indeed, through the use of such solvers, Galerkin methods are competitive with other ways of handling stochastic components of such models, such as stochastic collocation methods [6]. Their utility for more complex models remains an open question.

Abstract

Polynomial chaos (PC)-based intrusive methods for uncertainty quantification reformulate the original deterministic model equations to obtain a system of equations for the PC coefficients of the model outputs. This system of equations is larger than the original model equations, but solving it once yields the uncertainty information for all quantities in the model. This chapter gives an overview of the literature on intrusive methods, outlines the approach on a general level, and then applies it to a system of three ordinary differential equations that model a surface reaction system. Common challenges and opportunities for intrusive methods are also highlighted.

1 Introduction

Polynomial chaos expansions (PCEs) are spectral representations of random variables in terms of a set of polynomial basis functions that are orthogonal with respect to the density of a reference random variable. By treating uncertain quantities as random variables, PCEs provide a convenient way to represent uncertainty in model parameters or other inputs such as boundary and initial conditions. The current chapter focuses on propagating such input uncertainty through a forward model to obtain a PCE for the quantities of interest (QoIs) that are predicted by the model.

There are many approaches for the forward propagation of uncertainty, but largely they can be divided into collocation methods, which match a PCE to the forward model output for sampled values of the input uncertainty, and Galerkin projection methods, which obtain a PCE by projecting the model output onto the space covered by the PC basis functions. Within the family of Galerkin projection methods, there are Nonintrusive spectral projection (NISP) methods, which perform the Galerkin projection using samples of the model output, for specific values of the uncertain inputs. The focus of this section, however, is on intrusive spectral projection (ISP) methods, which apply the Galerkin projection to the forward model as a whole, leading to a reformulated system of equations for the coefficients of the spectral PCE for all uncertain model variables. The need to reformulate the system of equations is what gives this method the label of *intrusive*. All other sampling-based approaches can rely on the original deterministic implementation of the forward model to generate samples, thereby making them *non-intrusive* to the forward model.

The foundations for spectral representations of random variables were laid out in a 1938 paper by Wiener [56] and brought into the engineering community for the purpose of intrusive uncertainty quantification in the early 1990s [13]. In the early 2000s, PCEs were generalized to a wider family of basis types [57], and ISP was extended to a wider range of functions including transcedentals [8]. This allowed application to a wider class of problems, including fluid flow [15, 16, 29, 58], multi-physics microfluidics [7], and chemical reactions [29, 51], as well as many others.

Challenges encountered in these applications led to many advances in the use of PCEs for representing random variables. One development is the use of decompositions of the stochastic space, with local PCEs defined in each region, rather than global PCEs, which are defined over the full stochastic domain. This stochastic space decomposition allows the effective representation of random variables with very challenging distributions (e.g., multimodal distributions) [18, 19, 21, 38, 49, 53–55]. Other developments involve the use of variable transformations [22, 37], custom solvers, and preconditioners [10, 17, 24, 40, 41, 47, 48] to make the Galerkin-projected systems of equations easier or faster to solve, as well as methods to automate the construction of the Galerkin-projected systems [32, 33].

Clearly, intrusive uncertainty propagation is a very active research field with rich mathematical, algorithmic, and computational developments. The aim of this chapter is to give an introduction to the foundations of ISP. As such, rather than

trying to cover all of the material in this research field, it focuses on the Galerkin projection of governing equations in the context of global PCEs only.

The next section outlines the main theoretical and algorithmic concepts for ISP methods, followed by a specific example of propagation of parametric uncertainty through a set of ordinary differential equations (ODEs). After that, some of the challenges as well as opportunities for intrusive spectral propagation of uncertainty are covered. Finally, pointers are provided to some software packages that are set up for ISP uncertainty quantification.

2 Theory and Algorithms

Consider spectral PCEs following Wiener [56]. Let u be a real second-order random variable, i.e., a Lebesgue-measurable mapping from a probability space (Ω, Θ, P) into \mathbb{R} , where Ω is the set of elementary events, $\Theta(\xi)$ is a σ -algebra on Ω generated by the germ ξ , and P is a probability measure on (Ω, Θ) [13]. Such a random variable can be represented by a PCE as follows [11, 13, 56]:

$$u = \sum_{k=0}^{\infty} u_k \psi_k(\xi) \quad (17.1)$$

where the functions ψ_k are orthogonal polynomials of a set of random variables ξ and the u_k are deterministic coefficients, referred to as PC coefficients in this section. The random variables ξ in the germ of the PCE have zero mean and a unit standard deviation. The polynomials ψ_k are orthogonal with respect to the density $w(\xi)$ of their germ:

$$\langle \psi_i \psi_j \rangle \equiv \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \psi_i(\xi) \psi_j(\xi) w(\xi) d\xi = \delta_{ij} \langle \psi_i^2 \rangle \quad (17.2)$$

In the original Gauss-Hermite PCE type, the basis functions are Hermite polynomials as a function of Gaussian random variables ξ . Other commonly used choices are Legendre polynomials as a function of uniform random variables, referred to as Legendre-Uniform PCEs.

In practice, the choice of the germ and the associated basis functions affects the ease of representing the random variables of interest. For example, if a random variable can possibly take on any value on the real line, then a Gauss-Hermite expansion is often preferred since the basis functions have infinite support. However, if a random variable is subject to physical bounds on its possible values, then a basis with compact support, such as the Legendre-Uniform PCEs, is more convenient. A compact support basis makes it much easier to enforce hard bounds on the values that a PCE can take on. Sometimes quantities have a lower bound, but no upper bound, such as the temperature T in a chemically reacting system. In this case, a gamma-Laguerre PCE may be the most appropriate as the gamma distribution has support from 0 to $+\infty$. The gamma distribution can also be tailored to have a tail

that extends to higher values of ξ in case random variables with long tails need to be represented. Many other choices of random variables and associated polynomials are available, as detailed in [57].

A related question is how many basis terms are needed to accurately represent a random variable with a PCE. In general, the more similar the germ is to the random variable that needs to be represented, the fewer terms will be needed. For example, to represent a normally distributed random variable u with mean μ and standard deviation σ , a Gauss-Hermite expansion only needs two terms

$$u = \mu + \sigma \xi \quad (17.3)$$

while a Legendre-Uniform expansion would need many more terms. Even a 10th order Legendre-Uniform expansion offers only a very crude approximation [43].

While this rule of thumb is quite intuitive, the formal study of the convergence of PCEs is not as straightforward. For Gauss-Hermite expansions, a lot of convergence results are available, but this is not the case for most other types of bases. A careful analysis is presented by Ernst *et al.* [11]. One of the key findings in this chapter is that the distribution of a random variable needs to be uniquely determined by its moments in order for this random variable to be a valid germ for a PCE. One notable example that fails this test is a lognormal random variable. Further, for a given ξ , a proof is provided that shows that any random variable with finite variance that resides in the probability space with a Sigma algebra that is generated by ξ can be represented with a PCE that has ξ as its germ. While these conditions are very informative, it is clear however that the formal convergence of PCEs is a topic of ongoing research.

In practice, the choice of the PCE basis type and the order of the representation are often an engineering choice that depends on the amount of information provided about the random variable that needs to be represented.

To determine the PC coefficients for an arbitrary random variable u , the inner product (17.2) can be used as follows: First, multiply both sides of Eq. (17.1) with the basis function ψ_k , dropping the dependence on ξ for clarity of notation:

$$\psi_k u = \psi_k \sum_{i=0}^{\infty} u_i \psi_i \quad (17.4)$$

Then, move ψ_k inside the summation on the right-hand side, and take the expectation:

$$\langle \psi_k u \rangle = \left\langle \sum_{i=0}^{\infty} u_i \psi_i \psi_k \right\rangle \quad (17.5)$$

After rearranging some terms and recognizing that u_i does not depend on ξ , it can be factored outside of the expectation operator:

$$\langle \psi_k u \rangle = \sum_{i=0}^{\infty} u_i \langle \psi_i \psi_k \rangle \quad (17.6)$$

Taking into account the orthogonality of Eq. (17.2):

$$u_k = \frac{\langle u \psi_k \rangle}{\langle \psi_k^2 \rangle} \quad (17.7)$$

In other words, the PC coefficients u_k can be obtained by projecting the random variable u onto the space spanned by the PC basis functions, which is commonly referred to as a Galerkin projection.

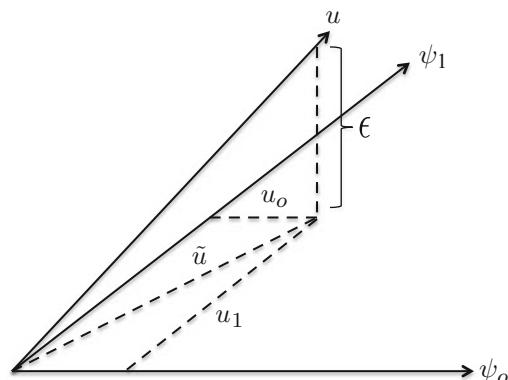

Figure 17.1 graphically illustrates the Galerkin projection for a two-term PCE. In practice, the PCE summation is generally truncated at some suitable high order, such that

$$u \approx \tilde{u} = \sum_{k=0}^P u_k \psi_k(\xi) \quad (17.8)$$

One nice property of the Galerkin projection is that the residual ϵ between the random variable u and its PC representation \tilde{u} is orthogonal to the space covered by the basis functions. In essence, \tilde{u} is the best possible representation of u with the given basis set (in the corresponding ℓ_2 norm on that same space).

Note that so far, the dimensionality of the PCE germ ξ has not been specified. In general, the dimensionality of ξ corresponds to the number of degrees of freedom in the random variable that is represented by the PCE. For example, if a quantity depends on two other uncertain inputs, then its PCE would depend on $\xi = \{\xi_1, \xi_2\}$. In a more general context, consider a random field, which has infinitely many degrees of freedom. To properly capture random fields with finite dimensional representations, a commonly used tool is the Karhunen-Loève (KL) expansion [13, 26]. The KL expansion represents a random field in terms of the eigenfunctions of its covariance matrix, multiplied with random variables that are uncorrelated. If the spectrum of the eigenvalues of the covariance matrix decays rapidly, then only a few eigenfunctions are needed to properly represent the random field with a truncated KL expansion. This generally occurs when the random field

Fig. 17.1 Galerkin projection of a random variable u onto the space covered by the PC basis functions

has long correlation lengths. However, when the random field has short correlation lengths, its realizations will have a lot of small-scale variability, which results in a slowly decaying eigenspectrum. In this case, many more terms are needed in the KL expansion to properly capture the random field, and a high-dimensional spectral representation is required.

As far as ISP is concerned, however, all methods described here apply naturally to PCEs of any dimension. The only thing that changes is the number of terms $P + 1$ in the PCE. As such, in this work, all PCEs will be expressed as a function of the germ ξ without specifying its dimensionality. In many cases, ξ will even be omitted from the notations for clarity.

In intrusive spectral uncertainty propagation, the Galerkin projection (17.7) is applied to the model equations in order to obtain a set of reformulated equations in the PCE coefficients. Consider, e.g., a simple ODE with an uncertain parameter λ .

$$\frac{du}{dt} = \lambda u \quad (17.9)$$

Assume a PCE is specified for λ :

$$\lambda = \sum_{i=0}^P \lambda_i \Psi_i(\xi) \quad (17.10)$$

Since the uncertainty in λ will create uncertainty in u , a PCE for u is specified:

$$u(t) = \sum_{j=0}^P u_j(t) \Psi_j(\xi) \quad (17.11)$$

with unknown coefficients $u_j(t)$. The task of forward propagation of uncertainty then is to determine the unknown PC coefficients $u_i(t)$, given the known coefficients λ_i and the governing Equation (17.9).

To accomplish this, substitute the PCEs for u and λ into the governing Equation (17.9):

$$\frac{d}{dt} \left(\sum_{j=0}^P u_j(t) \Psi_j(\xi) \right) = \left(\sum_{i=0}^P \lambda_i \Psi_i(\xi) \right) \left(\sum_{j=0}^P u_j(t) \Psi_j(\xi) \right) \quad (17.12)$$

and rearrange terms to get

$$\sum_{j=0}^P \frac{du_j(t)}{dt} \Psi_j(\xi) = \sum_{i=0}^P \sum_{j=0}^P \lambda_i u_j(t) \Psi_i(\xi) \Psi_j(\xi) \quad (17.13)$$

The next step applies a Galerkin projection onto the spectral basis functions by multiplying both sides of the equation with Ψ_k and taking the expectation with respect to the basis germ ξ :

$$\left\langle \sum_{j=0}^P \frac{du_j(t)}{dt} \Psi_j(\xi) \Psi_k(\xi) \right\rangle = \left\langle \sum_{i=0}^P \sum_{j=0}^P \lambda_i u_j(t) \Psi_i(\xi) \Psi_j(\xi) \Psi_k(\xi) \right\rangle \quad (17.14)$$

Since only the basis functions depend on ξ , the expectation operator can be moved inside the summations and products to yield

$$\sum_{j=0}^P \frac{du_j(t)}{dt} \langle \Psi_j(\xi) \Psi_k(\xi) \rangle = \sum_{i=0}^P \sum_{j=0}^P \lambda_i u_j(t) \langle \Psi_i(\xi) \Psi_j(\xi) \Psi_k(\xi) \rangle \quad (17.15)$$

Given the orthogonality of the basis functions, Equation (17.2), and dropping the dependence on ξ for notational clarity, this can be simplified to

$$\frac{du_k}{dt} \langle \Psi_k^2 \rangle = \sum_{i=0}^P \sum_{j=0}^P \lambda_i u_j \langle \Psi_i \Psi_j \Psi_k \rangle \quad (17.16)$$

After dividing by $\langle \Psi_k^2 \rangle$, this becomes

$$\frac{du_k}{dt} = \sum_{i=0}^P \sum_{j=0}^P \lambda_i u_j C_{ijk} \quad (17.17)$$

where

$$C_{ijk} = \frac{\langle \Psi_i \Psi_j \Psi_k \rangle}{\langle \Psi_k^2 \rangle} \quad (17.18)$$

Note that Equation (17.17), when written for $k = 0, \dots, P$ represents a system of $P + 1$ deterministic equations in the coefficients u_k of the PCE for u . The triple products C_{ijk} in these equations do not depend on either u or ξ ; so they can be precomputed at the beginning of a simulation based on the knowledge of the basis functions.

The procedure outlined above for the reformulation of the original governing equation into a set of equations for the PC coefficients can be applied to any model for which a governing equation is available in order to perform intrusive uncertainty quantification. However, the nature of the equations that result from this reformulation depends on the complexity of the original governing equation. Summations and subtractions are straightforward. Products between two uncertain variables can be handled similarly to the example above. For example, for the product of u and v , one gets

$$w_k = \sum_{i=0}^P \sum_{j=0}^P u_i v_j C_{ijk} \quad k = 0, \dots, P \quad (17.19)$$

which can be written symbolically as $w = u * v$ with “ $*$ ” representing a product between two PCEs. However, when three or more variables are multiplied with each other, e.g., in u^3 , the most practical way to proceed is often to perform the operation in pairs, i.e., compute u^3 as $(u*u)*u$. This is often referred to as a *pseudo-spectral* operation, since at each stage in the computation, the intermediate results are projected back onto a PCE of the same order as the basis functions, before the next operation is executed. Alternatively, a fully spectral multiplication can be done,

which multiplies all factors in the product at once and keeps all higher-order terms in the process. However, this leads to the need to compute the norms of the products of many basis functions, which becomes unwieldy and expensive as the number of factors in a product increases [8]. In practice, the pseudo-spectral approach is used most often for its ease of use. However, it is important to choose a PC expansion with a high-enough order to minimize the errors associated with the loss of information when intermediate results with higher-order terms are truncated in the process.

Divisions of variables represented by PC expansions can be handled by constructing an appropriate system of equations. Consider, e.g., $w = u/v$, which can be rewritten as $u = v * w$. By writing out this product using Equation (17.19), and substituting in the known PC expansions for u and v , a system of $P + 1$ equations in the unknown PC coefficients of w is obtained.

Through the sum, product, and division, polynomial expressions of PC expansions as well as ratios of such expressions can be evaluated. However, non-polynomial expressions can be more challenging to compute intrusively. One approach is to expand non-polynomial functions as a Taylor series around the mean of the random variable that is the function argument. This approach is often very effective when the function has a Taylor series that converges rapidly and when the uncertainty in the function argument is low. In the present context, low uncertainty means that realizations of the random variable that is represented with the PCE fall within the radius of convergence of the Taylor series around the mean. For functions that have a very large or infinite radius of convergence, such as the exponential function, this is not an issue, and Taylor series tend to be quite robust. However, other functions, such as the logarithm, have a narrow radius of convergence, which can make convergence tricky. In particular, when Gauss-Hermite expansions are used, the corresponding random variable can in theory take on any value on the real line. In practice, the Taylor series for the logarithm of Gauss-Hermite PCEs will only converge if the uncertainty is very low so that the probability of realizations falling outside the radius of convergence is very low [8].

For some specific functions, namely, those whose derivative can be written as a rational expression of the function outcome or its argument, the PC expansion of the function evaluation can be found through an integration approach. Consider, e.g., the `exp()` function. If $v = e^u$, then $dv = e^u du = v du$. As such,

$$e^b - e^a = \int_a^b v \, du \quad (17.20)$$

where the integration is performed along a suitable path from a to b . A convenient choice is often to choose the mean of b as the starting point for the integration. In essence, $a = b_0$, such that e^a is trivial to compute as the PC coefficient b_0 is a deterministic, scalar number. For more details on the integration approach, as well as illustrations of its applicability, see [8].

The key takeaway of this section is that for many operations, the stochastic reformulation is quite straightforward, allowing the application of the intrusive spectral projection approach to the governing equations of a wide variety of problems. ISP has been applied to elliptic equations [2, 3, 6, 17, 27, 44, 46],

hyperbolic equations [5, 34–36, 52], the Navier-Stokes equations [14–16, 20, 31, 58], systems with oscillatory behavior [4, 23, 28, 60], flow through porous media [12], the heat equation [59], systems with complex multiphysics coupling [7], chemically reacting systems [42], and many other fields. In the next section, it will be applied to a set of ODEs that govern a chemically reacting system.

3 Example: Intrusive Propagation of Uncertainty Through ODEs

To illustrate the intrusive UQ approach on a simple but non-trivial example, consider the system of three ODEs below:

$$\frac{du}{dt} = az - cu - 4duv \quad (17.21)$$

$$\frac{dv}{dt} = 2bz^2 - 4duv \quad (17.22)$$

$$\frac{dw}{dt} = ez - fw \quad (17.23)$$

$$z = 1 - u - v - w \quad (17.24)$$

with initial conditions:

$$u(0) = v(0) = w(0) = 0.0 \quad (17.25)$$

and the following nominal values for the six parameters:

$$a = 1.6 \quad b = 20.75 \quad c = 0.04 \quad (17.26)$$

$$d = 1.0 \quad e = 0.36 \quad f = 0.016 \quad (17.27)$$

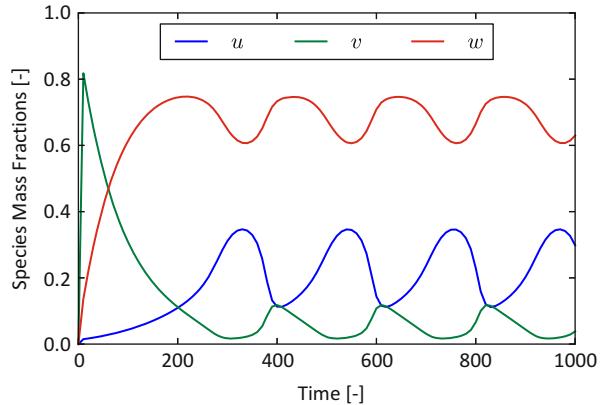

This set of equations models a heterogeneous surface reaction involving a monomer and a dimer that can react with each other after adsorbing onto a surface out of a gas phase. The reaction product is released back into the gas phase. An inert species competes for vacancies on the surface [25, 50]. In the set of equations above, u represents the coverage fraction on the surface of the monomer, v represents the coverage fraction of the dimer, w represents the coverage fraction of the inert species, and z represents the vacant fraction.

While this system of equations is relatively simple, it describes a rich set of dynamics, including oscillatory behavior for $b \in [20.2, 21.2]$. For the nominal values of the parameters, the system behavior is shown in Fig. 17.2.

For values of b outside of this interval, either damped oscillations or asymptotic approaches to steady-state values are observed.

Assuming b is an uncertain input to this system, its uncertainty can be propagated into the model outputs u , v , and w using the intrusive approach. As outlined above,

Fig. 17.2 System dynamics for nominal parameter values

PCEs for the model variables are first postulated, which are then substituted into the governing equations.

$$b = \sum_{i=0}^P b_i \Psi_i(\xi) \quad (17.28)$$

$$u(t) = \sum_{i=0}^P u_i(t) \Psi_i(\xi) \quad v(t) = \sum_{i=0}^P v_i(t) \Psi_i(\xi) \quad (17.29)$$

$$w(t) = \sum_{i=0}^P w_i(t) \Psi_i(\xi) \quad z(t) = \sum_{i=0}^P z_i(t) \Psi_i(\xi) \quad (17.30)$$

Substituting those PCEs first into Equation (17.21), multiplying with Ψ_k , and taking the expectation w.r.t. ξ results in

$$\frac{du}{dt} = az - cu - 4duv \quad (17.31)$$

$$\frac{d}{dt} \sum_{i=0}^P u_i \Psi_i = a \sum_{i=0}^P z_i \Psi_i - c \sum_{i=0}^P u_i \Psi_i - 4d \sum_{i=0}^P u_i \Psi_i \sum_{j=0}^P v_j \Psi_j \quad (17.32)$$

$$\begin{aligned} \left\langle \Psi_k \frac{d}{dt} \sum_{i=0}^P u_i \Psi_i \right\rangle &= \left\langle a \Psi_k \sum_{i=0}^P z_i \Psi_i \right\rangle - \left\langle c \Psi_k \sum_{i=0}^P u_i \Psi_i \right\rangle \\ &\quad - \left\langle 4d \Psi_k \sum_{i=0}^P u_i \Psi_i \sum_{j=0}^P v_j \Psi_j \right\rangle \end{aligned} \quad (17.33)$$

after rearranging terms and invoking the orthogonality of the basis functions, this results in

$$\frac{d}{dt} u_k \langle \Psi_k^2 \rangle = az_k \langle \Psi_k^2 \rangle - cu_k \langle \Psi_k^2 \rangle - 4d \sum_{i=0}^P \sum_{j=0}^P u_i v_j \langle \Psi_i \Psi_j \Psi_k \rangle \quad (17.34)$$

$$\frac{d}{dt} u_k = az_k - cu_k - 4d \sum_{i=0}^P \sum_{j=0}^P u_i v_j C_{ijk} \quad (17.35)$$

where Equation (17.35) is solved for $k = 0, \dots, P$, using the same C_{ijk} constants as defined before in Equation (17.18).

For the dimer coverage fraction, the same procedure is applied to Equation (17.22) to get

$$\frac{dv}{dt} = 2bz^2 - 4duv \quad (17.36)$$

$$\frac{d}{dt} \sum_{i=0}^P v_i \Psi_i = 2 \sum_{h=0}^P b_h \Psi_h \sum_{i=0}^P z_i \Psi_i \sum_{j=0}^P z_j \Psi_j - 4d \sum_{i=0}^P u_i \Psi_i \sum_{j=0}^P v_j \Psi_j \quad (17.37)$$

$$\begin{aligned} \left\langle \Psi_k \frac{d}{dt} \sum_{i=0}^P v_i \Psi_i \right\rangle &= \left\langle 2\Psi_k \sum_{h=0}^P b_h \Psi_h \sum_{i=0}^P z_i \Psi_i \sum_{j=0}^P z_j \Psi_j \right\rangle \\ &\quad - \left\langle 4d \Psi_k \sum_{i=0}^P u_i \Psi_i \sum_{j=0}^P v_j \Psi_j \right\rangle \end{aligned} \quad (17.38)$$

which, after rearranging terms and accounting for orthogonality, results in

$$\frac{d}{dt} v_k \langle \Psi_k^2 \rangle = 2 \sum_{h=0}^P \sum_{i=0}^P \sum_{j=0}^P b_h z_i z_j \langle \Psi_h \Psi_i \Psi_j \Psi_k \rangle - 4d \sum_{i=0}^P \sum_{j=0}^P u_i v_j \langle \Psi_i \Psi_j \Psi_k \rangle \quad (17.39)$$

$$\frac{d}{dt} v_k = 2 \sum_{h=0}^P \sum_{i=0}^P \sum_{j=0}^P b_h z_i z_j \frac{\langle \Psi_h \Psi_i \Psi_j \Psi_k \rangle}{\langle \Psi_k^2 \rangle} - 4d \sum_{i=0}^P \sum_{j=0}^P u_i v_j \frac{\langle \Psi_i \Psi_j \Psi_k \rangle}{\langle \Psi_k^2 \rangle} \quad (17.40)$$

$$\frac{d}{dt} v_k = 2 \sum_{h=0}^P \sum_{i=0}^P \sum_{j=0}^P b_h z_i z_j D_{hijk} - 4d \sum_{i=0}^P \sum_{j=0}^P u_i v_j C_{ijk} \quad (17.41)$$

In Equation (17.41), the factors D_{hijk} result from the fact that the original equation contains a product of three uncertain variables, and all terms in the product are retained (full spectral product). However, as discussed in the previous section, precomputing and storing the D_{hijk} can get pretty tedious. Further, even though

the product is performed fully spectrally, only the first $(P + 1)$ terms are retained, since Equation (17.41) is only solved for $k = 0, \dots, P$.

To avoid the need for computing the D_{hijk} factors, a pseudo-spectral approach is used by rewriting Equation (17.22) using an auxiliary variable g as follows:

$$g = z^2 \quad (17.42)$$

$$\frac{dv}{dt} = 2bg - 4d\bar{uv} \quad (17.43)$$

Using this transformation, the product of three uncertain variables has been removed, and the Galerkin-projected equations for the PC coefficients become

$$g_k = \sum_{i=0}^P \sum_{j=0}^P z_i z_j C_{ijk} \quad (17.44)$$

$$\frac{d}{dt} v_k = 2 \sum_{i=0}^P \sum_{j=0}^P b_i g_j C_{ijk} - 4d \sum_{i=0}^P \sum_{j=0}^P u_i v_j C_{ijk} \quad (17.45)$$

which is solved for $k = 0, \dots, P$.

Equation (17.23) for w is similarly reformulated to

$$\frac{d}{dt} w_k = ez_k - fw_k \quad k = 0, \dots, P \quad (17.46)$$

For z , Equation (17.25) becomes

$$z_0 = 1 - u_0 - v_0 - w_0 \quad (17.47)$$

$$z_k = -u_k - v_k - w_k \quad k = 1, \dots, P \quad (17.48)$$

The combined set of reformulated Equations (17.35), (17.44), (17.45), (17.46), (17.47), and (17.48) results in a system of $4(P + 1)$ equations in the unknowns u_k , v_k , w_k , and z_k .

As an illustration, this system of equations is solved here for the case where the parameter b is uniformly distributed with an uncertainty of 0.5% (mean over standard deviation). All other parameters are kept at their nominal values. As b is uniformly distributed and the model has some nonlinearities, a 5th order Legendre-Uniform PC basis set is used to represent the uncertain variables in the system.

Figure 17.3 shows the means and standard deviations for the main quantities of interest. Starting from a deterministic initial condition, the uncertainty in each quantity is initially very small, but it grows as time goes on. This is also visible in Fig. 17.4, which shows the PC coefficients of u as a function of time. The coefficient for the mean, u_0 , shows a steady oscillatory behavior. The first-order coefficient, u_1 , grows as a function of time, and the higher-order coefficients also become nonzero

Fig. 17.3 Mean and standard deviation for u , v , and w up to $t = 1000$

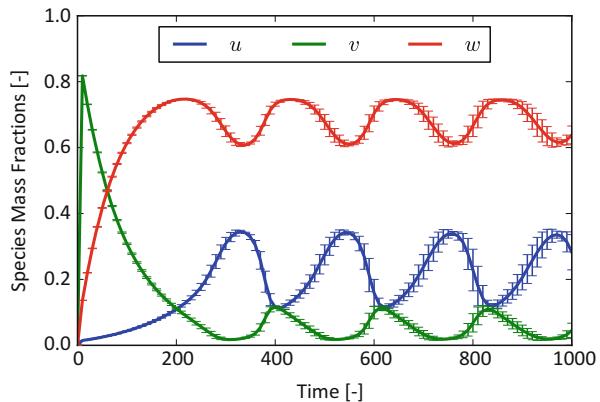

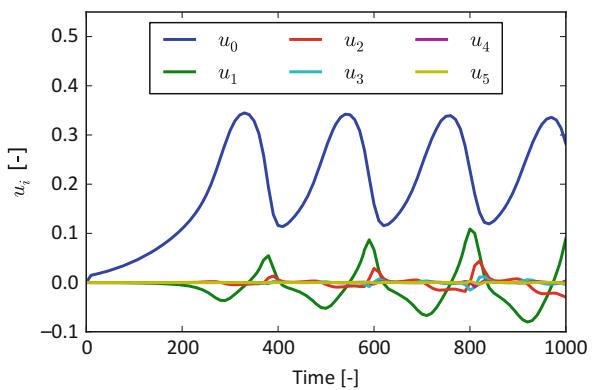

Fig. 17.4 PC coefficients for u as a function of time

later on in the simulation, suggesting that both the uncertainty and skewness of the distribution of u are changing in time. Note that the higher-order terms are the smallest in magnitude when the mean value goes through a local maximum or minimum and the largest in magnitude when the mean value has the largest gradients in time. This indicates that a lot of the uncertainty in u is due to phase shifts in the oscillation due to uncertainty in b .

To get a feel for the distribution of u , Fig. 17.5 shows PDFs of u at selected instances in time. To generate these PDFs, the PCEs of u at the corresponding points in time were evaluated for 100,000 samples of the PCE germ, and the resulting u samples were used as data to get the PDFs with kernel density estimation (KDE). For the points in time where the mean of u has a high value (left plot in Fig. 17.5), the PDFs show a distinct peak, but there is tail toward lower values that gets broader in time. For the cases where the standard deviation has a local maximum (right plot in Fig. 17.5), the PDFs of u show a more and more distinctive bimodal behavior as time goes on.

Figure 17.6 shows a comparison between PDFs for u , generated with intrusive spectral projection (ISP), nonintrusive spectral projection (NISP), and Monte Carlo

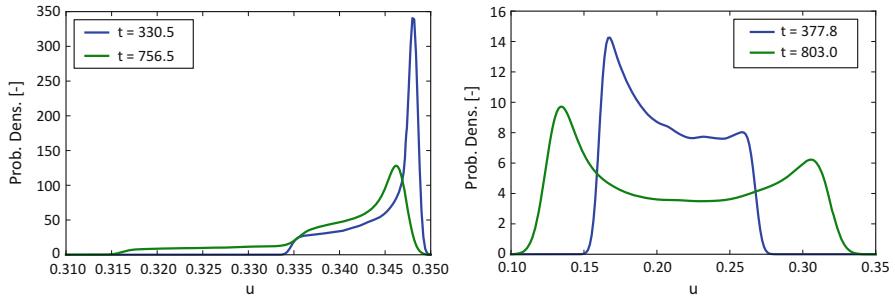

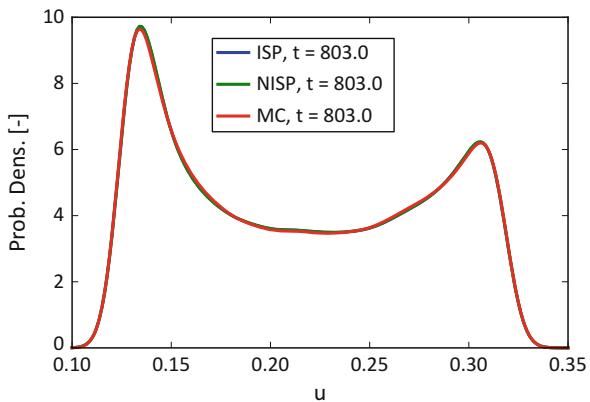

Fig. 17.5 Probability density functions (PDFs) of u at select points in time. *Left:* two instances in time where the mean value of u reaches a maximum. *Right:* two instances in time where the standard deviation of u reaches a maximum

Fig. 17.6 Comparison between the PDFs for u as obtained with intrusive spectral projection (ISP), nonintrusive spectral projection (NISP), and Monte Carlo sampling (MC). There is very good agreement in the results from all three approaches

sampling (MC). For the NISP results, the deterministic system of ODEs was evaluated for six values of b , sampled at the Gauss-Legendre quadrature points. The resulting u samples were then used to project u onto the PC basis function with quadrature integration. For more information on this approach, see ▶ Chap. 21, “Sparse Collocation Methods for Stochastic Interpolation and Quadrature.” In the Monte Carlo approach, the deterministic ODE system was evaluated for 50,000 randomly sampled values of b . The resulting u values were not used to construct a PCE, but instead fed directly into KDE to generate a PDF. All three approaches show very good agreement with each other, which validates the implementation of the ISP and NISP methods and also confirms that the choice of a 5th-order PCE was appropriate for this example.

A more detailed comparison between the ISP and NISP results is shown in Fig. 17.7, which compares the 4th- and 5th-order terms in the PCE of u as a function of time.

The lower-order terms in the PCE of u are indistinguishable (not shown) between the ISP and NISP approaches. The 4th- and 5th-order terms are also nearly indistinguishable, except at late time, when very minor differences become

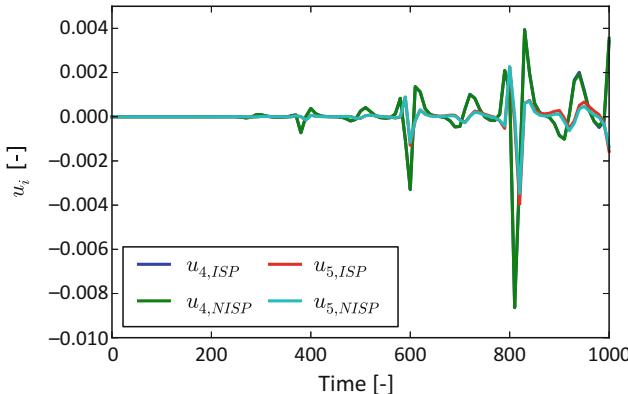

Fig. 17.7 Comparison of the 4th- and 5th-order terms in the PCE of u as a function of time, generated with intrusive (ISP) and nonintrusive (NISP) spectral projection

visible. If the integration time horizon were further extended, those differences would become larger, due to the need to use higher-order representations to properly capture all intermediate variables in the computations and avoid phase errors in the oscillatory dynamics [38]. This touches on some of the challenges with the ISP approach, which are discussed in the next section.

4 Challenges and Opportunities

As illustrated in the previous sections, the intrusive spectral projection approach offers an elegant way to solve for the PC coefficients of uncertain quantities in a computational model. However, in practice, some challenges may emerge.

A first drawback of the intrusive approach is that a governing equation needs to be present for the quantities of interest. This is usually not an issue, but for some applications it is a concern. Consider, e.g., the period of oscillation in the surface reaction example in the previous section. While governing equations are present for u , v , w , and z , there is no governing equation for the period of oscillation. With a sampling-based approach, on the other hand, the periodicity can be extracted from the time trace of each realization, making NISP readily applicable.

A second concern is that the basis and the order of the PCEs in ISP need to be chosen so that they can represent not only the output quantities of interest but all intermediate variables that are needed to compute the outputs as well. This is especially a concern if the model has strong nonlinearities. For example, if any of the computations involve $v = u^{12}$, then the PCE needs to be able to represent the high-order information that will show up in v , even if the outputs of the model only contain lower-order information [8]. Another example would be chemically reacting systems, where quantities such as temperature and species concentrations need to be strictly positive and highly nonlinear reaction dynamics create a lot of higher-order

information, with both of these conditions placing a lot of demands on the spectral representation of uncertain quantities.

The reformulation of the governing equations actually alters the nature of the equations to be solved. Not only is the system of equations larger than the original deterministic system of equations, but its dynamics can change, e.g., through the emergence of spurious eigenvalues [45]. All of this requires careful construction of solvers for the systems of equations resulting from intrusive Galerkin projection [1, 30].

Due to these challenges, intrusive uncertainty quantification approaches have mostly found use in problems with near linear behavior. Also, the fact that intrusive methods require a code rewrite remains a significant barrier to their adoption. Instead, the various nonintrusive approaches are much more widely used, thanks to their relative ease of implementation and the fact that they rely on the same solvers that are used for the original deterministic equations. As of recently, however, intrusive UQ methods are gathering increased attention, for their potential to make better use of extreme scale computing architectures. Using proper preconditioners and solvers, the large systems of equations resulting from the intrusive Galerkin reformulation are often well suited to take advantage of intra-node concurrency, e.g., via multi-core nodes or GPUs [40]. As such, research in intrusive methods for uncertainty propagation is alive and well.

5 Software for Intrusive UQ

Given the complexities of creating and solving the systems of equations for intrusive UQ, and its status more of a research topic rather than a mainstream application method, relatively few software packages are available for intrusive UQ. Two open-source packages are mentioned here: UQTk and Stokhos.

UQTk stands for *UQ Toolkit* [9], containing libraries and tools for the quantification of uncertainty in computational models. It includes tools for intrusive Galerkin projection of many numerical operations. It is geared toward algorithm prototyping, tutorial, and academic use.

Stokhos [39] is part of the Trilinos project. It provides methods for computing well-known intrusive stochastic Galerkin projections such as polynomial chaos and generalized polynomial chaos, interfaces for forming the resulting nonlinear systems, and linear solver methods for solving block stochastic Galerkin linear systems. Stokhos is geared toward handling large systems of equations and, through its connection with other Trilinos libraries, is set up for high performance computing platforms.

6 Conclusions

Intrusive methods for uncertainty quantification provide a powerful and elegant way to propagate uncertainties through computational models. Through the Galerkin projection of the original governing equations of a deterministic problem with

uncertain inputs, a new system of equations is obtained for the PC coefficients of the quantities of interest in the problem. Solving this system once provides the PCEs for all quantities of interest. For most problems, this reformulation of the governing equations is straightforward, and software is available to automate part(s) of this process. There are some challenges, however, for intrusive methods, as the Galerkin projection for some operations is not straightforward, e.g., some transcendental functions, and the resulting systems of equations can be difficult to solve. In recent years, intrusive methods have been garnering renewed attention as the large systems of equations that they generate are often well suited for extreme scale computing hardware.

Abstract

We survey the application of multiresolution analysis (MRA) methods in uncertainty propagation and quantification problems. The methods are based on the representation of uncertain quantities in terms of a series of orthogonal multiwavelet basis functions. The unknown coefficients in this expansion are then determined through a Galerkin formalism. This is achieved by injecting the multiwavelet representations into the governing system of equations and exploiting the orthogonality of the basis in order to derive suitable evolution equations for the coefficients. Solution of this system of equations yields the evolution of the uncertain solution, expressed in a format that readily affords the extraction of various properties.

One of the main features in using multiresolution representations is their natural ability to accommodate steep or discontinuous dependence of the solution on the random inputs, combined with the ability to dynamically adapt the resolution, including basis enrichment and reduction, namely, following the evolution of the surfaces of steep variation or discontinuity. These capabilities are illustrated in light of simulations of simple dynamical system exhibiting a bifurcation and more complex applications to a traffic problem and wave propagation in gas dynamics.

1 Introduction

A severe difficulty arising in the analysis of stochastic systems concerns the situation where the solution exhibits steep or discontinuous dependence on the random variables that are used to parametrize the uncertain inputs. Well-known examples where these situations arise include complex systems involving shock formation or an energy cascade [1, 2], bifurcations [3, 4], and chemical system ignition [5].

It is well known that these complex settings result in severe difficulties in representing the solution in terms of smooth global functionals. For instance, Gaussian processes frequently exhibit large errors when the solution is discontinuous and generally become impractical. When global polynomial basis functions are used [6], the representation generally suffers from low convergence rate when the solution varies steeply with the random inputs and requires an excessively large basis when discontinuities arise.

In order to address and overcome these difficulties, it is generally desirable to develop methodologies that can provide appropriate resolution in regions of (smooth) steep variation and in the extreme cases isolate the regions where discontinuities occur. When discontinuities occur along hypersurfaces of well-defined regions, one can generally decompose the random parameter domain into regions over which the solution varies smoothly and consequently build a global representation as a collection of smooth representations defined over subdomains.

The domain decomposition approach [4] is relatively straightforward in situations where the hypersurfaces across which the solution varies discontinuously have fixed positions and when the latter are known. When this is not the case, the hypersurfaces must be first localized. Various approaches have been recently developed to address this problem, including detection approaches [7].

In many cases, however, one is faced with the additional complexity that the hypersurfaces of discontinuity can evolve according to the dynamics of the system as well as the uncertain inputs. This necessitates a methodology that can dynamically adapt the representation of the solution response in such a way as to accommodate such behavior. The focus of this chapter is to provide a brief outline of a class of adaptive multiresolution analysis (MRA) methods that can achieve this capability.

In contrast to methods based on global polynomials [6], experiences with the application of MRA methods to uncertain systems have been more limited [3–5, 8–14]. Our goals in the present discussion are twofold: (1) to outline the basic construction of multiresolution representations in a probabilistic setting and their implementation in the context of a Galerkin formalism for uncertainty propagation [15] and (2) to illustrate applications in which dynamic adaptation of the representation is particularly essential.

This chapter is organized as follows. Section 2 provides an introduction to the multiresolution system (MRS) for the case of a single dimension. Section 3 details the construction of multiresolution spaces in higher dimension, relying on binary trees, and introduces essential multiscale operators. Section 4 discusses adaptivity based on the multiresolution framework, detailing crucial criteria for deciding the coarsening and enrichment of the approximation spaces. Illustrations of simulations using multiresolution schemes are provided in Sect. 5, in light of applications to an elementary dynamical system and to a traffic flow problem. Concluding remarks are given in Sect. 6.

2 One-Dimensional Multiresolution System

We are interested in the output of a (generally nonlinear) model involving uncertain input quantities. For simplicity, we shall assume that the uncertain inputs can be parametrized by a finite number of N independent real-valued random variables $\xi := \{\xi_1 \dots \xi_N\}$ with known distributions. We further restrict ourselves to situations where each random variable ξ_i can be mapped to a random variable x_i with uniform distribution on the unit interval $\mathcal{U} \doteq [0, 1]$. In other words, the parameters can be expressed in terms of the random vector $\mathbf{X} \in \mathbb{R}^N$ having independent components and uniform density $p_{\mathbf{X}}$ over the unit hypercube $\Xi \doteq \mathcal{U}^N$:

$$p_{\mathbf{X}}(\mathbf{x} \in \mathbb{R}^N) = \begin{cases} 1 & x_{i=1,\dots,N} \in \mathcal{U} \\ 0 & \text{otherwise} \end{cases}. \quad (18.1)$$

Let $L_2(\Xi)$ be the space of second-order random variables defined on the probability space $\mathcal{P}_{\Xi} := (\Xi, \mathcal{B}_{\Xi}, p_{\mathbf{X}})$, where \mathcal{B}_{Ξ} is the Borel set of Ξ . The

space $L_2(\Xi)$ is equipped with the inner product denoted $\langle \cdot, \cdot \rangle_{\Xi}$ and norm $\|\cdot\|_2$ given by

$$\langle U, V \rangle_{\Xi} \doteq \int_{\Xi} U(x) V(x) p_{\mathbf{X}}(\mathbf{x}) d\mathbf{x}, \quad \|U\|_2^2 = \langle U, U \rangle. \quad (18.2)$$

We recall that

$$\|U\|_2 < +\infty \Leftrightarrow U \in L_2(\Xi). \quad (18.3)$$

The objective is then to construct an approximation of the model output, say $U \in \mathbb{R}$, which is a functional of the random input \mathbf{X} . We shall assume that $U : \mathbf{X} \in \Xi \mapsto U(\mathbf{X}) \in L_2(\Xi)$. In practice, the approximation is obtained by projecting U on a finite dimensional subspace of $L_2(\Xi)$. To this end, Hilbertian bases of random functionals in \mathbf{X} spanning $L_2(\Xi)$ are often considered. Upon truncation of the Hilbertian basis, the problem reduces to the determination of a finite number of coordinates defining the approximation of U in the truncated basis. It is obvious that the approximation error depends heavily on the subspace of $L_2(\Xi)$ spanned by the random functionals retained in the approximation. When sufficient smoothness in the mapping $\mathbf{X} \mapsto f(\mathbf{X})$ is expected, it is well known that using smooth spectral functionals in \mathbf{X} , for instance, multivariate polynomials, is an effective approach to achieve high convergence of the approximation error as the dimension of the subspace increases. However, as discussed in the introduction, steep or even non-smooth dependences of $U(\mathbf{X})$ may significantly delay or even compromise the convergence of the approximation. The multiresolution analysis provides a convenient framework to construct an alternative approximation space spanned by piecewise smooth random functionals, and eventually to adapt the approximation subspace to the random function U , therefore minimizing the computational complexity of determining its approximation.

In this section, we restrict ourselves to the case of a single random parameter, $X = X_1$, so $\Xi = \mathcal{U}$. In Sect. 2.1, we introduce the sequence of one-dimensional multiresolution spaces. We then discuss in Sects. 2.2 and 2.3 two different bases for the multiresolution spaces. These two bases have different hierarchical structures that are outlined. The extension of these concepts to higher-dimensional spaces is addressed in Sect. 3.

2.1 Multiresolution Analysis and Multiresolution Space

Let \mathcal{U} be the unit interval. For given integer $k \geq 0$, called the resolution level, we define the partition $\mathcal{P}^{(k)}$ of \mathcal{U} into 2^k non-overlapping subintervals $\mathcal{U}_l^{(k)}$ having equal size,

$$\mathcal{P}^{(k)} = \left\{ \mathcal{U}_l^{(k)}, l = 1, \dots, 2^k \right\}, \quad \mathcal{U}_l^{(k)} \doteq \left[\frac{l-1}{2^k}, \frac{l}{2^k} \right],$$

so we have

$$\bigcup_{l=1}^{2^k} \mathcal{U}_l^{(k)} = \mathcal{U}, \quad \mathcal{U}_l^{(k)} \cap \mathcal{U}_{l'}^{(k)} = \emptyset \text{ for } l \neq l'.$$

The partition $\mathcal{P}^{(k)}$ can also be defined recursively, through successive dyadic partitioning starting from $\mathcal{P}^{(0)} = \mathcal{U}$.

For $No = 0, 1, \dots$ and $k = 0, 1, 2, \dots$, we consider the space $\mathbf{V}_{No}^{(k)}$ of piecewise polynomial functions associated to the partition $\mathcal{P}^{(k)}$ according to:

$$\mathbf{V}_{No}^{(k)} = \left\{ U : x \in \mathcal{U} \mapsto \mathbb{R}; U|_{\mathcal{U}_l^{(k)}} \in \pi_{No} \left(\mathcal{U}_l^{(k)} \right), l = 1, \dots, 2^k \right\}, \quad (18.4)$$

where we have denoted by $\pi_{No}(\mathcal{J})$ the space of polynomials with degree less or equal to No defined over \mathcal{J} .

In other words, the space $\mathbf{V}_{No}^{(k)}$ consists of the functions that are polynomials of degree at most No over each subintervals $\mathcal{U}_l^{(k)}$ of the partition $\mathcal{P}^{(k)}$. Observe that $\dim(\mathbf{V}_{No}^{(k)}) = (No + 1) \times 2^k$. In addition, these spaces have a nested structure in the sense that

$$\mathbf{V}_{No}^{(0)} \subset \mathbf{V}_{No}^{(1)} \subset \mathbf{V}_{No}^{(2)} \subset \dots \quad \text{and} \quad \mathbf{V}_0^{(k)} \subset \mathbf{V}_1^{(k)} \subset \mathbf{V}_2^{(k)} \subset \dots$$

Denoting \mathbf{V}_{No} and $\mathbf{V}^{(k)}$ the union of all spaces,

$$\mathbf{V}_{No} = \overline{\bigcup_{k \geq 0} \mathbf{V}_{No}^{(k)}} \quad \text{and} \quad \mathbf{V}^{(k)} = \overline{\bigcup_{No \geq 0} \mathbf{V}_{No}^{(k)}},$$

it is remarked [16] that these union spaces are dense in $L_2(\mathcal{U})$, the space of square integrable functions equipped with the inner product denoted $\langle \cdot, \cdot \rangle_{\mathcal{U}}$.

We now construct two distinct orthonormal bases for $\mathbf{V}_{No}^{(k)}$.

2.2 Stochastic Element Basis

For the stochastic element (SE) bases, we start from the Legendre basis for $\mathbf{V}_{No}^{(0)}$, that is, the space at resolution level $k = 0$,

$$\mathbf{V}_{No}^{(0)} = \text{span} \{ \mathcal{L}_\alpha, \alpha = 0, \dots, No \}. \quad (18.5)$$

Here, we denoted $\mathcal{L}_\alpha(x)$ the normalized Legendre polynomial of degree α , rescaled to \mathcal{U} , such that

$$\langle \mathcal{L}_\alpha, \mathcal{L}_\beta \rangle_{\mathcal{U}} = \begin{cases} 1, & \alpha = \beta \\ 0, & \alpha \neq \beta \end{cases}, \quad \|\mathcal{L}_\alpha\| = 1. \quad (18.6)$$

Introducing the affine mapping $M_l^{(k)} : \mathcal{U}_l^{(k)} \mapsto \mathcal{U}$ through

$$M_l^{(k)}(x) \doteq (2^k x - l + 1), \quad (18.7)$$

we construct the associated shifted and scaled versions of the Legendre polynomials \mathcal{L}_α as follows:

$$\Phi_{\alpha,l}^{(k)}(x) = \begin{cases} 2^{k/2} \mathcal{L}_\alpha(M_l^{(k)} x), & x \in \mathcal{U}_l^{(k)}, \\ 0, & \text{otherwise.} \end{cases} \quad (18.8)$$

The resulting functions $\Phi_{\alpha,l}^{(k)}(x)$ obviously belong to $\mathbf{V}_{\text{No} \geq \alpha}^{(k)}$, and, for given resolution level k , one can easily verify that they form an orthonormal set

$$\langle \Phi_{\alpha,l}^{(k)}, \Phi_{\beta,l'}^{(k)} \rangle_{\mathcal{U}} = \begin{cases} 1, & \alpha = \beta \text{ and } l = l', \\ 0, & \text{otherwise.} \end{cases} \quad (18.9)$$

Thus, $\{\Phi_{\alpha,l}^{(k)}; \alpha = 0, \dots, \text{No}; l = 1, \dots, 2^k\}$ is an orthonormal basis of $\mathbf{V}_{\text{No}}^{(k)}$ since $\dim(\mathbf{V}_{\text{No}}^{(k)}) = 2^k (\text{No} + 1)$.

Therefore, any function $U \in \mathbf{V}_{\text{No}}^{(k)}$ can be expanded as

$$\mathbf{V}_{\text{No}}^{(k)} \ni U(x) = \sum_{\alpha=0}^{\text{No}} \sum_{l=1}^{2^k} u_{\alpha,l}^{(k)} \Phi_{\alpha,l}^{(k)}(x), \quad (18.10)$$

where the coefficients $u_{\alpha,l}^{(k)}$ are the SE coefficients of U . Also, the orthogonal projection of $U \in L_2(\mathcal{U})$ in $\mathbf{V}_{\text{No}}^{(k)}$, denoted hereafter $\mathbb{P}_{\text{No}}^{(k)} U$, minimizes $\|U - V\|_{\mathcal{U}}$ over all $V \in \mathbf{V}_{\text{No}}^{(k)}$ and has for expression

$$\mathbb{P}_{\text{No}}^{(k)} U(x) = \sum_{\alpha=0}^{\text{No}} \sum_{l=1}^{2^k} u_{\alpha,l}^{(k)} \Phi_{\alpha,l}^{(k)}(x), \quad u_{\alpha,l}^{(k)} = \langle U, \Phi_{\alpha,l}^{(k)} \rangle_{\mathcal{U}}. \quad (18.11)$$

The projection error $U - \mathbb{P}_{\text{No}}^{(k)} U$ can be reduced by considering richer projection spaces, that is, by refining the partition $\mathcal{P}^{(k)}$ (increasing the resolution level k), or the polynomial degree (increasing No), or both.

From Eq. (18.11), we remark that for a fixed resolution level k , the projection coefficient $u_{\alpha,l}^{(k)}$ associated to polynomial degrees $\alpha = 1, \dots, \text{No}$ are not affected when considering spaces with higher polynomial degrees. In other words, increasing the polynomial degree amounts to complement the SE expansion with additional (higher degree), leaving unchanged the previous ones. On the contrary, the whole

SE expansion is affected when one changes the resolution level k , for instance, considering a finer partition $\mathcal{P}^{(k)}$, even if the polynomial degree No is kept constant. This is due to the structure of the SE basis functions which are not orthogonal (in general) for different resolution levels. The absence of orthogonality between SE basis functions at different resolution levels makes it difficult to control and reduce the projection error through partition refinement. This motivates the introduction of hierarchical enrichments having the *orthogonal* properties between resolution levels. Stochastic multiwavelet (MW) expansions exactly achieve this task.

2.3 Multiwavelet Basis

2.3.1 Detail Spaces

Let us denote by $\mathbf{W}_{No}^{(k)}$, $k = 0, 1, 2, \dots$, the subspace corresponding to the orthogonal complement of $\mathbf{V}_{No}^{(k)}$ in $\mathbf{V}_{No}^{(k+1)}$; that is,

$$\mathbf{V}_{No}^{(0)} \oplus \mathbf{W}_{No}^{(k)} = \mathbf{V}_{No}^{(k+1)}, \quad \mathbf{W}_{No}^{(k)} \perp \mathbf{V}_{No}^{(k)}. \quad (18.12)$$

The spaces $\mathbf{W}_{No}^{(k)}$ are called detail spaces; we have

$$\overline{\mathbf{V}_{No}^{(0)} \bigoplus_{k \geq 0} \mathbf{W}_{No}^{(k)}} = L_2(\mathcal{U}). \quad (18.13)$$

The objective is now to construct an orthonormal basis for these detail spaces $\mathbf{W}_{No}^{(k)}$. To this end, we first observe that

$$\dim(\mathbf{W}_{No}^{(k)}) = \dim(\mathbf{V}_{No}^{(k)}) = 2^k (No + 1),$$

since $\dim(\mathbf{V}_{No}^{(k+1)}) = 2^{k+1}(No + 1)$. Focusing on the case $k = 0$, we have to determine orthonormal functions Ψ_α , $\alpha \in [0, No + 1]$, spanning $\mathbf{W}_{No}^{(0)}$. Clearly, $\Psi_\alpha \in \mathbf{V}_{No}^{(1)}$ so each function has an SE expansion of the form

$$\Psi_\alpha = \sum_{\beta=0}^{No} \sum_{l=1}^2 a_{\beta,l}^\alpha \Phi_{\beta,l}^{(1)}. \quad (18.14)$$

As a result, a total of $2(No + 1)^2$ coordinates define the $No + 1$ basis functions spanning the detail space $\mathbf{W}_{No}^{(0)}$.

To derive equations for these coefficients, we enforce the orthonormality conditions for the Ψ_α , that is,

$$\langle \Psi_\alpha, \Psi_\beta \rangle_{\mathcal{U}} = \delta_{\alpha,\beta}, \quad 0 \leq \alpha, \beta \leq No. \quad (18.15)$$

Equation (18.15) then provides $(No + 2)(No + 1)/2$ distinct conditions on the coefficients. Accounting for the orthogonality $\mathbf{W}_{No}^{(0)} \perp \mathbf{V}_{No}^{(0)}$, one obtains another set of $(No + 1)^2$, vanishing moment conditions for the functions Ψ_α :

$$\langle \Psi_\alpha, x^\beta \rangle_{\mathcal{U}} = 0, \quad 0 \leq \alpha, \beta \leq No. \quad (18.16)$$

Orthonormal and vanishing moment properties are the only conditions needed to be enforced for the Ψ_α to obtain an orthonormal basis of $\mathbf{W}_{No}^{(0)}$. Having less conditions than coefficients determining all the Ψ_α reflects the fact that there is an infinite number of orthonormal bases for $\mathbf{W}_{No}^{(0)}$. Higher moment vanishing conditions could then be introduced on some of the functions Ψ_α . This could be particularly useful for the compression of the MW expansions (see the thresholding procedure described below). However, improved vanishing moments properties will not be exploited here, and the orthogonality between functions at different resolution levels is really what matters; therefore, we shall rely in Sect. 2.3.2 on a simple but systematic construction procedure to obtain a set of functions Ψ_α satisfying conditions (18.15) and (18.16).

When the so-called mother functions Ψ_α are obtained, bases for the whole hierarchy of subspaces $\mathbf{W}_{No}^{(k)}$ can readily be defined by means of simple transformations. Using the affine mapping in (18.7), we define the MW basis functions $\Psi_{\alpha,l}^{(k)}$ through

$$\Psi_{\alpha,l}^{(k)}(x) = \begin{cases} 2^{k/2} \Psi_\alpha(M_l^{(k)} x), & x \in \mathcal{U}_l^{(k)}, \\ 0, & \text{otherwise.} \end{cases} \quad (18.17)$$

It is easily shown that

$$\langle \Psi_{\alpha,l}^{(k)}, \Psi_{\beta,l'}^{(k')} \rangle_{\mathcal{U}} = \begin{cases} 1, & \text{if } k = k', \alpha = \beta, l = l' \\ 0, & \text{otherwise.} \end{cases} \quad (18.18)$$

In addition, by construction, we have

$$\langle \Psi_{\alpha,l}^{(k)}, \Phi_{\beta,l'}^{(k')} \rangle_{\mathcal{U}} = 0 \quad \forall k' \leq k \text{ and } l' \leq l. \quad (18.19)$$

As a result, the projection of $U \in L_2(\mathcal{U})$ in $\mathbf{V}_{No}^{(k)}$ can be expressed in the MW basis as

$$\mathbb{P}_{No}^{(k)} U(x) = \sum_{\alpha=0}^{No} u_{\alpha,1}^{(0)} \Phi_{\alpha,1}^{(0)}(x) + \sum_{i=0}^{k-1} \sum_{l=1}^{2^i} \sum_{\alpha=0}^{No} \tilde{u}_{\alpha,l}^{(i)} \Psi_{\alpha,l}^{(i)}(x). \quad (18.20)$$

The first sum in (18.20) corresponds to the projection of U on $\mathbf{V}_{No}^{(0)}$, whereas the remaining contributions are orthogonal details at successive resolution levels $i = 0$

to $i = k - 1$. Owing to the properties of the MW basis functions, the detail coefficients are given by

$$\tilde{u}_{\alpha,l}^{(i)} = \left\langle U, \Psi_{\alpha,l}^{(i)} \right\rangle_{\mathcal{U}} \quad i \geq 0, \alpha = 0, \dots, \text{No} \text{ and } l = 1, \dots, 2^i. \quad (18.21)$$

2.3.2 Construction of the MW Mother Functions

In this section, we briefly summarize a generation procedure proposed in [16] to produce a set of $\text{No} + 1$ orthonormal functions $\Psi_{\alpha} \in \mathbf{V}_{\text{No}}^{(1)}$, satisfying (18.15) and (18.16).

The procedure is initiated with two sets of $\text{No} + 1$ polynomial functions $p_{\alpha}(x) \in \mathbf{V}_{\text{No}}^{(0)}$ and $\tilde{q}_{\alpha}(x) \in \mathbf{V}_{\text{No}}^{(1)}$, for $\alpha = 0, \dots, \text{No}$, respectively defined as:

$$p_{\alpha}(x) = x^{\alpha}, \quad \tilde{q}_{\alpha}(x) = \begin{cases} x^{\alpha}, & 0 \leq x < 1/2 \\ -x^{\alpha}, & \text{otherwise.} \end{cases} \quad (18.22)$$

In a first step, each function \tilde{q}_{α} is orthogonalized with respect to all the functions $p_{\beta}(x)$ for $\beta = 0, \dots, \text{No}$. That is, we determine a new set of functions $q_{\alpha}(x)$ as

$$q_{\alpha}(x) \doteq \tilde{q}_{\alpha}(x) + \sum_{\beta=0}^{\text{No}} c_{\alpha\beta} p_{\beta}(x), \quad (18.23)$$

so that

$$\langle q_{\alpha}, p_{\beta} \rangle_{\mathcal{U}} = 0, \quad \text{for } \alpha, \beta = 0, 1, \dots, \text{No}. \quad (18.24)$$

The resulting functions $\{q_{\alpha}, \alpha = 0, \dots, \text{No}\}$ have clearly the required vanishing moment properties (18.16). In a second step, the functions q_{α} are orthonormalized, for instance, through a standard Gram-Schmidt procedure [17]. Because the orthonormalization involves linear combinations of the initial functions q_i , which all have first $\text{No} + 1$ vanishing moments, the final orthonormal functions also have the desired moment properties. These functions are then the sought functions Ψ_{α} . This constructive procedure can be carried out numerically, using an exact quadrature to compute scalar products between polynomial functions. Since the procedure involves and manipulates functions in $\mathbf{V}_{\text{No}}^{(1)}$, the scalar products are broken into sub-integrals over the two subintervals of $\mathcal{P}^{(1)}$. For instance, Gauss-type quadrature rules can be used over $\mathcal{U}_1^{(1)}$ and $\mathcal{U}_2^{(1)}$ to ensure sufficient polynomial exactness.

Figure 18.1 depicts the MW mother functions Ψ_{α} , $\alpha = 0, \dots, \text{No}$, for different polynomial orders No . The case $\text{No} = 0$ corresponding to the Haar system (piecewise constant approximation) is not shown but corresponds to a single mother function which is the step function (see [3] for more details). The case $\text{No} = 1$ (top left panel) has two functions Ψ_0 and Ψ_1 which are seen to be both piece-polynomials of degree $\text{No} = 1$, with discontinuities of order 1 and 0, respectively, at the center

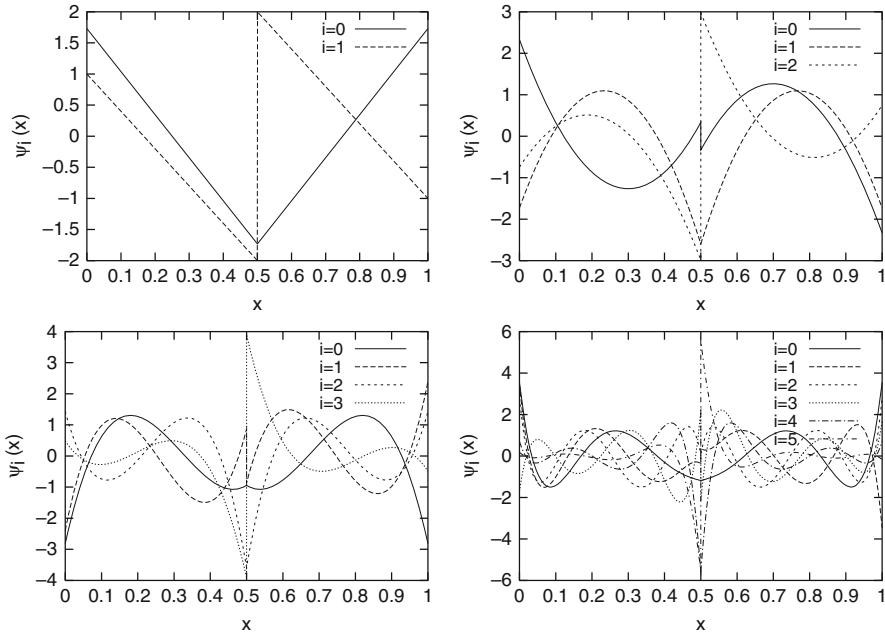

Fig. 18.1 Mother MW functions $\Psi_\alpha(x)$ for polynomial degrees $No = 1, 2, 3$ and 5 (Adapted from [6])

point of \mathcal{U} . For higher polynomial degrees, the functions are similarly piecewise No-degree polynomials with discontinuities at different orders ranging from 0 to No localized at the center of \mathcal{U} .

3 Multidimensional Extension and Multiscale Operators

3.1 Binary-Tree Representation

The partitions $\mathcal{P}^{(k)}$ and their associated approximation spaces can be conveniently represented in terms of binary trees. In a binary tree T , every node has either zero or two children, and every node, except the root node denoted by n_0 , has a unique parent. Nodes are collected in the set $\mathcal{N}(T)$. Nodes with no children are called leaves and are collected in the set $\mathcal{L}(T)$, while nodes with children are collected in the set $\widehat{\mathcal{N}}(T) := \mathcal{N}(T) \setminus \mathcal{L}(T)$. The two children of a node $n \in \widehat{\mathcal{N}}(T)$ are called left and right children (and also sisters) and are denoted by $c^-(n)$ and $c^+(n)$, respectively. The parent of a node $n \in \mathcal{N}(T) \setminus \{n_0\}$ is denoted by $p(n)$. To each node $n \in \mathcal{N}(T)$, we assign an element of a partition $S(n) = \mathcal{U}_i^{(k)}$ as follows. The support of a node is denoted $S(n) = [x_n^-, x_n^+] \subseteq \mathcal{U}$. We set $S(n_0) = \mathcal{U}$. The supports of the other nodes are defined recursively by a dyadic partition of the support of the parent node. Then,

the supports of the left and right children are, respectively, $S(c^-(n)) = [x_n^-, (x_n^- + x_n^+)/2]$ and $S(c^+(n)) = [(x_n^- + x_n^+)/2, x_{n,d}^+]$. This construction leads to a partition of \mathcal{U} in the form

$$\mathcal{U} = \bigcup_{l \in \mathcal{L}(T)} S(l). \quad (18.25)$$

For a node $n \in \mathcal{N}(T)$, its depth $|n|$ is defined as the number of generations it takes to reach n from the root node n_0 . It is readily seen that the support of node n has measure $|S(n)| := 2^{-|n|}$. Finally, for any node $n \in \mathcal{N}(T)$, M_n denotes the affine map from $S(n)$ onto the reference stochastic domain \mathcal{U} .

In practice, we consider binary trees T with a fixed maximum number of successive partitions allowed. This quantity is called the resolution level and is denoted by N_r in the following. As a result, there holds, for all $n \in \mathcal{N}(T)$, $|S(n)| \geq 2^{-N_r}$. A particular case of a binary tree is the complete binary tree where $|S(l)| = 2^{-N_r}$ for all the leaves. As there are 2^{N_r} leaves in a complete binary tree, each of the leaves is identified as an element of the partition \mathcal{P}^{N_r} . An example of a complete binary tree with $N_r = 4$ is provided in the top plot of Fig. 18.2. However, trees need not be complete, and in view of adaptivity, we consider general binary trees with leaves having different depth $|n|$. An example of such incomplete binary tree is reported in the bottom plot of Fig. 18.2.

Even if the binary tree is incomplete, one can identify with each leaf an element $U_i^{(k)}$ of a certain partition \mathcal{P}^k with $k \leq N_r$. As a result, we can associate to a binary tree T an approximation space $V(T)$ which is the space of functions in $L_2(\mathcal{U})$ being polynomials of degree at most N_0 over the support of each leaf of T . Note that the notation does not explicitly mention the polynomial degree as it will be considered

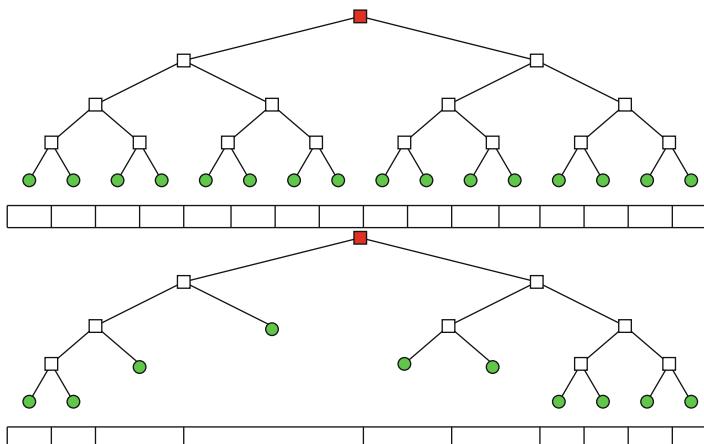

Fig. 18.2 Complete binary tree (top) and incomplete binary tree (bottom) in one dimension; the corresponding partitions of $\mathcal{U} = [0, 1]$ are shown below the trees

and kept constant. On the contrary, we aim at adapting the tree to the functional to be approximated. The SE expansion of $U \in \mathbf{V}(\mathbb{T})$ can further be expressed as

$$\mathbf{V}(\mathbb{T}) \ni U(x) = \sum_{n \in \mathcal{L}(\mathbb{T})} \sum_{\alpha=0}^{N_0} u_\alpha^n \Phi_\alpha^n(x), \quad (18.26)$$

where $u_\alpha^n \doteq \langle U, \Phi_\alpha^n \rangle_{\mathcal{U}}$ for $\alpha = 0, \dots, N_0$ are the SE coefficients associated to the leaf $n \in \mathcal{L}(\mathbb{T})$. Similarly, the MW expansion can be expressed as

$$\mathbf{V}(\mathbb{T}) \ni U(x) = \sum_{\alpha=0}^{N_0} u_\alpha^{n_0} \Phi_\alpha^{n_0}(x) + \sum_{n \in \widehat{\mathcal{N}}(\mathbb{T})} \sum_{\alpha=0}^{N_0} \tilde{u}_\alpha^n \Psi_\alpha^n(x), \quad (18.27)$$

where the detail coefficients of a node, which is not a leaf, are given by $\tilde{u}_\alpha^n \doteq \langle U, \Psi_\alpha^n \rangle_{\mathcal{U}}$ for $\alpha = 0, \dots, N_0$.

3.2 Multidimensional Extension

Using the binary tree structure to represent partitions and define approximation spaces, the extension of the one-dimensional multiresolution framework to higher number of dimensions becomes quite straightforward. We shall now consider the case of an N -dimensional parameter space consisting of the N dimensional hypercube $\mathcal{E} \doteq \mathcal{U}^N$. Regarding the partitioning of \mathcal{E} , instead of extending the previous approach to general N -ary trees, which would become quickly intractable as N increases, we require to keep the binary structure (each node has zero or two children), starting from the root node $n_0 = \mathcal{E}$. This requires the introduction of an indicator for each node $n \in \widehat{\mathcal{N}}(\mathbb{T})$ which keeps track of the direction along which n is partitioned dyadically to produce its two children. Denoted by $d(n) \in \{1 \dots N\}$ the direction along which the dyadic partition of the support $S(n)$ is performed, the left and right children have for respective support

$$S(c^-(n)) = [x_{n,1}^-, x_{n,1}^+] \times \dots \times [x_{n,d(n)}^-, (x_{n,d(n)}^- + x_{n,d(n)}^+)/2] \times \dots \times [x_{n,N}^-, x_N^+]$$

and

$$S(c^+(n)) = [x_{n,1}^-, x_{n,1}^+] \times \dots \times [(x_{n,d(n)}^- + x_{n,d(n)}^+)/2, x_{n,d(n)}^+] \times \dots \times [x_{n,N}^-, x_N^+].$$

The process is illustrated in Fig. 18.3.

There is however an essential difference between one-dimensional and multidimensional binary trees: for $N > 1$, there are in general more than one tree with the same set of leaves, i.e., yielding the same partition of \mathcal{E} . This is illustrated in Fig. 18.4 for $N = 2$. Consequently, we say that two trees T and T' are equivalent if

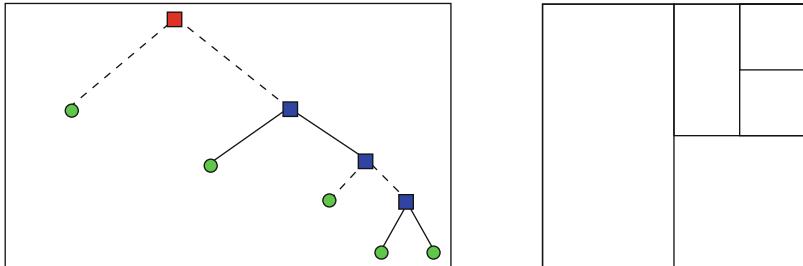

Fig. 18.3 Multidimensional binary tree for $N = 2$ (left). Dash (resp. full) segments represent a partition along the first (resp. second) direction. Corresponding partition of $\mathcal{E} = [0, 1]^2$ (right)

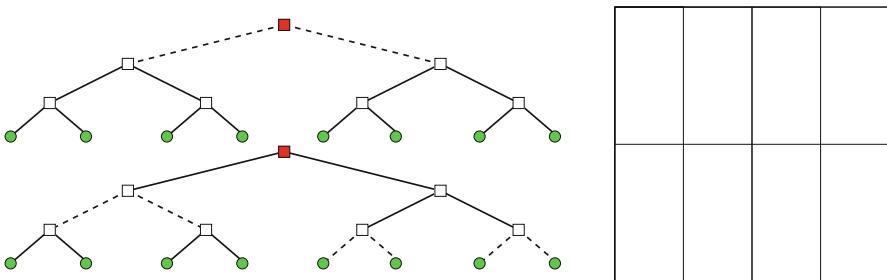

Fig. 18.4 Example of two equivalent trees for $N = 2$. The solid (resp. dash) segments represent a partition along the first (resp. second) direction. The partition of \mathcal{E} is shown on the right

they share the same set of leaves:

$$T \equiv T' \Leftrightarrow \mathcal{L}(T) = \mathcal{L}(T'). \quad (18.28)$$

The notion of equivalent trees is needed in the coarsening and enrichment procedures of Sect. 4.

In practice, we shall consider binary trees T with a fixed maximum number of successive partitions allowed in each direction $d \in \{1 \dots N\}$. As for the one-dimensional case, this quantity is called the resolution level and is denoted by N_r . Thus, there are 2^{N_r} leaves in a complete binary tree in N dimensions, showing that adaptive strategies are mandatory to apply these multiresolution schemes in high dimensions.

The construction of the SE basis in the multidimensional case can proceed as in the one-dimensional case. Let us denote as Π a prescribed polynomial space over \mathcal{E} , P the dimension of the polynomial space, and $\{\Phi_1, \dots, \Phi_P\}$ an orthonormal basis of Π . For instance, one may consider to construct Π from a tensorization of the normalized Legendre basis of $\pi_{N_0}(\mathcal{U})$, resulting in $P = (N_0 + 1)^N$ for a full tensorization of the Legendre polynomials or $P + 1 = (N_0 + N!)/(N_0!N!)$ for a total degree truncation strategy. In any case, the SE basis functions Φ_α^n associated to a leaf n are defined from the N -variate polynomials Φ_α using the mapping M_n

between $S(n)$ and \mathcal{E} and a scaling factor $|S(n)|^{-1/2}$. We are then in position to define the multiresolution space $\mathbf{V}(T)$, as the space of functions whose restrictions to each leaves of T are polynomials belonging to Π . Clearly, equivalent trees are associated to the same multiresolution space.

For $U \in L_2(\mathcal{E})$, we shall denote U^T its approximation in $\mathbf{V}(T)$. The SE expansion U^T has a general structure similar to Eq. (18.26), specifically

$$\mathbf{V}(T) \ni U^T(\mathbf{x}) = \sum_{n \in \mathcal{L}(T)} \sum_{\alpha=1}^P u_\alpha^n \Phi_\alpha^n(\mathbf{x}), \quad u_\alpha^n = \langle U, \Phi_\alpha^n \rangle_{\mathcal{E}}. \quad (18.29)$$

Extending to the multidimensional case, the MW expansion in (18.27) is slightly more complicated than for the SE expansion. The main reason is that, because of the binary structure of the dyadic partition, we have to consider MW detail functions that depend on the direction $d(n)$ along which the support of the node $S(n)$ is split. In fact, when a split direction $d(n_0)$ is provided, the procedure provided in Sect. 2.3.2 to generate the one-dimensional detail mother functions Ψ_α can be extended to the multidimensional case. It amounts to construct, for every direction, P , mother functions Ψ_α^d having SE expansions of the form

$$\Psi_\alpha^d = \sum_{\beta=1}^P \left[a_{\alpha,\beta}^d \Phi_\beta^{c^-(n_0)} + b_{\alpha,\beta}^d \Phi_\beta^{c^+(n_0)} \right]. \quad (18.30)$$

It is required that the directional MW mother functions are all orthogonal to any function of Π (*i.e.*, they have vanishing moments) or equivalently

$$\langle \Psi_\alpha^d, \Phi_\beta^{n_0} \rangle_{\mathcal{E}} = 0, \quad 1 \leq \alpha, \beta \leq P \text{ and } d = 1, \dots, N. \quad (18.31)$$

For a direction d , the corresponding P mother functions should also form an orthonormal set:

$$\langle \Psi_\alpha^d, \Psi_\beta^d \rangle_{\mathcal{E}} = \delta_{\alpha,\beta}, \quad 1 \leq \alpha, \beta \leq P, \text{ for } d = 1, \dots, N. \quad (18.32)$$

Once the N sets of mother functions are determined, the affine mapping M_n can be used to derive the MW functions of any node $n \in \widehat{\mathcal{N}}(T)$, through

$$\Psi_\alpha^n(\mathbf{x}) = \begin{cases} |S(n)|^{-1/2} \Psi_\alpha^{d(n)}(M_n \mathbf{x}), & \mathbf{x} \in S(n) \\ 0, & \text{otherwise.} \end{cases} \quad (18.33)$$

It can be easily verified that

$$\text{span}_\alpha \{ \Phi_\alpha^{c^-(n)}, \Phi_\alpha^{c^+(n)} \} = \text{span}_\alpha \{ \Phi_\alpha^n \} \oplus \text{span}_\alpha \{ \Psi_\alpha^n \}. \quad (18.34)$$

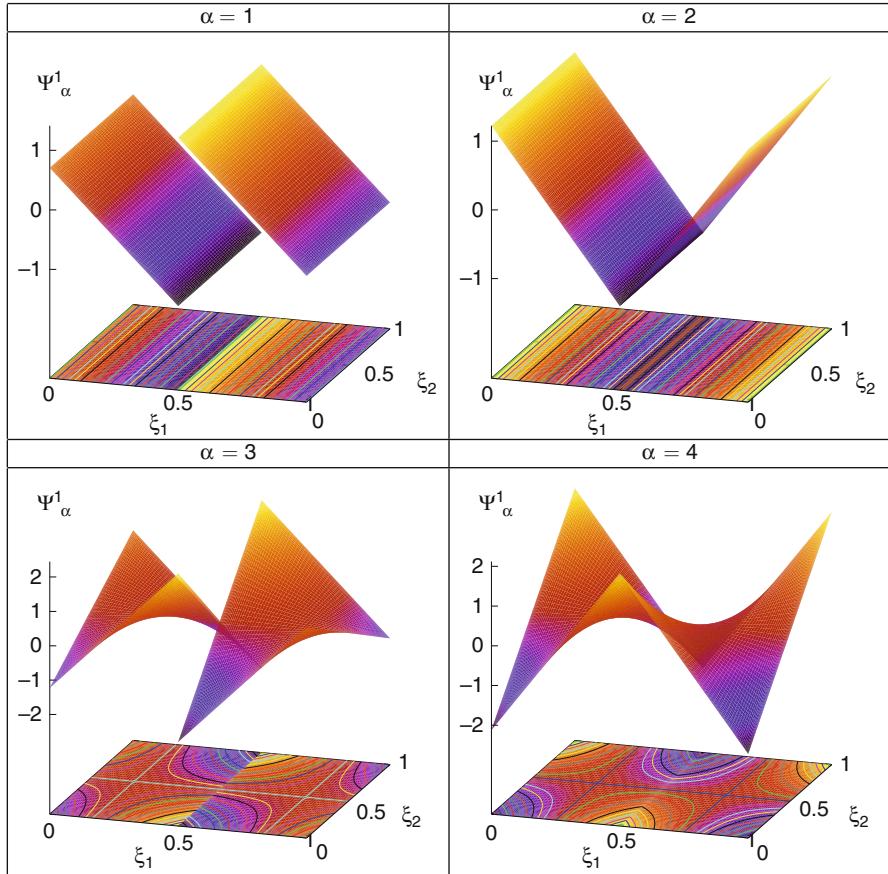

Fig. 18.5 Mother multiwavelets Ψ_α^d for $N = 2$, $No = 1$ in direction $d = 1$

As an illustration, the mother functions $\Psi_\alpha^{d=1}$ are reported in Fig. 18.5 for the two-dimensional case ($N = 2$) and a polynomial space Π consisting of the full tensorization of the degree one polynomials, so $P = (No + 1)^2 = 4$. The plots of the MW mother functions show the different types of singularity across the line $x_{d=1} = 1/2$ corresponding to the split into the two children.

Then, the approximation of $f \in L_2(\mathcal{E})$ in $\mathbf{V}(T)$ has the hierarchical expansion in the MW basis given by

$$\mathbf{V}(T) \ni U^T(\mathbf{x}) = \sum_{\alpha=1}^P u_\alpha^{n_0} \Phi_\alpha^{n_0}(\mathbf{x}) + \sum_{n \in \widehat{\mathcal{N}}(T)} \sum_{\alpha=1}^P \tilde{u}_\alpha^n \Psi_\alpha^n(\mathbf{x}), \quad \tilde{u}_\alpha^n = \langle U, \Psi_\alpha^n \rangle_{\mathcal{E}}. \quad (18.35)$$

3.3 Multiscale Operators

In this section, we introduce two essential multiscale operators, the restriction and prediction operators, that are useful tools in the adaptive context. We start by introducing the notion of inclusion over trees. Let T_1 and T_2 be two binary trees. We say that $T_1 \subset T_2$ if

$$\forall l_2 \in \mathcal{L}(T_2), \exists ! l_1 \in \mathcal{L}(T_1) \text{ s.t. } S(l_1) \subset S(l_2). \quad (18.36)$$

Clearly, if $T_1 \subset T_2$, then $\mathbf{V}(T_1) \subset \mathbf{V}(T_2)$.

3.3.1 Restriction Operator

Let T_1 and T_2 be two binary trees such that $T_1 \subset T_2$. Given $U^{T_2} \in \mathbf{V}(T_2)$, we define the restriction of U^{T_2} to $\mathbf{V}(T_1)$, denoted $\mathcal{R}_{\downarrow T_1} U^{T_2}$, as the orthogonal $L^2(\mathcal{E})$ -projection of U^{T_2} onto $\mathbf{V}(T_1)$, i.e., $(U^{T_2} - \mathcal{R}_{\downarrow T_1} U^{T_2}) \perp \mathbf{V}(T_1)$. In terms of MW coefficients, the restriction operation is straightforward. Letting \tilde{u}_α^n be the MW coefficients of U^{T_2} and using the orthonormality of the MW basis yields, for all $n \in \widehat{\mathcal{N}}(T_1)$ and all $\alpha \in \mathcal{P}$,

$$\widetilde{(\mathcal{R}_{\downarrow T_1} U^{T_2})}_\alpha^n = \tilde{u}_\alpha^n. \quad (18.37)$$

(The large tilde over the left-hand-side stresses that we express a *MW coefficient* of the restriction of U^{T_2} to $\mathbf{V}(T_1)$). It shows that the restriction of the approximation space, from $\mathbf{V}(T_2)$ to $\mathbf{V}(T_1)$, preserves the MW coefficients, but reduces the set of nodes supporting these coefficients: $\widehat{\mathcal{N}}(T_1) \subset \widehat{\mathcal{N}}(T_2)$. The computation of the SE coefficients of the restriction is not as immediate. Assuming that the SE expansion of U^{T_2} is known, we construct a sequence of trees $T^{(i)}$ such that $T_2 = T_{(0)} \supset \dots \supset T_{(i)} \supset \dots \supset T_{(l)} = T_1$, where two consecutive trees differ by one generation only, i.e., a leaf of $T_{(i+1)}$ is either a leaf or a node with leaf children in $T_{(i)}$. Therefore, the transition from $T^{(i)}$ to $T^{(i+1)}$ consists in removing pairs of sister leaves. The process is illustrated in the left part of Fig. 18.6 for the removal of a single pair of sister leaves. Focusing on the removal of a (left-right ordered) pair of sister leaves

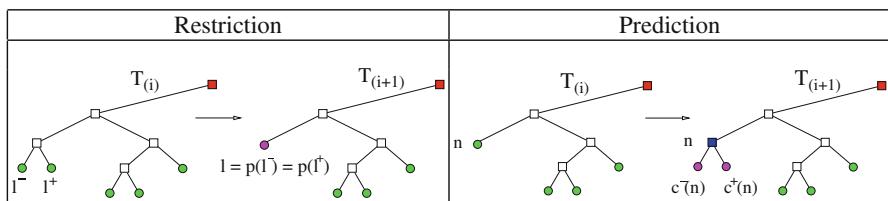

Fig. 18.6 Schematic representation of the elementary restriction (*left*) and prediction (*right*) operators through the removal and creation respectively of the (leaves) children of a node

$\{l^-, l^+\}$, the SE coefficients of the restriction of $U^{T(i)}$ associated with the new leaf $l = p(l^-) = p(l^+) \in \mathcal{L}(T_{(i+1)})$ in direction $d(l)$ are

$$u_\alpha^l = \sum_{\beta \in \mathcal{P}} \left[R_{\alpha,\beta}^{-,d(l)} u_\beta^{l^-} + R_{\alpha,\beta}^{+,d(l)} u_\beta^{l^+} \right], \quad (18.38)$$

where, for all $d \in \{1 \dots N\}$, the transition matrices $R^{\pm,d}$ of order P have entries given by $R_{\alpha,\beta}^{\pm,d} = \left\langle \Phi_\alpha^{n_0}, \Phi_\beta^{c_d^{\pm(n_0)}} \right\rangle$.

3.3.2 Prediction Operator

Let T_1 and T_2 be two binary trees such that $T_1 \subset T_2$. The prediction operation consists of extending $U^{T_1} \in \mathbf{V}(T_1)$ to the larger stochastic space $\mathbf{V}(T_2)$. We denote by $\mathcal{P}_{\uparrow T_2} U^{T_1}$ this prediction. Different predictions can be used (see [18, 19]); here we have considered the simplest one, where no information is generated by the prediction. As for the restriction operation, the MW expansion of the prediction is immediately obtained from the MW coefficients of U^{T_1} . We obtain, for all $n \in \widehat{\mathcal{N}}(T_2)$ and all $\alpha \in \mathcal{P}$,

$$\left(\widetilde{\mathcal{P}_{\uparrow T_2} U^{T_1}} \right)_\alpha^n = \begin{cases} \tilde{u}_\alpha^n, & n \in \widehat{\mathcal{N}}(T_2), \\ 0, & \text{otherwise.} \end{cases} \quad (18.39)$$

For the SE coefficients of $\mathcal{P}_{\uparrow T_2} U^{T_1}$, we can again proceed iteratively, starting from the SE expansion over T_1 , using a series of increasing intermediate trees, differing by only one generation from one to the other. This time, the elementary operation consists in adding to some node n , being a leaf of the current tree, children in a prescribed direction $d(n)$. The process is illustrated in the right part of Fig. 18.6. The SE coefficients associated to the new leaves of a node n are given by

$$u_\alpha^{c^-(n)} = \sum_{\beta \in \mathcal{P}} R_{\alpha,\beta}^{-,d(n)} u_\beta^n, \quad u_\alpha^{c^+(n)} = \sum_{\beta \in \mathcal{P}} R_{\alpha,\beta}^{+,d(n)} u_\beta^n, \quad (18.40)$$

with the same transition coefficients as those used in (18.38). For two trees $T_1 \subset T_2$, we observe that $\mathcal{R}_{\downarrow T_1} \circ \mathcal{P}_{\uparrow T_2} = \mathcal{I}_{T_1}$, while in general $\mathcal{P}_{\uparrow T_2} \circ \mathcal{R}_{\downarrow T_1} \neq \mathcal{I}_{T_2}$ (\mathcal{I} denoting the identity).

4 Adaptivity

In this section, we detail the essential adaptivity tools needed for the control of the local stochastic resolution, with the objective of efficiently reducing the complexity of the computations. There are two essential ingredients: the coarsening and enrichment procedures. Below we detail the criteria needed to perform these

two operations. These thresholding and enrichment criteria were initially proposed in [11].

Recall that for $n \in \mathcal{N}(T)$, $|n|$ is the distance of n from the root node n_0 so the measure of its support is $|S(n)| := 2^{-|n|}$. We shall also need the measure of $S(n)$ in specific direction $d \in [1, N]$, that is $|S(n)|_d := x_{n,d}^+ - x_{n,d}^-$, its diameter $\text{diam}(S(n)) := \max_d |S(n)|_d$, and its volume in all directions except d as $|S(n)|_{\sim d} := |S(n)| / |S(n)|_d$.

4.1 Coarsening

Let T be a binary tree and let $U^T \in \mathbf{V}(T)$. The coarsening procedure aims at constructing a subtree $T^- \subset T$ (or, equivalently, a stochastic approximation subspace $\mathbf{V}(T^-) \subset \mathbf{V}(T)$) through a thresholding of the MW expansion coefficients of U^T .

4.1.1 Thresholding Error

Let $\eta > 0$ be a tolerance and recall that Nr denotes the resolution level. Let \tilde{u}_α^n denote the MW expansion coefficients of U^T ; see (18.35). We define $\mathcal{D}(\eta, Nr)$ as the subset of $\widehat{\mathcal{N}}(T)$ such that

$$\mathcal{D}(\eta, Nr) := \left\{ n \in \widehat{\mathcal{N}}(T); \|\tilde{\mathbf{u}}^n\|_{\ell^2} \leq 2^{-|n|/2} (NNr)^{-1/2} \eta \right\}, \quad (18.41)$$

where $\tilde{\mathbf{u}}^n := (\tilde{u}_\alpha^n)_{\alpha \in P}$ and $\|\tilde{\mathbf{u}}^n\|_{\ell^2}^2 = \sum_{\alpha \in P} (\tilde{u}_\alpha^n)^2$. The motivation for (18.41) is that, letting \widehat{U}^T be the thresholded version of U^T obtained by omitting in the second sum of (18.35) the nodes $n \in \mathcal{D}(\eta, Nr)$, there holds

$$\|\widehat{U}^T - U^T\|_{L^2(\mathcal{E})}^2 = \sum_{n \in \mathcal{D}(\eta, Nr)} \|\tilde{\mathbf{u}}^n\|_{\ell^2}^2 \leq \sum_{n \in \mathcal{D}(\eta, Nr)} 2^{-|n|} (NNr)^{-1} \eta^2 \leq \eta^2 \quad (18.42)$$

since

$$\sum_{n \in \mathcal{D}(\eta, Nr)} 2^{-|n|} = \sum_{j=0}^{NNr-1} \#\{n \in \mathcal{D}(\eta, Nr); |n| = j\} 2^{-j} \leq \sum_{j=0}^{NNr-1} 1 = NNr.$$

Therefore, using the definition in (18.41) for the thresholding the MW expansion of a function in $\mathbf{V}(T)$, we can guaranty an L_2 error less than η .

4.1.2 Coarsening Procedure

Two points deserve particular attention. The first one is that $\mathcal{N}(T) \setminus \mathcal{D}(\eta, Nr)$ does not have a binary tree structure in general, so that a procedure is needed to maintain this structure when removing nodes of T . Here, we choose a conservative approach where the resulting subtree T^- may still contain some nodes in the set $\mathcal{D}(\eta, Nr)$.

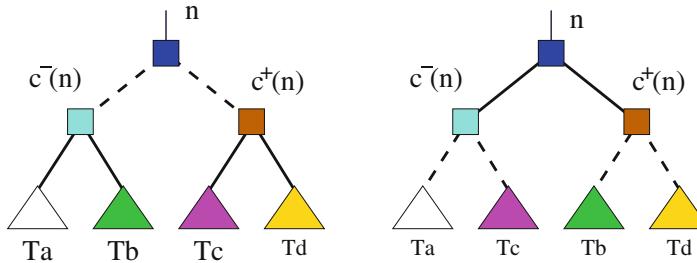

Fig. 18.7 Illustration of the elementary operation to generate equivalent trees: the pattern of a node with its children divided along the same direction (*left*) is replaced by the same pattern but with an exchange of the partition directions (*right*) plus the corresponding permutation of the descendants of the children

Specifically, we construct a sequence of nested trees, obtained through the removal of pairs of sister leaves from one tree to the next: a couple of sister leaves having node n for parent is removed if $n \in \mathcal{D}(\eta, N_r)$. The coarsening sequence is stopped whenever no couple of sister leaves can be removed, and this yields the desired subtree T^- while ensuring the binary structure. In addition, the procedure preserves the error bounds.

The second point is that the above algorithm only generates trees such that, along the sequence, the successive (coarser and coarser) partitions of \mathcal{E} follow, in backward order, the partition directions $d(n)$ prescribed by T . This is unsatisfying because for $N > 1$, there are many trees equivalent to T , and we would like the coarsened tree to be independent of any particular choice in this equivalence class. To avoid arbitrariness, the trees of the sequence are periodically substituted by equivalent ones, generated by searching in the current tree for the pattern of a node n whose children $c^-(n)$ and $c^+(n)$ are not leaves and are subsequently partitioned along the same direction $d(c^+(n)) = d(c^-(n))$ which differs from $d(n)$; when such a pattern is found, the two successive partition directions are exchanged, $d(n) \leftrightarrow d(c^-(n)) = d(c^+(n))$, together with the corresponding permutation of the descendants of the children nodes. This operation, illustrated in Fig. 18.7, is applied periodically and randomly during the coarsening procedure.

4.2 Anisotropic Enrichment

Let T be a binary tree and let $U^T \in \mathbf{V}(T)$. The purpose of the enrichment is to increase the dimension of $\mathbf{V}(T)$, by adding descendants to some of its leaves. Enrichment of the stochastic space is required to adaptively construct approximations of particular quantities. Another typical situation where enrichment is necessary is in dynamical problems, with the possible emergence in time of new features in the stochastic solution, such as shocks, that require more resolution. Classically, the enrichment of a tree T is restricted to at most one partition along each dimension in

dynamical problems. For steady problems, the enrichment procedure can be simply applied multiple times to end up with sufficiently refined approximations.

The simplest enrichment procedure consists in systematically partitioning *all* the leaves $\mathfrak{l} \in \mathcal{L}(T)$ once for all $d \in \{1 \dots N\}$ provided $|S(\mathfrak{l})|_d > 2^{-Nr}$. This procedure generates a tree T^+ that typically has $2^N \text{card}(\mathcal{L}(T))$ leaves, which is only practical when N is small.

More economical strategies are based on the analysis of the MW coefficients in U^T to decide which leaves of T need be partitioned and along which direction (see, for instance, [4, 5]). We derive below two directional enrichment criteria in the context of N -dimensional binary trees.

4.2.1 Multidimensional Enrichment Criterion

Classically, the theoretical decay rate of the MW coefficients with resolution level is used to decide the partition of a leaf from the norm of MW coefficients of its parent (see, for instance, [18, 20] in the deterministic case).

We first recall some background in the 1D case ($N = 1$). Let $U \in L^2(\mathcal{U})$. Let T_{1D} be a 1D binary tree and let $U^{T_{1D}}$ be the $L^2(\mathcal{U})$ -orthogonal projection of U onto $\mathbf{V}(T_{1D})$. Let \tilde{u}_α^n denote the MW coefficients of $U^{T_{1D}}$. Then, if U is locally smooth enough, the magnitude of the MW coefficients \tilde{u}_α^n of a generic node $n \in \widehat{\mathcal{N}}(T_{1D})$ can be bounded as

$$|\tilde{u}_\alpha^n| = \inf_{P \in \pi_{No}(\mathcal{U})} |((U - P), \Psi_\alpha^n)_U| \leq C |S(n)|^{No+1} \|U\|_{H^{No+1}(S(n))}, \quad (18.43)$$

where $H^{No+1}(S(n))$ is the usual Sobolev space of order $(No + 1)$ on $S(n)$. Recalling that $|S(n)| = 2^{-|n|}$, the bound (18.43) shows that the norm of the MW coefficients decays roughly as $\mathcal{O}(2^{-|n|(No+1)})$ for smooth U . Therefore, the norm of the (unknown) MW coefficients of a leaf $\mathfrak{l} \in \mathcal{L}(T_{1D})$ can be estimated from the norm of the (known) MW coefficients of its parent as

$$\|\tilde{\mathbf{u}}^\mathfrak{l}\|_{\ell^2} \sim 2^{-(No+1)} \|\tilde{\mathbf{u}}^{\mathfrak{p}(\mathfrak{l})}\|_{\ell^2}.$$

This estimate can, in turn, be used to derive an enrichment criterion; specifically, a leaf \mathfrak{l} is partitioned if the estimate of $\|\tilde{\mathbf{u}}^\mathfrak{l}\|_{\ell^2}$ exceeds the thresholding criterion (18.41), that is, if

$$\|\tilde{\mathbf{u}}^{\mathfrak{p}(\mathfrak{l})}\|_{\ell^2} \geq 2^{No+1} 2^{-|\mathfrak{l}|/2} Nr^{-1/2} \eta \quad \text{and} \quad |S(\mathfrak{l})| > 2^{-Nr}. \quad (18.44)$$

The extension to $N > 1$ of the enrichment criterion (18.44) is not straightforward in the context of binary trees. Indeed, the MW coefficients associated with a node n carry information essentially related to the splitting direction $d(n)$. Thus, for a leaf $\mathfrak{l} \in \mathcal{L}(T)$, they cannot be used for an enrichment criterion in a direction $d \neq d(\mathfrak{p}(\mathfrak{l}))$. To address this issue, we define, for any leaf $\mathfrak{l} \in \mathcal{L}(T)$ and any direction $d \in \{1 \dots N\}$, its virtual parent $\mathfrak{p}^d(\mathfrak{l})$ as the (virtual) node that would have \mathfrak{l} as a child after a dyadic partition along the d th direction. Consistently, $\mathfrak{s}^d(\mathfrak{l})$ denotes the

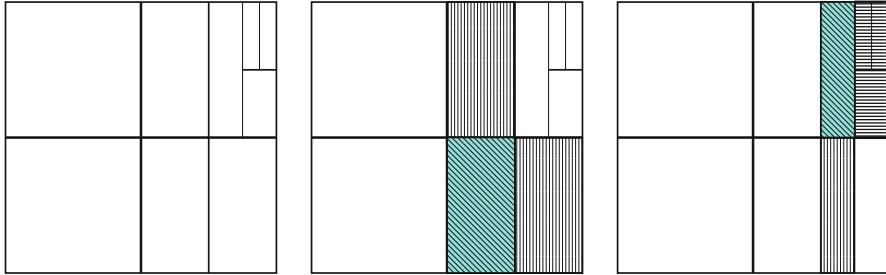

Fig. 18.8 Illustration of the virtual sisters of a leaf l of a tree T whose partition is shown in the *left plot*. In the *center plot*, the leaf l is hatched diagonally in *blue* and its two virtual sisters for $d = 1$ and 2 (hatched horizontally and vertically respectively) are leaves of T , both being $c^+(\mathbf{p}^d(l))$. In the *right plot*, a different leaf l is considered (still hatched diagonally in *blue*) with virtual sisters $\mathbf{s}^d(l)$ which for $d = 1$ (hatched horizontally) is a node of T but not a leaf and which for $d = 2$ (hatched vertically) is not a node of T

virtual sister of l along direction d . Note that $\mathbf{p}^d(l) \in \mathcal{N}(T)$ only for $d = d(\mathbf{p}(l))$; moreover, in general, $\mathbf{s}^d(l) \notin \mathcal{N}(T)$. These definitions are illustrated in Fig. 18.8 which shows for $N = 2$ the partition associated with a tree T (left plot) and the virtual sisters of two leaves.

The SE coefficients of the virtual sisters,

$$u_\alpha^{s^d(l)} := \left\langle U^\top, \Phi_\alpha^{s^d(l)} \right\rangle_{\mathcal{E}}, \quad \alpha = 1, \dots, P, \quad (18.45)$$

are efficiently computed by exploiting the binary structure of T and relying on the elementary restriction and prediction operators defined in Sect. 3.3. Without going into too many details, let us mention that the computation of the SE coefficients of $\mathbf{s}^d(l)$ amounts to (i) finding the subset of leaves in $\mathcal{L}(T)$ whose supports overlap with $S(\mathbf{s}^d(l))$, (ii) constructing the subtree having for leaves this subset, and (iii) restricting the solution over this subtree up to \mathbf{s}^d . In practice, one can reuse the restriction operator defined in Sect. 3.3 to compute the usual details in the $\{\Psi_\alpha^{n,d}\}_{\alpha=1,\dots,P}$ basis for a chosen direction d .

We now return to the design of a multidimensional enrichment criterion. Assuming an underlying isotropic polynomial space Π , with degree No in all directions, a natural extension of (18.44) is that a leaf l is partitioned in the direction d if

$$\|\tilde{\mathbf{u}}^{p^d(l)}\|_{\ell^2} \geq \left(\frac{\text{diam}(S(\mathbf{p}^d(l)))}{\text{diam}(S(l))} \right)^{No+1} 2^{-|l|/2} (NNr)^{-1/2} \eta \quad \text{and} \quad |S(l)|_d > 2^{-Nr}. \quad (18.46)$$

We recall that $\text{diam}(S(n))$ is the diameter of the support of the considered node. The criterion in (18.46) is motivated by the following multidimensional extension of the bound (18.43) for the magnitude of the MW coefficients \tilde{u}_α^n in the direction d for a

generic node \mathbf{n} ,

$$|\tilde{u}_\alpha^{\mathbf{n}}| = \inf_{P \in \Pi} |\langle (U - P), \Psi_\alpha^{\mathbf{n},d} \rangle_{\Xi}| \leq C \operatorname{diam}(S(\mathbf{n}))^{N_0+1} \|U\|_{H^{N_0+1}(S(\mathbf{n}))}. \quad (18.47)$$

4.2.2 Directional Enrichment Criterion

We want to improve the criterion (18.46) since the isotropic factor

$$\rho_l \doteq \operatorname{diam}(S(\mathbf{p}^l(l)))/\operatorname{diam}(S(l))$$

can take the value 1 in the context of anisotropic refinement. An alternative is to devise a criterion with the factor 2^{N_0+1} , since this will lead to smaller enriched trees. For this purpose, we derive an alternative criterion that is fully directional. For any direction $d \in \{1 \dots N\}$ and any node $\mathbf{n} \in T$, we define the directional detail coefficients $\bar{u}_{\beta \in \{1 \dots N_0+1\}}^{\mathbf{n},d}$ through

$$\bar{u}_{\beta}^{\mathbf{n},d} := \left\langle U, \bar{\Psi}_{\beta}^{\mathbf{n},d} \right\rangle_{\Xi}, \quad \bar{\Psi}_{\beta}^{\mathbf{n},d}(\mathbf{x}) = \begin{cases} |S(\mathbf{n})|^{-1/2} \Psi_{\beta}^* \left(\frac{x_d - x_{\mathbf{n},d}^-}{x_{\mathbf{n},d}^+ - x_{\mathbf{n},d}^-} \right), & \xi \in S(\mathbf{n}), \\ 0, & \text{otherwise,} \end{cases} \quad (18.48)$$

where $\{\Psi_{\beta}^*\}_{\beta \in \{1 \dots N_0+1\}}$ is the set of 1D wavelet functions defined on $[0, 1]$. The vector of coefficients $\bar{\mathbf{u}}^{\mathbf{n},d}$ measures details in U at the scale $|S(\mathbf{n})|_d$, in direction d only, by averaging out any variability in U along the other directions.

For a direction $d \in \{1 \dots N\}$, let $\sim d$ denote all the directions except d . Because by construction $\|\bar{\Psi}_{\beta}^{\mathbf{n},d}\|_{\Xi} = 1$, it follows that

$$\begin{aligned} |\bar{u}_{\beta}^{\mathbf{n},d}| &= \inf_{P \in \pi_{N_0}} \left| \left\langle U - P, \bar{\Psi}_{\beta}^{\mathbf{n},d} \right\rangle_{\Xi} \right| \\ &= \inf_{P \in \pi_{N_0}} \left| \int_{S(\mathbf{n})} (U(\mathbf{x}_{\sim d}, x_d) - P(x_d)) \bar{\Psi}_{\beta}^{\mathbf{n},d}(x_d) d\mathbf{x} \right| \\ &= \inf_{P \in \pi_{N_0}} |S(\mathbf{n})|_{\sim d} \left| \int_{S_d(\mathbf{n})} (\bar{U}_{\sim d}^{\mathbf{n}}(x_d) - P(x_d)) \bar{\Psi}_{\beta}^{\mathbf{n},d}(x_d) d\mathbf{x} \right| \\ &\leq C |S(\mathbf{n})|_{\sim d} |S(\mathbf{n})|_d^{N_0+1} \|\bar{U}_{\sim d}^{\mathbf{n}}\|_{H^{N_0+1}(S_d(\mathbf{n}))} \|\bar{\Psi}_{\beta}^{\mathbf{n},d}\|_{L^2(S_d(\mathbf{n}))} \\ &= C |S(\mathbf{n})|_{\sim d}^{1/2} |S(\mathbf{n})|_d^{N_0+1} \|\bar{U}_{\sim d}^{\mathbf{n}}\|_{H^{N_0+1}(S_d(\mathbf{n}))}, \end{aligned} \quad (18.49)$$

where $\bar{U}_{\sim d}^{\mathbf{n}}(x_d) = |S(\mathbf{n})|_{\sim d}^{-1} \int_{S_d(\mathbf{n})} U(\mathbf{x}_{\sim d}, x_d) d\mathbf{x}_{\sim d}$ is the marginalization of $U(\mathbf{x})$ over the support $S(\mathbf{n})$ in all the directions $\sim d$. Furthermore, (omitting the reference to the node \mathbf{n}),

$$\begin{aligned}\|\bar{U}_{\sim d}\|_{H^{\text{No}+1}(S_d)}^2 &= \int_{S_d} \left| \frac{\partial^{\text{No}+1}}{\partial x_d} \frac{1}{|S|_{\sim d}} \left(\int_{S_{\sim d}} U(\mathbf{x}_{\sim d}, x_d) d\mathbf{x}_{\sim d} \right) \right|^2 dx_d \\ &= \frac{1}{|S|_{\sim d}^2} \int_{S_d} \left| \int_{S_{\sim d}} \frac{\partial^{\text{No}+1}}{\partial x_d} U(\mathbf{x}_{\sim d}, x_d) d\mathbf{x}_{\sim d} \right|^2 dx_d \leq |S|_{\sim d}^{-1} \\ &\quad \int_S \left| \frac{\partial^{\text{No}+1}}{\partial x_d} U \right|^2 dx,\end{aligned}$$

whence we deduce

$$\|\bar{U}_{\sim d}\|_{H^{\text{No}+1}(S_d)} \leq |S|_{\sim d}^{-1/2} \|U\|_{L^2(S_{\sim d}, H^{\text{No}+1}(S_d))}, \quad (18.50)$$

with anisotropic Sobolev norm $\|U\|_{L^2(S_{\sim d}, H^{\text{No}+1}(S_d))}^2 = \int_{S_{\sim d}} \|U(\mathbf{x}_{\sim d}, \cdot)\|_{H^{\text{No}+1}(S_d)}^2 d\mathbf{x}_{\sim d}$.

Combining (18.49) with (18.50), the estimate for the directional details magnitude is now

$$|\bar{u}_\beta^{\text{n},d}| = \inf_{P(\xi_d) \in \pi_{\text{No}}(\mathcal{U})} \left| \langle (U - P), \bar{\Psi}_\beta^{\text{n},d} \rangle_{\Xi} \right| \leq C |S(\mathbf{n})|_d^{\text{No}+1} \|U\|_{L_2(S_{\sim d}(\mathbf{n}), H^{\text{No}+1}(S_d(\mathbf{n})))}. \quad (18.51)$$

Proceeding as previously, the enrichment criterion states that a leaf \mathfrak{l} is partitioned along direction d if

$$\|\bar{\mathbf{u}}^{\mathfrak{p}^d(\mathfrak{l})}\|_{\ell^2} \geq 2^{\text{No}+1} 2^{-|\mathfrak{l}|/2} (\text{NNr})^{-1/2} \eta \quad \text{and} \quad |S(\mathfrak{l})|_d > 2^{-\text{Nr}}. \quad (18.52)$$

The details norm associated with the basis $\{\bar{\Psi}_\beta^{\text{n},d}\}_{\beta \in \mathcal{P}}$ can be obtained explicitly from the vector of MW coefficients $\tilde{\mathbf{u}}^{\text{n},d}$ by averaging it in all but the d th direction.

5 Illustrations

We illustrate the effectiveness of the multiresolution approach for parametric uncertainty problems with increasing complexity.

5.1 Simple ODE Problem

We start by considering a simple ordinary differential equation (ODE) involving a single random parameter; the ODE solution $U(t, \xi)$ satisfies the governing equation

$$\frac{d^2 U}{dt^2} + f \frac{dU}{dt} = F(U), \quad F(U) = -\frac{35}{2} U^3 + \frac{15}{2} U, \quad (18.53)$$

which describes the motion of a particle in a deterministic potential field F , with damping governed by the friction factor $f > 0$. The problem is completed with an initial condition at $t = 0$, assumed uncertain and given by a function $U^0(\xi)$. Because of the dissipative dynamics, the particle asymptotically reaches a fixed location

$$U^\infty(\xi) = \lim_{t \rightarrow \infty} U(t, \xi), \quad (18.54)$$

which depends on the initial position and so is uncertain. However, the mapping $\xi \mapsto U^\infty$ is not necessarily smooth; indeed $F(u) = 0$ has two (stable) roots $r_1 = -r_2 = \pm\sqrt{15/35}$ so the system has two stable steady points. For simplicity, we shall consider the uncertain initial condition $U^0(\xi) = 0.05 + 0.2\xi$, where ξ has a uniform distribution in $[-1, 1]$; the multiresolution scheme detailed above can then be applied with $x = (\xi + 1)/2$.

The problem is solved relying on a stochastic Galerkin projection method [15, 21], seeking an expansion of $U(t, \xi)$ according to

$$U(t, \xi) = \sum_{\alpha} u_{\alpha}(t) \theta_{\alpha}(\xi), \quad (18.55)$$

for selected functionals θ_{α} forming a Hilbertian basis. Introducing this expansion of U into the governing equation, and requiring the orthogonality of the equation

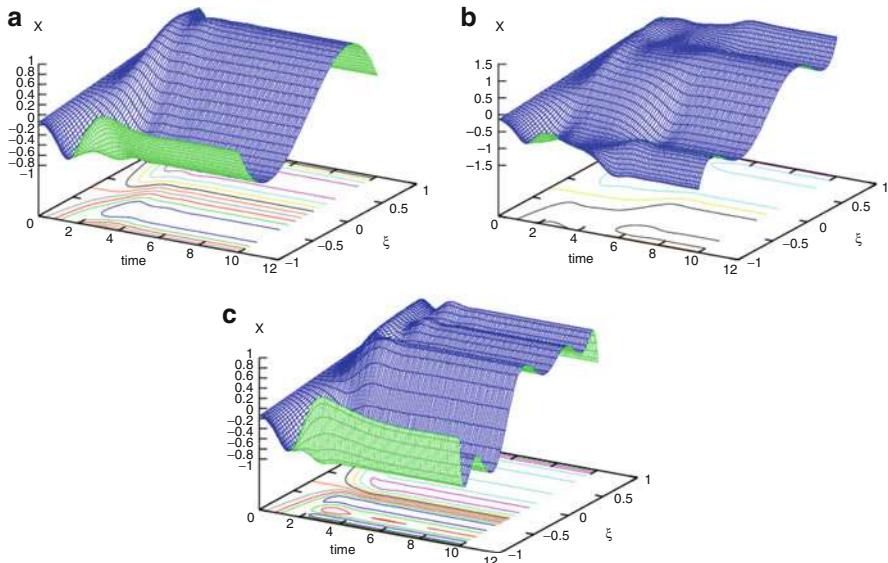

Fig. 18.9 Time evolution of the Galerkin solution of (18.53) discretized in spectral space $\mathbf{V}_{No}^{(0)}$ (scaled Legendre polynomials) with $No = 3, 5$, and 9 (from left to right)

residual with respect to the stochastic approximation space, one obtains the governing equations for the expansion coefficients; specifically this results in

$$\frac{du_\alpha}{dt} = \left\langle F \left(\sum_\beta u_\beta \theta_\beta \right), \theta_\alpha \right\rangle. \quad (18.56)$$

Upon truncation of the expansion, one has to solve a set of coupled nonlinear ODEs for the expansion coefficients. The initial conditions for these expansion coefficients are also obtained by projecting the uncertain initial data, yielding $u_\alpha(t = 0) = \langle U^0, \theta_\alpha \rangle$.

Figure 18.9 shows the time evolutions of the solution from the uniformly distributed initial condition, for different one-dimensional multiresolution spaces $\mathbf{V}_{N_0}^{(0)}$ as defined in Sect. 2.1. Computations for different polynomial orders $No = 3, 5$, and 9 are reported. It is seen that the smooth approximations at level 0, corresponding to spectral expansions with the functionals θ_α being the scaled Legendre polynomials, are not able to properly represent the evolutions and asymptotic behavior of U . Specifically, when increasing the polynomial order No , the computed asymptotic steady state is plagued with Gibb's oscillations.

In contrast, piecewise constant approximations in $\mathbf{V}_0^{(Nr)}$ quickly converge with the resolution level Nr , as can be appreciated from the plots of Fig. 18.10. The plots depict the solutions for increasing resolution levels $Nr = 2, 3$, and 5 . In particular, it is seen that the exact asymptotic steady solution is recovered for most values of ξ , except over the subinterval containing the discontinuity. When the resolution level increases, a finer definition of the discontinuity location is achieved, resulting in a highly accurate approximation.

Note that in the case of an approximation in $\mathbf{V}_{N_0}^{(Nr)}$, one can decide to formulate Galerkin problem in the SE or MW basis. From the computational point of view, using one or the other basis can dramatically affect the complexity of the computations. Specifically, for the SE element basis, the nonlinear systems of $2^{Nr} \times (No + 1)$ equations form in fact a set of 2^{Nr} uncoupled nonlinear systems with size $(No + 1)$, because of the limited number of overlapping supports. In contrast, formulating the Galerkin problem in the MW basis maintains the nonlinear coupling between all the MW coefficients of the solution, requiring the resolution of a significantly larger problem. As a general rule, determining approximations in multiresolution spaces is generally more conveniently performed for the SE expansions (i.e., computing local expansions over the set of leaves), while performing the multiresolution analysis to decide on enrichment/coarsening uses mostly the MW coefficients as shown in Sect. 4. The multiscale operators and the tree representation provide convenient means to efficiently translate one set of coefficients into another.

This example also illustrates the need for adaptivity tools that allow the tuning of the stochastic discretization effort, i.e., the resolution level, dynamically in time and locally in the stochastic space. For instance, it is seen that an essentially uniform resolution level is needed at early times while, asymptotically, one needs only detail

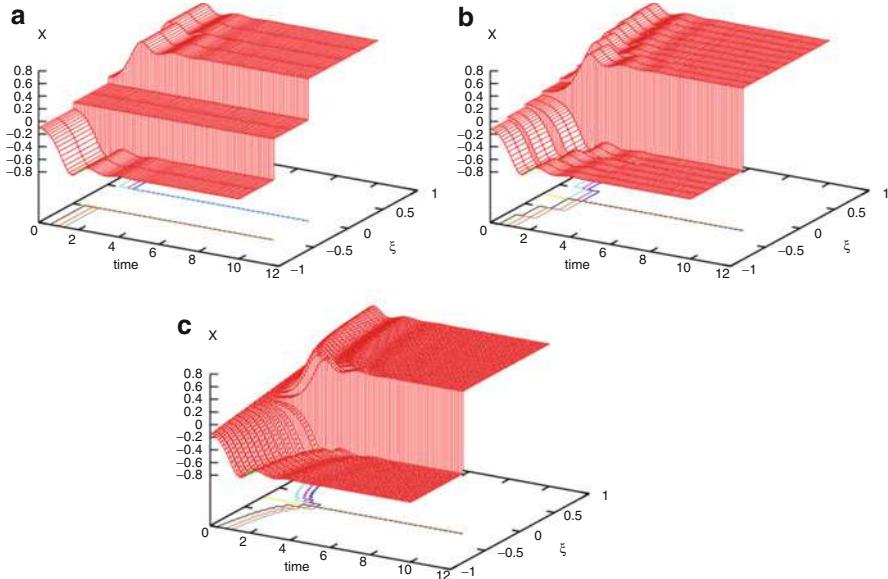

Fig. 18.10 Time evolution of the Galerkin solution of (18.53) discretized in spectral space $\mathbf{V}_0^{(\text{Nr})}$, that is, piecewise constant approximations, with $\text{Nr} = 2, 3$, and 5 (from left to right)

functions around the region of discontinuity, as the solution tends to an actual piecewise constant solution.

5.2 Scalar Conservation Law

In [11], a fully adaptive strategy of the stochastic discretization was proposed for the resolution of scalar conservation equations.

5.2.1 Test Problem

The test problem consists of the one-dimensional conservation equation:

$$\frac{\partial U}{\partial t} + \frac{\partial}{\partial x} F(U; \xi) = 0, \quad x \in [0, 1], \quad (18.57)$$

with periodic boundary conditions (here x denotes the spatial variable). This equation models the evolution of a normalized density of vehicles, U , on a road (closed track, in this case); the traffic model corresponds to a flux function having the form

$$F(U; \xi) = A(\xi)U(\xi)(1 - U(\xi)), \quad (18.58)$$

where $A(\xi)$ is almost surely positive and represents an (uncertain) reference velocity. The solution is then uncertain because the initial condition $U^{IC}(x, \xi)$ is uncertain, and because uncertainty in the characteristic velocity results in an uncertain flux function $F(\cdot; \xi)$. Specifically, the initial condition consists of four piecewise constant uncertain states in x , parametrized using four independent random variables ξ_1, ξ_2, ξ_3 , and ξ_4 , with uniform distributions in $[0, 1]$:

$$U^{IC}(x, \xi) = \bar{U}(\xi_1) - U^-(\xi_2)\mathbb{I}_{[0.1, 0.3]}(x) + U^+(\xi_3)\mathbb{I}_{[0.3, 0.5]}(x) - U^-(\xi_4)\mathbb{I}_{[0.5, 0.7]}(x), \quad (18.59)$$

where

$$\begin{aligned}\bar{U}(\xi_1) &= 0.25 + 0.01\xi_1 \sim \mathcal{U}[0.25, 0.26], \\ U^-(\xi_{2,4}) &= 0.2 + 0.015\xi_{2,4} \sim \mathcal{U}[0.2, 0.215],\end{aligned}$$

and

$$U^+(\xi_3) = 0.1 + 0.015\xi_3 \sim \mathcal{U}[0.1, 0.115].$$

In (18.59), \mathbb{I}_Z denotes the characteristic function of the set Z ,

$$\mathbb{I}_Z(x) = \begin{cases} 1, & x \in Z, \\ 0, & \text{otherwise.} \end{cases}$$

Because the uncertain reference velocity is independent of the initial conditions, it is parametrized with another independent random variable ξ_5 with uniform distribution in $[0, 1]$:

$$A(\xi_5) = 1 + 0.05(2\xi_5 - 1) \sim \mathcal{U}[0.95, 1.05]. \quad (18.60)$$

The problem has therefore five stochastic dimensions ($N = 5$) and the selected polynomial space Π is spanned by the partially tensorized Legendre polynomials

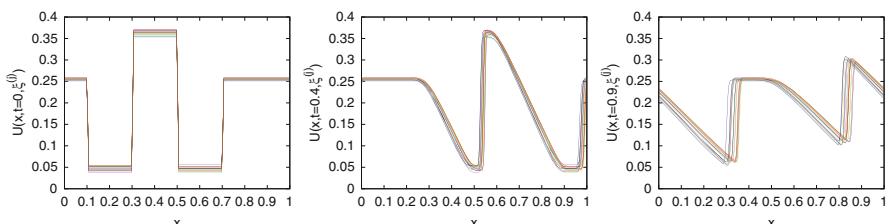

Fig. 18.11 Stochastic traffic equation: sample set of 20 realizations of the initial condition (left) and computed solution at $t = 0.4$ (middle) and $t = 0.9$ (right) (Adapted from [11])

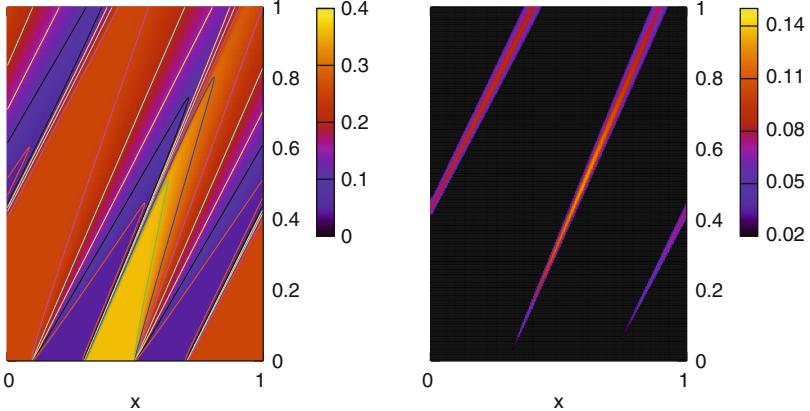

Fig. 18.12 Space-time diagrams of the solution expectation (left) and standard deviation (right) (Adapted from [11])

with degree $\leq N_o$, so that $P = \frac{(N+N_o)!}{N!N_o!}$. Regarding the spatial discretization, a uniform mesh of 200 cells is used to discretize the stochastic conservation law relying on a classical finite volume approach. However, the computation of the numerical fluxes between the finite volumes needs be carefully designed in the stochastic case. The stochastic Galerkin Roe solver proposed in [22, 23] is used in the simulations below.

The initial condition is illustrated in the left panel of Fig. 18.11, which depicts 20 realizations of $U^{IC}(\xi)$ drawn at random. The middle and right panels of Fig. 18.11 report the 20 realizations of the solution at times $t = 0.4$ and 0.9 , respectively. The generation of two expansion waves from $x = 0.1$ to $x = 0.5$ and of two shock waves from $x = 0.3$ to $x = 0.7$ is observed. As time evolves, the first expansion wave reaches the first shock, while the second expansion wave reaches the second shock. Because of the uncertainties in the wave velocities, the instants where the waves catch up are uncertain as well. The dynamics and the impact of uncertainties can be better appreciated on the space-time diagram of the solution expectation and standard deviation plotted for $t \in [0, 1]$ in the left and right panels of Fig. 18.12. The plots highlight the smooth nature of the solution expectation and the steep variations in the solution standard deviation, with maxima reached along the paths of the two shocks.

Clearly, one can expect the approximation of the solution to require a higher stochastic discretization effort along the path of these structures, particularly the shocks with uncertain locations. In addition, the uncertain solution $U(x, t, \xi)$ typically depends on a subset of the uncertain parameters in ξ for a given couple (x, t) . This is evidenced in Fig. 18.13 which illustrates the space-time diagram of the first-order sensitivity indices S_d of the solution (see [11, 24] for a complete definition and detailed procedure for the evaluation of the sensitivity indices). It is observed that, before the merging of the expansion and shock waves ($t < 0.4$), significant

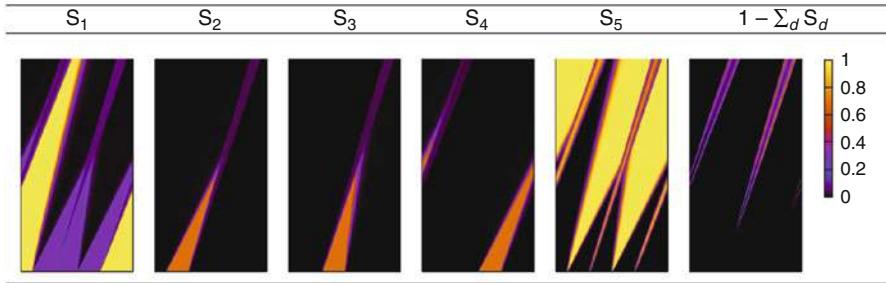

Fig. 18.13 Space-time diagrams $(x, t) \in [0, 1] \times [0, 1]$ of the first-order sensitivity indices and the contribution of sensitivity indices of higher order (Adapted from [11])

values are observed for S_1 , S_2 , S_3 , and S_4 over portions of the computational domain corresponding to the three dependence cones between the waves, where the solution takes one of the three initial uncertain states. The portions of the spatial domain where S_{1-4} take significant values decrease as time increases, indicating the emergence of more and more interactions between the random parameters. On the contrary, because ξ_5 parametrizes the uncertain velocity, A , the significant values of S_5 appear along paths of the different waves and affect a portion of the spatial domain that increases with time. The emergence of interactions between parameters can be appreciated from the rightmost panel of Fig. 18.13, where the quantity $1 - \sum_{d=1}^N S_d$, i.e., the fraction of the variance due to higher-order sensitivity indices, is plotted. This figure shows that interactions primarily take place along the shock paths. We also present the total sensitivity indices T_d which measure the total sensitivity of the solution with respect to the parameter ξ_d . These total sensitivity indices are displayed in Fig. 18.14 as functions of x at the same times as in Fig. 18.11. We recall that $T_d \leq 1$, while $\sum_d T_d > 1$ in general. We observe that T_2 and T_3 (resp. T_4) take significant values over supports that are compact in the neighborhood of the first (resp. second) shock wave and that their magnitude tends to decay in time. On the contrary, the portion of the spatial domain where T_5 reaches a value close to 1 becomes larger as time increases, indicating the extension of the domain of influence of the uncertainty in A . For instance, for $t = 0.9$, the set $\{T_5 \approx 0\}$ is included in $x \in [0.4, 0.5]$, that is, in the only remaining part of the domain where the stochastic solution is spatially constant (see the right plot of Fig. 18.11). Finally, the dynamics of T_1 , which is related to an uncertainty in the initial data that is nonlocal, is much more complex. Specifically, T_1 continues to be significant in areas where the stochastic solution is piecewise constant in space and along the shocks, while in rarefaction waves T_1 becomes quickly insignificant.

5.2.2 Adaptive Computations

Based on the understanding of the solution structure, it is clear that the stochastic discretization should be adapted in both time and space, anisotropically in the parameter domain. In the implementation proposed in [11], each cell of the spatial

mesh supports its own binary tree for its stochastic solution space, which is adapted at each time step of the simulation, by relying on the coarsening and refinement procedures detailed above.

The two enrichment criteria (multidimensional (18.46) and directional (18.52)) were tested for different values for η and No and a fixed maximal resolution $Nr = 6$. For fixed η and No , the multidimensional criterion leads to more refined stochastic discretizations but with only a marginal reduction of the approximation error (as measured by the stochastic approximation error ε_{sd} defined in (18.61) below) compared to the directional criterion. This is illustrated in Fig. 18.15 which shows the time evolution of the total number of SE for the two enrichment criteria, different values of η , and $No = 3$. The rightmost plot shows the corresponding error ε_{sd} as a function to the total number of SE at $t = 0.5$. Because the two enrichment criteria have similar computational complexity, the directional criterion (18.52) is generally preferred.

The dependence on space and time of the adapted trees can be appreciated from Fig. 18.16 which displays the averaged depths of the trees measured as $\log_2 \text{card}(\mathcal{L}(T_i^n))$ in the computation with $\eta = 10^{-4}$ and $No = 3$. This plot shows the adaptation to the local stochastic smoothness; as expected, a finer stochastic discretization along the path of the shock waves is necessary, while a coarser discretization suffices in the expansion waves and in the regions where the solution is spatially constant. The right plot in Fig. 18.16 shows the time evolution of the total number of leaves in the stochastic discretization. We observe a monotonic increase in the number of leaves, with higher rates when additional wave interactions occur and, subsequently, with a roughly constant rate since the stochastic shocks, which dominate the discretization need, affect a portion of the spatial domain growing linearly in time.

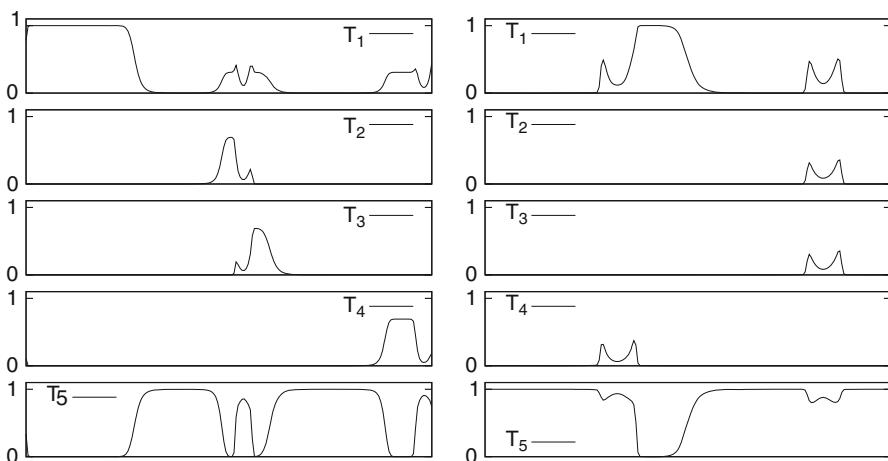

Fig. 18.14 Total sensitivity indices as a function of $x \in [0, 1]$ at $t = 0.4$ (left) and $t = 0.9$ (right) (Adapted from [11])

The anisotropy of the refinement procedure is illustrated in Fig. 18.17, which shows the space-time diagrams of the averaged directional depths defined for $d \in \{1 \dots 5\}$ by $D_d := -\log_2(\sum_{l \in \mathcal{L}(T_i^n)} |S(l)|_d / \text{card}(\mathcal{L}(T_i^n)))$ and the aspect ratio $\rho := \max_{l \in \mathcal{L}(T_i^n)} (\max_d |S(l)|_d / \min_d |S(l)|_d)$ in the rightmost panel. Because ξ_1 parametrizes the uncertain initial condition on the whole domain, this variable affects the velocity of the two shock waves, so that the discretization is finer in the neighborhood of the two shocks. Then, ξ_2 and ξ_3 (resp. ξ_4) affect the velocity of the first shock wave (resp. the second), so that the discretization is finer in the neighborhood of the first (resp. the second) shock. Finally, ξ_5 , which parametrizes the velocity A and therefore affects the velocity of the two shocks, is observed to be the most influential parameter, so that the trees are deeper in the fifth direction; this explains the high values of the aspect ratio near the shocks.

5.2.3 Convergence and Computational Time Analysis

The convergence of the adaptive stochastic method is numerically investigated for a fixed spatial discretization, by estimating the stochastic error at time $t = 0.5$ for different values of η and different polynomial order No. The error is then defined with respect to the semi-discrete solution using the following measure:

$$\varepsilon_{sd}^2 = \Delta x \sum_{i=1}^{Nc} \int_{\mathcal{E}} (U_i^n(\xi) - U_{ex,i}^n(\xi))^2 d\xi, \quad (18.61)$$

where $U_{ex,i}^n$ denotes the exact stochastic semi-discrete solution and $Nc = 200$ is the number of spatial cells. In practice, the error is approximated by means of a Monte Carlo simulation from a uniform sampling of \mathcal{E} . For each element of

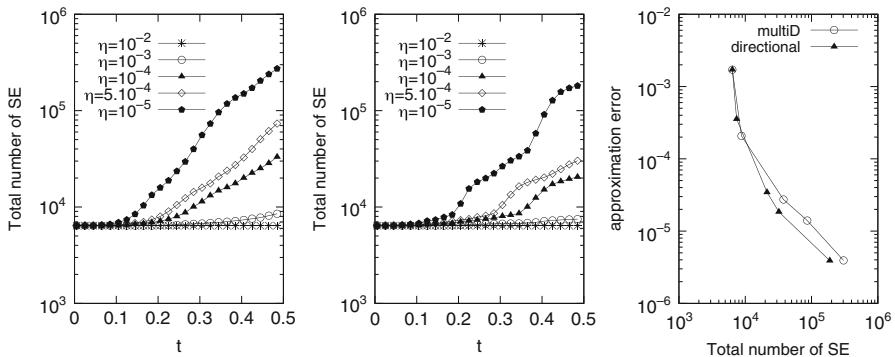

Fig. 18.15 Comparison of the two enrichment criteria for $No = 3$ and different values of η as indicated. Evolution in time of the total number of stochastic elements in the discretization for the multiD criterion (18.46) (left plot) and the directional criterion (18.52) (center plot). Right plot: corresponding error measures ε_{sd} at $t = 0.5$ as a function of the total number of SE for the two enrichment criteria (Adapted from [11])

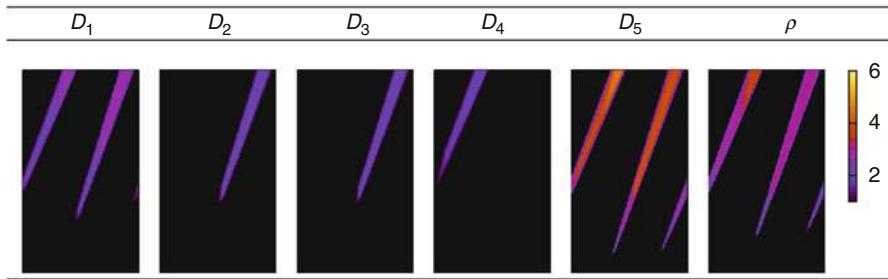

Fig. 18.17 Space-time diagrams $(x, t) \in [0, 1] \times [0, 1]$ of the averaged directional depths and of the aspect ratio (Adapted from [11])

the MC sample, the corresponding discrete deterministic problem is solved with a deterministic Roe solver and the difference with the computed adapted solution is obtained. A total of 10,000 MC samples were used to obtain a well-converged error measure.

Figure 18.18 shows the decay of error $\varepsilon_{\text{sd}}^2$ when the tolerance η in the adaptive algorithm is decreased. The different curves correspond to polynomial degrees $\text{No} \in \{2 \dots 5\}$. The left plot depicts the error measure as a function of the total number of elements (leaves) in the adaptive stochastic discretization at $t^n = 0.5$, namely, the sum over all spatial cells i of $\text{card}(\mathcal{L}(T_i^n))$. The convergence of the semi-discrete solution as η is lowered is first observed for all polynomial degrees tested. In fact, the higher is No , the lower is the error and the faster is the convergence rate, owing to richer approximation spaces for an equivalent number of stochastic elements. However, plotting the error measure ε_{sd} as a function of the total number of degrees of freedom (expansion coefficients), i.e., the total number of leaves times P , as shown in the right plot of Fig. 18.18, we observe that for low resolution (largest η), low polynomial degrees are more efficient than larger ones. On the

contrary, for highly resolved computations (lowest values of η), high polynomial degrees achieve a more accurate approximation for a lower number of degrees of freedom. Such behavior is typical of multiresolution schemes; when numerical diffusion slightly smoothes out the discontinuity, at high-enough resolution, high-degree approximations recover their effectiveness.

To complete this example on stochastic adaptation, computational efficiency is briefly discussed. The purpose is limited here to demonstrate that the overhead arising from adapting the stochastic discretization in space and time is limited. It is first recalled that when considering SE expansions, the determination of the solution is independent from a leaf to another. This characteristic offers opportunities for designing efficient parallel solvers, with different processors dealing with independent subsets of leaves. For the present example, for instance, the computation of the stochastic (Roe) flux over different leaves was performed in parallel, and the only remaining issue concerns the load balancing in the case of complicated trees, particularly for trees evolving dynamically in time. Regarding the other parts of the adaptive procedure, namely, the enrichment and coarsening steps, it is important that they do not consume too much computational resources; otherwise, the gain in adapting the approximation space would be lost. For the present example, numerical experiments demonstrate that the computational times of the enrichment and coarsening steps roughly scale with the number of leaves. This is shown in the plots of Fig. 18.19 which report the CPU times (in arbitrary units) for the advancement of the solution over a single time step as a function of the number of leaves, when using the discretization parameters $No = 2$, $\eta = 10^{-3}$, and $No = 3$, $\eta = 10^{-4}$, respectively. The global CPU times reported are in fact split into different contributions, including flux computation times and coarsening and enrichment

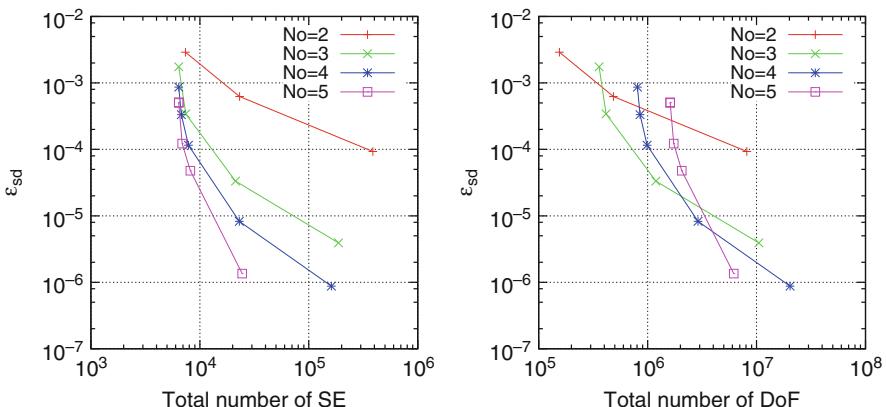

Fig. 18.18 Convergence of the semi-discrete error ε_{sd} at time $t^n = 0.5$ for different values of $\eta \in [10^{-2}, 10^{-5}]$ and different polynomial degrees $No \in \{2 \dots 5\}$. The *left plot* reports the error as a function of the total number of stochastic elements, while the *right plot* shows the error as a function of the total number of degrees of freedom in the stochastic approximation space (Adapted from [11])

computational times. These numerical experiments demonstrate that for the present problem, owing to the representation of the stochastic approximation spaces using binary tree structures, an asymptotically linear computational time in the number of leaves is achieved for the adaptation specific steps of the computation. Further, in this example, the computational times dedicated to adaptivity management (the coarsening and enrichment procedures) are not significant compared to the rest of the computations.

6 Conclusions

This chapter has presented a multiresolution approach for propagating input uncertainties in a model output. The multiresolution is designed to handle situations where the uncertain model solution has complex dependences with respect to the parameters. These include steep variations and discontinuities, a situation that is extremely challenging for classical spectral approaches based on smooth global basis functions.

The key feature of the multiresolution spaces is their piecewise polynomial nature that can, with sufficient resolution, accommodate singularities of various kinds. However, this capability comes at the cost of a potentially significant increase in the dimensionality of approximation spaces, making it essential to consider effective adaptive strategies that are able to tune the local resolution level according to the local complexity of the model solution. We have shown that this can be efficiently achieved by relying on a suitable data structure, namely, binary trees. One significant advantage of the binary tree structure is that, not only does it scale reasonably with the dimensionality of the input parameter space, but it also facilitates the conversion of local expansions (in the SE basis) to detail expansions (in the MW basis), namely, through the recursive application of scale-independent operators. As a result, fast enrichment and coarsening procedures can be implemented without slowing down significantly the computation and so taking full advantage of having a stochastic discretization which is adapted to the solution

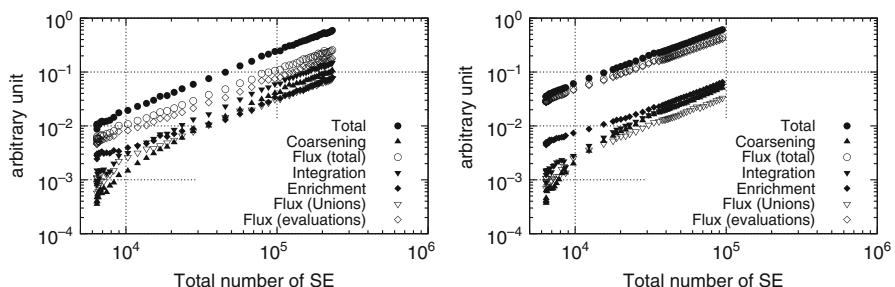

Fig. 18.19 Dependence of the CPU time (per time iteration) on the stochastic discretization measured by the total number of leaves; *left*: $No = 2$ and $\eta = 10^{-3}$; *right*: $No = 3$ and $\eta = 10^{-4}$. The contributions of the various steps of the adaptive algorithm are also shown (Adapted from [11])

needs. All these characteristics are crucial to make the problem tractable from the efficiency perspective.

Multiresolution frameworks and algorithms have enabled the resolution of engineering uncertainty quantification problems that could not be solved with classical spectral approaches, such as global PC representations. These successes include application to conservation law models, compressible flows, stiff chemical systems, and dynamical systems with uncertain parametric bifurcations. MRA schemes, however, are complex to implement, especially in high-dimensional problems. So far, applications have only considered a limited set of uncertain input variables. Another aspect preventing a wider spread of the MRA approach is the absence of available software libraries automating the adaptive refinement procedures. It is expected that such numerical tools will be made available in the coming years. Another area that could also result in wider adoption of MRA schemes concerns the application of associated MW representations in a nonintrusive context. Recent advances in compressive sensing, sparse approximations, and low rank approximation methodologies offer promising avenues toward the emergence of new, highly attractive capabilities.

Surrogate Models for Uncertainty Propagation and Sensitivity Analysis

19

Khachik Sargsyan

Abstract

For computationally intensive tasks such as design optimization, global sensitivity analysis, or parameter estimation, a model of interest needs to be evaluated multiple times exploring potential parameter ranges or design conditions. If a single simulation of the computational model is expensive, it is common to employ a precomputed surrogate approximation instead. The construction of an appropriate surrogate does still require a number of training evaluations of the original model. Typically, more function evaluations lead to more accurate surrogates, and therefore a careful accuracy-vs-efficiency tradeoff needs to take place for a given computational task. This chapter specifically focuses on polynomial chaos surrogates that are well suited for forward uncertainty propagation tasks, discusses a few construction mechanisms for such surrogates, and demonstrates the computational gain on select test functions.

1 Introduction

Over the last decade, improved computing capabilities have enabled computationally intensive model studies that seemed infeasible before. In particular, models nowadays are being explored in a wide range of condition targeting, e.g., optimal input parameter settings or predictions with uncertainties that correspond to the variability of input conditions. In turn, the algorithmic improvements of such inverse and forward modeling studies have pushed the boundaries of the state-of-the-art computational resources *if* a single simulation of the complex model at hand is expensive enough. In this regard, fast-to-evaluate surrogate models serve to alleviate the computational expense of having to simulate a complex model prohibitively many times. In various applications, while leading to major computational efficiency improvements, such inexpensive approximations of full models across a range of conditions have also been called response surface models [25, 55], metamodels [39, 78], fully equivalent operational models (FEOM) [38, 49], or emulators [5, 8]. Such synthetic, surrogate approximations have been utilized in various computationally intensive studies, such as design optimization [48], parameter estimation [41], global sensitivity analysis [62], uncertainty propagation [25], and reliability analysis [70]. It is useful to differentiate surrogate models as completely unphysical functional approximations unlike, say, reduced order models that tend to preserve certain physical or application-specific mechanisms. Furthermore, parametric surrogates have a predefined form thus formulating surrogate construction as a parameter estimation problem. Polynomial chaos (PC) surrogates, due to orthogonality of the underlying polynomial bases, offer closed-form formulae for the output moment and sensitivity computations. They also allow orthogonal projection formulae with quadrature integration for PC coefficient estimation. However, the projection may not scale well into high-dimensional settings and is generally inaccurate if the function evaluations are noisy. Regression methods – in particular, Bayesian regression – suffer from these difficulties in a much more controllable fashion. Besides reviewing the PC regression approach in general and in a Bayesian setting, the focus of this chapter is on two key forward uncertainty quantification tasks, uncertainty propagation and sensitivity analysis, and the assessment of how surrogate models help accelerate such studies. The proof-of-concept demonstrations will be based on synthetic models that are not expensive to simulate but will help demonstrate the efficiency gains in terms of the number of times the “expensive” model is evaluated.

In this chapter, general principles of surrogate modeling are presented, with specific focus on PC surrogates that offer convenient means for forward uncertainty propagation and sensitivity analysis. Various methods of constructing PC surrogates are presented with an emphasis on Bayesian regression methods that are well positioned to work with noisy, sparse function evaluations and provide efficient

tools for uncertain model prediction, as well as model comparison and selection. The chapter will also highlight key challenges of surrogate modeling, such as model selection, high dimensionality, and nonsmoothness, and review the available methods for tackling these challenges.

2 Surrogate Modeling for Forward Propagation

Consider a model of interest $f(\lambda)$ that depends on d parameters $\lambda = (\lambda_1, \dots, \lambda_d)$ and is defined on a hypercube $[-1, 1]^d$, without loss of generality. The underlying premise is that the model is expensive to simulate at any given value of λ , suggesting potential acceleration of any sampling-intensive study by employing a surrogate approximation $g(\lambda) \approx f(\lambda)$.

Typical surrogate construction requires a set of *training* simulations. In other words, one selects a set $\mathcal{T} = \{\lambda^{(i)}\}_{i=1}^N$ of N training samples and evaluates the model at these parameter settings to obtain $f^{(i)} = f(\lambda^{(i)})$ and arrive at model simulation data pairs $(\lambda^{(i)}, f^{(i)})_{i=1}^N$. Two general classes for surrogates are listed below.

- *Parametric*, where the surrogate has a predefined form with a set of parameters that need to be determined. A parametric surrogate is convenient since one simply needs to store a vector of parameters to fully describe it. However, it typically entails an underlying assumption about some features of the function, e.g., smoothness. Most often, parametric surrogates also are equipped with a mechanism to increase the “resolution” or accuracy within the same functional form, e.g., polynomial order in polynomial chaos (PC) surrogates [44] or Padé approximations [12], or the resolution level for wavelet-based approximations [35].
- *Nonparametric*, where underlying assumptions help derive rules to construct the surrogate for any given λ , without a predefined functional form. Thus, nonparametric surrogates often provide more flexibility, albeit at an extra computational cost associated with their construction and evaluation. It is worth noting that nonparametric surrogates also rely on some structural assumptions about the function and may involve a controlling parameter set, such as correlation length in Gaussian process [51] surrogates, regularization parameter in radial basis function construction [45], or knot locations for spline-based approximations [64].

A useful categorization in surrogate construction is distinction between *interpolation* methods, which require function evaluations to match exactly with the surrogate at the training simulation points, and *regression* approaches that generally aim to “fit” a surrogate function without necessarily matching exactly at the training locations. Interpolation methods are usually nonparametric as they typically do not presume a parameterized functional form. For example, Lagrange polynomial interpolation has a polynomial expansion form but is nonparametric as the specific polynomial bases depend on the training set of input locations [44, 76]. Another

important characterization in surrogate modeling is the distinction between *local* and *global* surrogates. Global surrogates seek for an approximation $g(\boldsymbol{\lambda}) \approx f(\boldsymbol{\lambda})$ that is valid across the full domain, in this case, $\boldsymbol{\lambda} \in [-1, 1]^d$, while local surrogates typically entail a splitting of the domain adaptively or according to a predefined rule, with each partition being associated with its own surrogate construction. As such, local surrogates are essentially nonparametric according to the definition of the latter given above. This chapter primarily focuses on global, parametric surrogates denoted by $g_c(\boldsymbol{\lambda})$, where c is a vector of K parameters describing the surrogate model. Note that for a well-defined parameter estimation problem, one needs $K < N$, i.e., fewer surrogate parameters than the number of training data points. This setting implies that interpolation, i.e., guaranteeing $g_c(\boldsymbol{\lambda}^{(i)}) = f(\boldsymbol{\lambda}^{(i)})$ for all $i = 1, \dots, N$, is essentially infeasible, and one has to operate in the regression setting, i.e., seeking the best set of surrogate parameters c such that $g_c(\boldsymbol{\lambda}) \approx f(\boldsymbol{\lambda})$ with respect to some distance measure.

Uncertainty propagation through the model $f(\boldsymbol{\lambda})$ then generally refers to the representation and analysis of the probability distribution for $f(\boldsymbol{\lambda})$ or summaries of it, given a probability distribution on $\boldsymbol{\lambda}$. Assuming $f(\boldsymbol{\lambda})$ is an expensive function to evaluate, the goal of efficient surrogate construction is to obtain an approximate function $g_c(\boldsymbol{\lambda}) \approx f(\boldsymbol{\lambda})$ with as few training samples $\{f(\boldsymbol{\lambda}^{(i)})\}_{i=1}^N$ as possible and then evaluate $g_c(\boldsymbol{\lambda})$ instead of $f(\boldsymbol{\lambda})$ for the estimation of any statistics of $f(\boldsymbol{\lambda})$. Further in this chapter, the effect of surrogate construction – in terms of both accuracy and efficiency – will be demonstrated on two major uncertainty propagation tasks:

- *Moment evaluation:* This work will specifically focus on the first two moments and demonstrate the computation of model mean $\mathbb{E}f(\boldsymbol{\lambda})$ and model variance $\mathbb{V}f(\boldsymbol{\lambda})$ with surrogates.
- *Sensitivity analysis:* This forward propagation task is otherwise called global sensitivity analysis or variance-based decomposition which helps attribute the output variance to the input dimensions, thus enabling parameter importance ranking and dimensionality reduction studies. The main effect sensitivity of dimension i refers to the fractional contribution of the i -th parameter toward the total variance via $S_i = \frac{\mathbb{V}_{\lambda_i}[\mathbb{E}_{\lambda_{-i}}f(\boldsymbol{\lambda}|\lambda_i)]}{\mathbb{V}f(\boldsymbol{\lambda})}$, where \mathbb{V}_{λ_i} and $\mathbb{E}_{\lambda_{-i}}$ refer to variance with respect to the i -th parameter and mean with respect to the rest of the parameters, respectively.

In lieu of a surrogate, Monte Carlo (MC) methods are often employed for such uncertainty propagation tasks. Further in this chapter, such MC estimators for moments and sensitivities, used for comparison, will be described. With the underlying premise of computationally expensive forward model $f(\boldsymbol{\lambda})$, the measure of success of the surrogate construction will be the estimation of moments and sensitivity indices that requires a smaller number of training samples to achieve an accuracy comparable to the MC method.

Polynomial chaos (PC) expansions are chosen here for the illustration of the surrogate-based acceleration of computationally intensive studies. In fact, they offer

the additional convenience for the selected uncertainty propagation tasks since the first two moments and the sensitivity indices are analytically computable from the PC surrogate [14, 69]. Generally, if analytical expressions are not available, assuming surrogate evaluation is much cheaper than the model evaluation itself, one can employ MC estimates for moments and sensitivities of the surrogate with a much larger number of model evaluations otherwise infeasible with the original function $f(\lambda)$.

3 Polynomial Chaos Surrogate

3.1 Input PC Specification

Polynomial chaos expansions serve as convenient means for propagating input uncertainties to outputs of interest for general computational models [20, 33, 44, 73, 77]. They have been successfully employed in a wide range of applications, from reacting systems [53, 54] to climate science [62, 72], both as means of accelerating forward problems [75] and inverse problems [40, 41]. Consider a vector λ of a finite number of model inputs. In general, a model can possess inputs that are functions, e.g., boundary conditions. Such inputs typically allow some parameterization with a finite number of parameters stemming from, e.g., principal component analysis or discretization. Without losing generality, it is assumed that λ encapsulates all such parameters. Additionally, assume that these parameters are uncertain and are equipped with a joint continuous probability density function (PDF) $\pi_\lambda(\cdot)$, i.e., λ is a random vector. Then, for any random vector $\xi = \{(\xi_1, \dots, \xi_L)\}$ with finite marginal moments and a continuous PDF, one can represent components of λ as polynomial expansions

$$\lambda_i = \sum_{k=0}^{\infty} \lambda_{ik} \Psi_k(\xi) \quad (19.1)$$

that converge in an L_2 sense, *provided* that the moment problem for each ξ_m is uniquely solvable. The latter condition means that the moments of ξ_m uniquely determine the probability density function of ξ_m . This is a key condition and a special case of more general results developed in Ernst et al. [16]. The polynomials in the expansion (19.1) are constructed to be orthogonal with respect to the PDF of ξ , $\pi_\xi(\cdot)$, i.e.,

$$\langle \Psi_k \Psi_j \rangle = \int \Psi_k(\xi) \Psi_j(\xi) \pi_\xi(\xi) d\xi = \delta_{kj} \|\Psi_k\|^2, \quad (19.2)$$

where δ_{kj} is the Kronecker delta, and the polynomial norms are defined as

$$\|\Psi_k\| = \left(\int \Psi_k^2(\xi) \pi_\xi(\xi) d\xi \right)^{1/2}. \quad (19.3)$$

Selection of the best underlying random variable ξ and its dimensionality is generally a nontrivial task. However, for the convenience of the PC construction, and given a generic expectation that a model with d uncertain inputs be represented by a d -dimensional random vector, one selects $L = d$, i.e., λ and ξ to have the same dimensionality. Moreover, it is common to use standard, independent variables as components of ξ , such as uniform on $[-1, 1]$ or standard normal, leading to Legendre or Hermite polynomials, respectively. Typically, as a rule of “rule of thumb,” one chooses the Legendre-Uniform polynomial-variable pair, if the corresponding input parameter has a compact support, and the Hermite-Gauss PC, in case the underlying input parameter has infinite support. More generally, the standard polynomial-variable pairs can be chosen from the Wiener-Askey generalized PC scheme [77] depending on the form of the PDFs $\pi_\lambda(\cdot)$.

The PDF $\pi_\lambda(\cdot)$ or samples from it can be obtained from expert opinion or preliminary calibration studies. With such a PDF available, one can use the inverse of the Rosenblatt transformation that maps the random vector λ to a standard random vector ξ , creating a function $\lambda(\xi)$ and subsequently building a polynomial approximation (19.1) for such a map via projection formula

$$\lambda_{ik} = \frac{1}{||\Psi_k||^2} \langle \lambda_i \Psi_k \rangle = \frac{1}{||\Psi_k||^2} \int \lambda_i(\xi) \Psi_k(\xi) \pi_\xi(\xi) d\xi. \quad (19.4)$$

In practice, one truncates the infinite sum (19.1) to include only K_{in} terms

$$\lambda_i = \sum_{k=0}^{K_{in}-1} \lambda_{ik} \Psi_k(\xi) \quad (19.5)$$

according to a predefined truncation rule. The indexing $k = k(\alpha)$ in the polynomial expansion (19.5) can be selected, say, according to the graded lexicographic ordering [13] of the multi-indices $\alpha = (\alpha_1, \dots, \alpha_d)$ that comprise the dimension-specific orders of each polynomial term $\Psi_{k(\alpha)}(\xi_1, \dots, \xi_d) = \psi_{\alpha_1}(\xi_1) \dots \psi_{\alpha_d}(\xi_d)$ for standard univariate polynomials $\psi_i(\xi)$. A common truncation rule is according to the total degree of the retained polynomials, i.e., $\alpha_1 + \dots + \alpha_d \leq p_{in}$ for some degree p_{in} , leading to $K_{in} = (d + p_{in})! / (d! p_{in}!)$ basis terms. For a description and analysis of various truncation options, see Blatman and Sudret [7] and Sargsyan et al. [62].

In cases when input components λ_i are independent, one arrives at a much simpler, univariate PC expansion for each component, up to order p_i in the i -th dimension,

$$\lambda_i = \sum_{k=0}^{p_i} \lambda_{ik} \psi_k(\xi_i). \quad (19.6)$$

Frequently only the mean and standard deviation, or bounds, of λ_i are reported in the literature or extracted by expert elicitation. In such cases, the maximum entropy considerations lead to Gaussian and uniform random inputs, respectively [29]. The former case corresponds to a univariate, first-order Gauss-Hermite expansion

$\lambda_i = \mu_i + \sigma_i \xi_i$, where $\xi_i \sim N(0, 1)$, while the latter is a univariate, first-order Legendre-Uniform expansion of form

$$\lambda_i = \frac{a_i + b_i}{2} + \frac{b_i - a_i}{2} \xi_i, \quad (19.7)$$

where ξ_i are *i.i.d.* uniform random variables on $[-1, 1]$. The classical task of forward propagation of uncertainties for a black-box model $y = f(\boldsymbol{\lambda})$ is then to find the coefficients of the PC representation of the output y :

$$y \simeq \sum_{k=0}^{K-1} c_k \Psi_k(\boldsymbol{\xi}). \quad (19.8)$$

The implicit relationship between $\boldsymbol{\lambda}$ and y encoded in Eqs. (19.5) and (19.8) serves as a surrogate for the function $f(\boldsymbol{\lambda})$. While the general PC forms (19.5) and (19.6) should be used for uncertainty propagation from input $\boldsymbol{\lambda}$ to the output $f(\boldsymbol{\lambda})$, the PC surrogate in particular is constructed within the same framework using a first-order input (19.7) for all parameters. In such cases, the polynomial function with respect to scaled inputs

$$y = f(\boldsymbol{\lambda}) \simeq g_c(\boldsymbol{\lambda}) = \sum_{k=0}^{K-1} c_k \Psi_k(\boldsymbol{\xi}(\boldsymbol{\lambda})), \quad (19.9)$$

where $\boldsymbol{\xi}(\boldsymbol{\lambda})$ is the simple scaling relationship, in this case, derived from the Legendre-Uniform linear PC in Eq. (19.7), i.e., $\xi_i = -\frac{a_i+b_i}{b_i-a_i} + \frac{2}{b_i-a_i} \lambda_i$ for $i = 1, \dots, d$. Similar to the general input PC case (19.5), one typically truncates the polynomial expansion (19.9) according to a total degree p , such that the number of terms is $K = (p+d)!/p!d!$.

3.2 PC Surrogate Construction

Two commonly used approaches for finding PC coefficients c_k , *projection* and *regression*, are highlighted below.

- Projection relies on the orthogonality of the basis functions enabling the formula

$$c_k^{Proj} = \frac{1}{||\Psi_k||^2} \int_{\boldsymbol{\xi}} f(\boldsymbol{\lambda}(\boldsymbol{\xi})) \Psi_k(\boldsymbol{\xi}) \pi_{\boldsymbol{\xi}}(\boldsymbol{\xi}) d\boldsymbol{\xi} \quad (19.10)$$

and minimizes the L_2 -distance between the function f and its surrogate

$$\mathbf{c}^{Proj} = \arg \min_{\mathbf{c}} \int_{\boldsymbol{\xi}} \left(f(\boldsymbol{\lambda}(\boldsymbol{\xi})) - \sum_{k=0}^{K-1} c_k \Psi_k(\boldsymbol{\xi}) \right)^2 \pi_{\boldsymbol{\xi}}(\boldsymbol{\xi}) d\boldsymbol{\xi}. \quad (19.11)$$

The projection integral in (19.10) is typically computed by quadrature integration

$$c_k^{Proj} \approx \frac{1}{||\Psi_k||^2} \sum_{q=1}^Q f(\lambda(\xi^{(q)})) \Psi_k(\xi^{(q)}) w_q, \quad (19.12)$$

where quadrature point-weight pairs $\{(\xi^{(q)}, w_q)\}_{q=1}^Q$ are usually chosen such that the integration of the highest-degree polynomial coefficient is sufficiently accurate. For high-dimensional problems, one can use sparse quadrature [4, 19, 23, 76] in order to reduce the number of required function evaluations for a given level of integration accuracy.

- Regression-based approaches directly minimize a distance measure given any set of evaluations of the function $f = \{f(\lambda(\xi^{(n)}))\}_{n=1}^N$ and the surrogate that can be written in a matrix form

$$\mathbf{g}_c = \left\{ \sum_{k=0}^{K-1} c_k \Psi_k(\xi^{(n)}) \right\}_{n=1}^N = \mathbf{G} \mathbf{c} \quad (19.13)$$

denoting the *measurement* matrix by $\mathbf{G}_{nk} = \Psi_k(\xi^{(n)})$. The minimization problem can then generally be written as

$$\mathbf{c}^{Regr} = \arg \min_{\mathbf{c}} \rho(f, \mathbf{g}_c), \quad (19.14)$$

where $\rho(\mathbf{u}, \mathbf{v})$ is a distance measure between two vectors, \mathbf{u} and \mathbf{v} . Most commonly, one chooses an ℓ_2 distance $\rho(f, \mathbf{g}_c) = ||f - \mathbf{g}_c||_2$, leading to a least-squares estimate

$$\mathbf{c}^{LSQ} = \arg \min_{\mathbf{c}} \sum_{n=1}^N \left(f(\lambda(\xi^{(n)})) - \sum_{k=0}^{K-1} c_k \Psi_k(\xi^{(n)}) \right)^2 = \arg \min_{\mathbf{c}} ||f - \mathbf{G} \mathbf{c}||_2 \quad (19.15)$$

that has a closed-form solution

$$\mathbf{c}^{LSQ} = (\mathbf{G}^T \mathbf{G})^{-1} \mathbf{G}^T f. \quad (19.16)$$

Both projection and regression fall into the category of *collocation* approaches in which the surrogate is constructed using a finite set of evaluations of $f(\lambda)$ [40, 74, 76]. While the projection typically requires function evaluations at predefined parameter values $\lambda(\xi^{(q)})$ corresponding to quadrature points, regression has the additional flexibility that the function evaluations or training samples can be located arbitrarily, although the accuracy of the resulting surrogate and numerical stability of the coefficient computation will depend on the distribution of the input parameter samples. Furthermore, if function evaluations are corrupted by noise or occasional faults, the projection loses its attractive properties – in particular, sparse quadrature

is extremely unstable due to negative weights [19]. Regression is much more stable in such noisy training data scenarios and is flexible enough to use various objective functions. For example, if the function is fairly smooth but one expects rare outliers in function evaluations due to, e.g., soft faults in computing environment, then an ℓ_1 objective function is more appropriate instead of the ℓ_2 objective function shown in (19.15) as it leads to a surrogate with the fewest number of “outlier” residuals, inspired by compressed sensing techniques [9, 10, 43, 63]. Besides, the regression approach allows direct extension to a *Bayesian* framework, detailed in the next subsection.

3.2.1 Bayesian Regression

Bayesian methods [6, 11, 65] are well positioned to deal with noisy function evaluations, allow a construction of an *uncertain* surrogate with any number of samples via posterior probability distributions on PC coefficient vector \mathbf{c} , and are efficient in sequential scenarios where the surrogate is updated *online*, i.e., as new evaluations of $f(\lambda)$ arrive [60]. Besides, Bayesian machinery, while computationally more expensive than the simple minimization (19.14), puts the construction of the objective function $\rho(f, g_c)$ within a formal probabilistic context where the objective function can be interpreted as a Bayesian log-likelihood and, say, ℓ_2 or least-squares objective function corresponds to an *i.i.d.* Gaussian assumption for the misfit random variable $f(\lambda) - g_c(\lambda)$. The probabilistic interpretation is particularly attractive when training function evaluations are corrupted by noise or the complex model $f(\lambda)$ itself is stochastic. In these cases projection methods suffer due to instabilities in quadrature integration, while deterministic regression lacks mechanisms to appropriately incorporate the data noise into predictions.

Bayes’ formula in the regression context reads as

$$\overbrace{p(\mathbf{c}|\mathcal{D})}^{\text{Posterior}} = \frac{\overbrace{p(\mathcal{D}|\mathbf{c})}^{\text{Likelihood}} \overbrace{p(\mathbf{c})}^{\text{Prior}}}{\underbrace{p(\mathcal{D})}_{\text{Evidence}}}, \quad (19.17)$$

relating a prior probability distribution on surrogate parameters \mathbf{c} to the posterior distribution via the likelihood function

$$\mathcal{L}_{\mathcal{D}}(\mathbf{c}) = p(\mathcal{D}|\mathbf{c}), \quad (19.18)$$

which essentially measures the goodness of fit of the model training data $\mathcal{D} = \{f\}$ to the surrogate model evaluations \mathbf{g}_c for a parameter set \mathbf{c} . As far as the estimation of \mathbf{c} is concerned, the evidence $p(\mathcal{D})$ is simply a normalizing factor. Nevertheless, it plays a crucial role in model comparison and model selection studies, discussed further in this chapter. Since for general likelihoods and high-dimensional parameter vector \mathbf{c} the posterior distribution in (19.17) is hard to compute, one often employs Markov chain Monte Carlo (MCMC) approaches to sample from it. MCMC

methods perform search in the parameter space exploring potential values for \mathbf{c} and, via an accept-reject mechanism, generate a Markov chain that has the posterior PDF as its stationary distribution [17, 22]. MCMC methods require many evaluations of the surrogate model. However, such construction is performed once only, and the surrogates are typically inexpensive to evaluate. Therefore, the main computational burden is in simulating the complex model $f(\cdot)$ at training input locations in order to generate the dataset \mathcal{D} for Bayesian inference via MCMC. As such, one should try to find the most accurate surrogate with as few model evaluations as possible.

The posterior distribution reaches its maximum at the maximum a posteriori (MAP) value. Working with logarithms of the prior and posterior distributions as well as the likelihood, the MAP value solves the optimization problem

$$\mathbf{c}^{MAP} = \arg \max_{\mathbf{c}} \log p(\mathbf{c} | \mathcal{D}) = \arg \max_{\mathbf{c}} [\log L_{\mathcal{D}}(\mathbf{c}) + \log p(\mathbf{c})]. \quad (19.19)$$

Clearly, this problem is equivalent to the deterministic regression with the negative log-likelihood $-\log L_{\mathcal{D}}(\mathbf{c})$ playing the role of an objective function augmented by the regularization term that is the negative log-prior $-\log p(\mathbf{c})$. In principle, the Bayesian framework also allows inclusion of nuisance parameters, e.g., parameters of the prior or the likelihood, that are inferred together with \mathbf{c} and subsequently integrated out to lead to marginal posterior distributions on \mathbf{c} . In a classical case, assuming a uniform prior $p(\mathbf{c})$ and an *i.i.d* Gaussian likelihood with, say, constant variance σ^2 ,

$$-\log L_{\mathcal{D}}(\mathbf{c}) = \frac{N}{2} \log 2\pi + N \log \sigma + \frac{1}{2\sigma^2} \|\mathbf{f} - \mathbf{G}\mathbf{c}\|^2, \quad (19.20)$$

one arrives at a multivariate normal posterior distribution for

$$\mathbf{c} \sim \mathcal{MVN}(\underbrace{(\mathbf{G}^T \mathbf{G})^{-1} \mathbf{G}^T \mathbf{f}}_{\mu_c}, \underbrace{\sigma^2 (\mathbf{G}^T \mathbf{G})^{-1}}_{\Sigma_c}). \quad (19.21)$$

Clearly, the posterior mean value is equal to \mathbf{c}^{MAP} and also coincides with the least-squares estimate (19.16). With the probabilistic description of \mathbf{c} , the PC surrogate is *uncertain* and is in fact a Gaussian process with analytically computable mean and covariance functions

$$g_c(\lambda(\xi)) \sim \mathcal{GP}(\Psi(\xi)\mu_c, \Psi(\xi)\Sigma_c\Psi(\xi')^T), \quad (19.22)$$

where $\Psi(\xi)$ is the basis measurement vector at parameter value ξ , i.e., its k -th entry is $\Psi(\xi)_k = \Psi_k(\xi)$. Such an uncertain surrogate is particularly useful when there is a low number of training simulations, and one would like to quantify the epistemic uncertainty due to lack of information. This is the key strength of Bayesian regression – in the presence of noisy or sparse training data, it allows useful surrogate results with an uncertainty estimate that goes with it.

3.3 Surrogate Construction Challenges

3.3.1 Model Selection and Validation

The choice of the degree p of the PC surrogate is a *model selection* problem. It may be selected by the modeler according to prior beliefs about the degree of smoothness of the function $f(\lambda)$ or via a *regularization* term in addition to the objective function (19.14) which constrains the surrogate according to some a priori knowledge about the function $f(\cdot)$, such as smoothness or sparsity. In the Bayesian setting, such a regularization term is equivalent to the log-prior distribution on parameters of the surrogate. Nevertheless, typically, higher-degree surrogates allow more degrees of freedom and correspondingly are closer to the true function evaluated at the training points, i.e., the training error

$$e_{\mathcal{T}}(f, g_c) = \sqrt{\frac{1}{N} \sum_{n=1}^N \left(f(\lambda^{(n)}) - g_c(\lambda^{(n)}) \right)^2} \quad (19.23)$$

reduces with increasing p while the surrogate itself is becoming less and less accurate across the full range of values of λ . Such *overfitting* can be avoided using a separate *validation* set of samples $\mathcal{V} = \{\lambda^{(r)}\}_{r=1}^R$ that is held out, measuring the quality of the surrogate via an error measure

$$e_{\mathcal{V}}(f, g_c) = \sqrt{\frac{1}{R} \sum_{r=1}^R \left(f(\lambda^{(r)}) - g_c(\lambda^{(r)}) \right)^2}. \quad (19.24)$$

Often validation set is split from within the training set in a variety of ways, leading to cross-validation methods that can be used for selection of an appropriate surrogate degree. For a survey of cross-validation methods for model selection, see Arlot et al. [2]. In the absence of a computational budget for cross-validation, one can employ heuristic information criteria, e.g., Akaike information criterion (AIC) or Bayesian information criterion (BIC), that penalize models with too many parameters thus alleviating the overfitting issue to an extent [1]. Bayesian machinery generally allows for model selection strategies via the Bayes factor which has firm probabilistic grounds and is more general than AIC or BIC, albeit is often difficult to evaluate [30]. The Bayes factor is the ratio of the evidence $p(\mathcal{D})$ with one model versus another. While the evidence is difficult to compute in general, it admits a useful decomposition for any parameterized model (first integrating with respect to the posterior distribution then employing Bayes' formula),

$$\begin{aligned} \log p(\mathcal{D}) &= \int \log p(\mathcal{D}) p(c|\mathcal{D}) dc = \int \log \left[\frac{L_{\mathcal{D}}(c)p(c)}{p(c|\mathcal{D})} \right] p(c|\mathcal{D}) dc \\ &= \underbrace{\int \log [L_{\mathcal{D}}(c)] p(c|\mathcal{D}) dc}_{\text{Fit}} - \underbrace{\int \log \left[\frac{p(c|\mathcal{D})}{p(c)} \right] p(c|\mathcal{D}) dc}_{\text{Complexity}}. \end{aligned} \quad (19.25)$$

The posterior average of the log-likelihood measures the ability of the surrogate model to fit the data, while the second term in (19.25) is the relative entropy or the Kullback-Leibler divergence between the prior and posterior distributions [32]. In other words, it measures the information gain about the parameters \mathbf{c} given the training data set \mathcal{D} . The more complex model extracts more information from the data, therefore this “complexity” directly implements Ockham’s razor, which states that with everything else equal, one should choose the simpler model [28]. Most information criteria, such as AIC or BIC, enforce Ockham’s razor in a more heuristic way. For Bayesian regression described above in this chapter, the linearity of the model with respect to \mathbf{c} likelihood allow closed-form expressions for the fit and complexity scores from (19.25) and, consequently, for the evidence:

$$\text{Fit} = -\frac{N}{2} \log[2\pi\sigma^2] - \frac{1}{\sigma^2} \mathbf{f}^T [\mathbf{I} - \mathbf{G}(\mathbf{G}^T \mathbf{G})^{-1} \mathbf{G}^T] \mathbf{f} \quad (19.26)$$

$$\text{Complexity} = \frac{K}{2} \log[2\pi\sigma^2] - \frac{1}{2} \log[\det(\mathbf{G}^T \mathbf{G})] - K \log(2\Delta), \quad (19.27)$$

assuming uniform prior on coefficients, i.e., $p(\mathbf{c}) = (2\Delta)^{-K}$ on $\mathbf{c} \in [-\Delta, \Delta]^K$.

Figure 19.1 shows Bayesian regression results on training data of size $N = 11$ that is computed using a third-order polynomial and “corrupted” by a Gaussian *i.i.d* noise of variance $\sigma^2 = 0.01$. The eighth-order PC surrogate, while having a better fit than the second- or third-order surrogates at the training points, is a clear example of overfitting. It can easily be exposed by a separate set of validation points or by computing the evidence according to (19.25), (19.26), and (19.27). This is illustrated in Fig. 19.2. On the left plot, the log-evidence and its component fit and complexity scores are plotted. The fit score keeps improving with an increasing PC surrogate order, albeit the improvement gets smaller and smaller in general. At the same time, the complexity score keeps decreasing, indicating that higher-order surrogates are more complex, in this case, due to more degrees of freedom. The log-evidence, as a sum of fit and complexity scores, reaches its maximum at surrogate order $p = 3$, which is indeed the true order of the underlying function. On the right plot, the log-evidence is shown again, now with the validation error computed on a separate set of $R = 100$ points according to (19.24). Clearly, the log-evidence accurately finds the correct model with the lowest validation error.

Model selection also strongly depends on the quality of information, i.e., the training samples. As Fig. 19.3 shows, the differentiation between various surrogates and the selection of the best surrogate model is easier with more training data and with lower noise variance.

3.3.2 High Dimensionality

A major challenge for surrogate construction – and PC surrogates in particular – is high dimensionality, i.e., when $d \gg 1$. First of all, the number of function evaluations needed to cover the d -dimensional space grows exponentially with the dimensionality. In other words, in order for the surrogate to be sufficiently

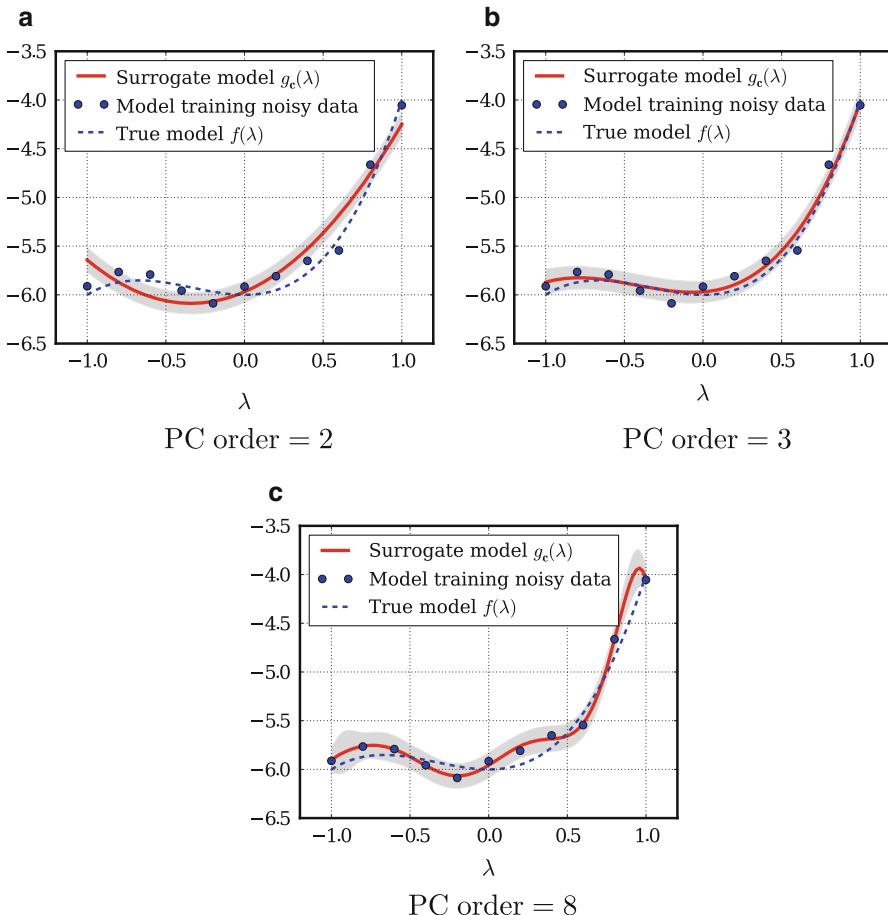

Fig. 19.1 Illustration of Bayesian regression with $N = 11$ training data extracted from noisy evaluations of a third-order polynomial $f(\lambda) = \lambda^3 + \lambda^2 - 6$, with noise variance $\sigma^2 = 0.01$. The gray region indicates the predictive variance of the resulting uncertain surrogate (19.22) together with the data noise variance. Three cases of the PC surrogate order are shown, demonstrating the high-order overfitting on the right plot. (a) PC order = 2. (b) PC order = 3. (c) PC order = 8

accurate, one needs an unfeasibly large number of function evaluations. Optimal computational design strategies can alleviate this to an extent, but they might be expensive and after all this *curse of dimensionality* remains in effect [24]. Second, the selection of multi-indices becomes a challenging task. Standard approaches, such as total-degree expansion or tensor-product expansion, lead to large multi-index sets, $K = (d + p)!/(d!p!)$ with total degree p and $K = p^d$ with degree p per dimension, correspondingly. Such large multi-index basis sets are computationally infeasible for $d \gg 1$ even with low values of p . In such cases, non-isotropic truncation rules [7] or a low-rank multi-index structure in the spirit

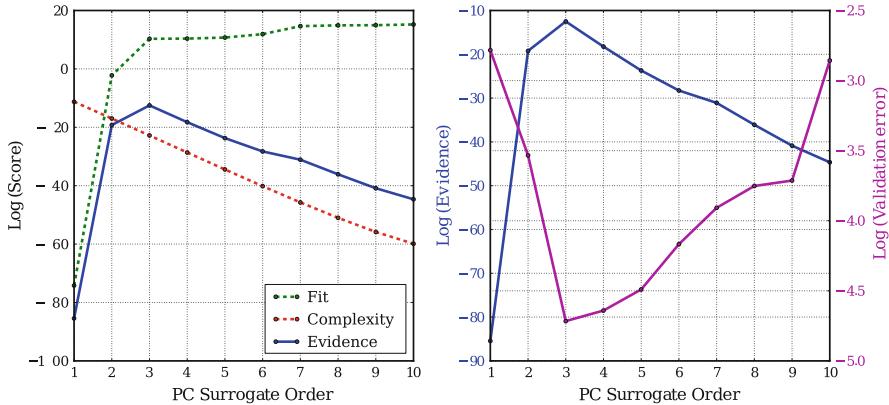

Fig. 19.2 (Left) Illustration of log-evidence together with its component scores for fit and complexity as functions of the PC surrogate order. (Right) The same log-evidence is plotted together with a validation error computed at $R = 100$ separate set of points according to (19.24)

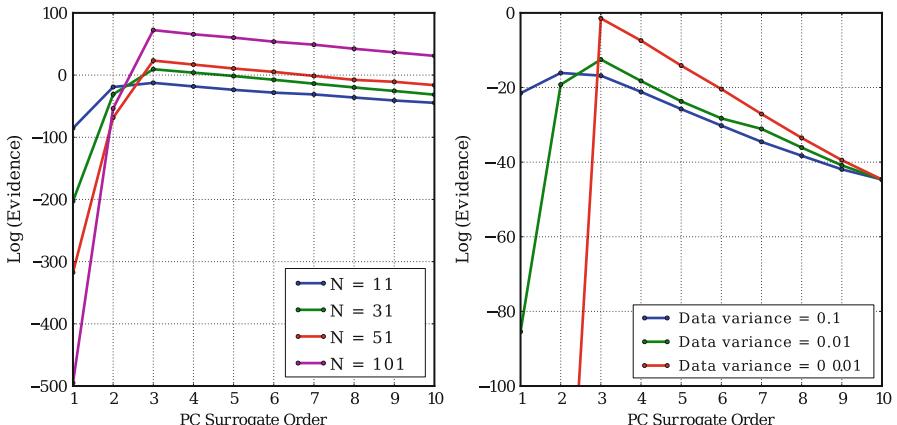

Fig. 19.3 Log-evidence as a function of the PC surrogate model for varying amount of training data (left), and for varying values of the data noise variance (right)

of high-dimensional model representation (HDMR) can be employed [50]. Further flexibility can be provided by adaptive multi-index selection methods as well as by enforcing sparsity constraints on multi-index sets in overdetermined cases, i.e., when $N < K$. In the regression setting, the latter is accomplished by adding an ℓ_1 regularization term to the objective function

$$\mathbf{c}^{Regr} = \arg \min_{\mathbf{c}} [\rho(\mathbf{f}, \mathbf{g}_c) + \mu \|\mathbf{c}\|_1], \quad (19.28)$$

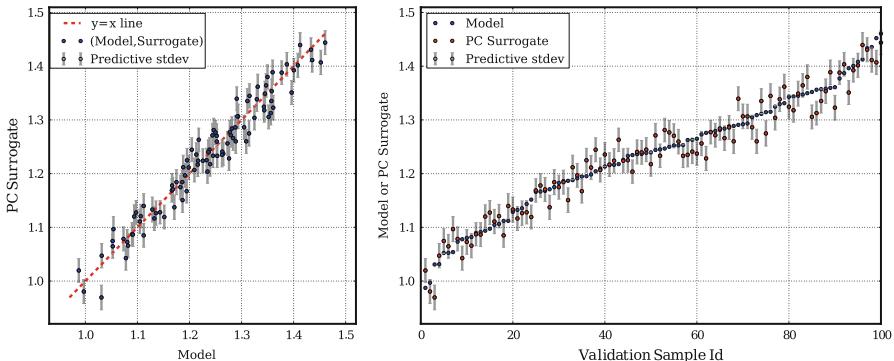

Fig. 19.4 Illustration of PC surrogate constructed via Bayesian compressive sensing, for a 50-dimensional exponential function, defined in the Appendix. The *left plot* shows PC surrogate values versus the actual model evaluations at a separate, validation set of $R = 100$ sample points. The *right plot* illustrates the same result in a different way. Namely, the validation samples are ordered according to ascending model values and plotted together with the corresponding PC surrogate values with respect to a counting index of the validation samples. The grey error bars correspond to posterior predictive standard deviations. The number of training samples used to construct the surrogate is $N = 100$, and the constructed sparse PC expansion has only $K = 11$ bases, with the highest order equal to three

in which the optimal value for μ is selected, e.g., by cross-validation. Such regularization helps find the sparsest, i.e., fewest nonzero values, parameter vector c . This approach originates from *compressed sensing* that made a breakthrough in image processing a decade ago [9, 10, 15]. There is a wide range of recent UQ studies that have benefited from such sparse reconstruction approaches specific to PC basis sets [26, 42, 47, 52, 62]. In a Bayesian context, sparse regression can be accomplished, e.g., via Bayesian compressive sensing (BCS) [3, 62] or Bayesian lasso [46]. A potential opportunity for tackling the curse of dimensionality presents itself if the function has low effective dimension, i.e., only a small set of parameters or combinations thereof impact the function in a nontrivial way. If such structure is discovered, both the computational design of training sets and PC multi-index selection should be informed appropriately, leading to computational efficiency gains. For example, Fig. 19.4 demonstrates PC surrogate construction results with BCS for a 50-dimensional exponential function, defined in the Appendix. The weight decay in the model warrants lower effective dimensionality, i.e., only a few parameters have considerable impact on the model output. A second-order PC surrogate would have $K_{\text{full}} = 52!/(50!2!) = 1326$ terms, while a third-order one would have $K_{\text{full}} = 53!/(50!3!) = 23426$ terms. With only $N = 100$ training samples, this would be a strongly underdetermined problem. Sparse regularization via BCS leads to only 11 terms in this case, producing a sparse PC surrogate – with uncertainty estimate – that is reasonably accurate for a regression in 50 dimensions with 100 training samples.

3.3.3 Nonlinear/Nonsmooth/Discontinuous Forward Model

Another major challenge for parametric surrogates arises when the function, or the forward model, $f(\lambda)$ itself is not amenable to the assumed parametric approximation. Specifically, global PC surrogates built using smooth bases have difficulty approximating functions that are nonsmooth and have discontinuities with respect to the parameters or strong nonlinearities exhibiting sharp growth in some parameter regimes. In such situations, domain decomposition or local adaptivity methods are employed allowing varying degree of resolution in different regions of parameter space and typically leading to piecewise-PC surrogates that can in principle be categorized as nonparametric. Such domain decomposition can be performed in the parameter space [34, 36, 37, 71], or in the “data” space, where the training model evaluations are clustered according to some physically meaningful criteria, followed by a surrogate construction on each cluster and employing classification to “patch” surrogates in the parameter space [59, 61, 62]. Other approaches include basis enrichment [21], or nonparametric surrogates, e.g., kriging [31, 68], that do not have a predefined form and are more flexible representing nonsmooth input-output dependences.

Having a sufficiently accurate and inexpensive surrogate in place, a forward uncertainty propagation task can then be greatly accelerated by replacing the function $f(\lambda)$ with its PC surrogate $g_c(\lambda)$ in sampling-based propagation approaches, e.g., to build an output PDF. Furthermore, because of the orthogonality of the polynomial bases in the output PC surrogate (19.9), one can obtain simple formulae for output statistics of interest that can be written as integral quantities. As discussed earlier, the main focus here will be on two basic uncertainty propagation tasks, moment evaluation and global sensitivity analysis.

3.4 Moment Evaluation

Assuming λ is distributed according to input PC expansion (19.7), i.e., uniform on $\prod_{i=1}^d [a_i, b_i]$, the moments of the function can be evaluated using standard Monte Carlo estimators with M function evaluations:

$$\mathbb{E} f(\lambda) \approx \hat{\mathbb{E}} f(\lambda) = \frac{1}{M} \sum_{m=1}^M f(\lambda(\xi^{(m)})), \quad (19.29)$$

$$\mathbb{V} f(\lambda) \approx \hat{\mathbb{V}} f(\lambda) = \frac{1}{M} \sum_{m=1}^M \left(f(\lambda(\xi^{(m)})) - \hat{\mathbb{E}} f(\lambda) \right)^2. \quad (19.30)$$

These estimates will be used to compare against surrogate-based moment evaluation. Moments of the function $f(\lambda)$ are approximated by the moments of the surrogate $g_c(\lambda)$, which can be computed exactly employing the orthogonality of the basis polynomials:

$$\mathbb{E} f(\lambda) \approx \mathbb{E} g_c(\lambda) = \int_{\lambda} g_c(\lambda) \pi_{\lambda}(\lambda) d\lambda = \int_{\xi} \sum_{k=0}^{K-1} c_k \Psi_k(\xi) \pi_{\xi}(\xi) d\xi = c_0, \quad (19.31)$$

$$\begin{aligned} \mathbb{V} f(\lambda) \approx \mathbb{V} g_c(\lambda) &= \int_{\lambda} (g_c(\lambda) - c_0)^2 \pi_{\lambda}(\lambda) d\lambda \\ &= \int_{\xi} \left(\sum_{k=1}^{K-1} c_k \Psi_k(\xi) \right)^2 \pi_{\xi}(\xi) d\xi = \sum_{k=1}^{K-1} c_k^2 \|\Psi_k\|^2. \end{aligned} \quad (19.32)$$

Note that the exact expressions for surrogate moments (19.31) and (19.32) presume that λ is distributed uniformly on $\prod_{i=1}^d [a_i, b_i]$. For more complicated PDFs $\pi_{\lambda}(\lambda)$, one can employ MC estimates with a much larger ensemble than would have been possible without using the surrogate. This is the main reason for surrogate construction – to replace the complex model in computationally intensive studies. In this chapter, however, specific moment evaluation and sensitivity computation tasks are selected that allow exact analytical formulae with PC surrogates in order to neglect errors due to finite sampling of the surrogate itself.

For the demonstration of moment estimation as well as sensitivity index computation in the next subsection, the classical least-squares regression problem (19.15) is employed for surrogate construction and estimation of PC coefficients, with a solution in (19.16). Note that if Bayesian regression is employed, the resulting uncertain surrogate can lead to an uncertainty estimate in uncertainty estimate in the evaluation of moments as well. Figure 19.5 illustrates the relative error in the estimation of mean and variance for varying number of function evaluations and PC surrogate order, for the oscillatory function, described in the Appendix, with dimensionality $d = 3$. Also, the dimensionality $d = 3$. Also, the MC estimates from (19.29) and (19.30) are shown for comparison. Clearly, for the estimate of the mean of this function, even a linear PC surrogate outperforms MC. In fact, it can be shown that the MC estimate is i.e., constant fit value with the solution of the least-squares problem (19.15). At the same time, the variance problem (19.15). At the same time, the variance estimate requires at least a second-order PC surrogate to guarantee improvement over MC error for all inspected values of the number of function evaluations.

Similar results hold across all the tested models, listed in the Appendix, as Fig. 19.6 suggests. It illustrates relative error convergence with respect to the number of function evaluations, as well as with respect to the PC surrogate order, for all the considered model functions with $d = 3$. Again, one can see that typically the mean and, to the lesser extent, the variance is much more efficient to estimate with the PC surrogate approximation than with the naïve MC estimator. In fact, continuous (model #4, discontinuous first derivative) and corner-peak (model #5, sharp peak at the domain corner) functions are less amenable to polynomial approximation, as the third column suggests, leading to moment estimates that are comparable in accuracy with MC estimates, at least for low surrogate orders.

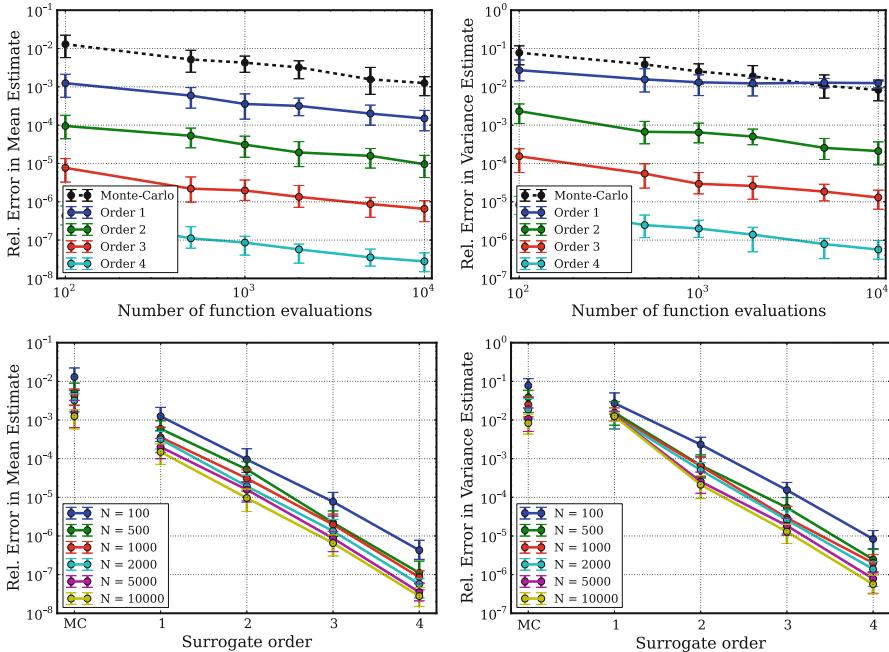

Fig. 19.5 Relative error in the estimation of mean (left column) and variance (right column) with varying number of function evaluations (top row) and PC surrogate order (bottom row) for the three-dimensional oscillatory function. The corresponding MC estimates are highlighted for comparison with dashed lines or as a separate abscissa value. Presented values of relative errors are based on medians over 100 different training sample sets, while error bars indicate 25% and 75% quantiles

3.5 Global Sensitivity Analysis

Sobol's sensitivity indices are useful statistical summaries of model output [57, 67]. They measure fractional contributions of each parameter or group of parameters toward the total output variance. In this chapter, the *main effect sensitivities* are explored, also called first-order sensitivities, that are defined as

$$S_i = \frac{\mathbb{V}_{\lambda_i} \mathbb{E}_{\lambda_{-i}}[f(\boldsymbol{\lambda}) | \lambda_i]}{\mathbb{V} f(\boldsymbol{\lambda})}, \quad (19.33)$$

where \mathbb{V}_{λ_i} and $\mathbb{E}_{\lambda_{-i}}$ indicate variance with respect to the i -th parameter and expectation with respect to the rest of the parameters, respectively. The sampling-based approach developed in Saltelli et al. [58]

$$\hat{S}_i = \frac{1}{\hat{\mathbb{V}} f(\boldsymbol{\lambda})} \left[\frac{1}{M} \sum_{m=1}^M f(\boldsymbol{\lambda}(\xi^{(m)})) \left(f(\boldsymbol{\lambda}(\bar{\xi}_{-i}^{(m)})) - f(\boldsymbol{\lambda}(\bar{\xi}^{(m)})) \right) \right] \quad (19.34)$$

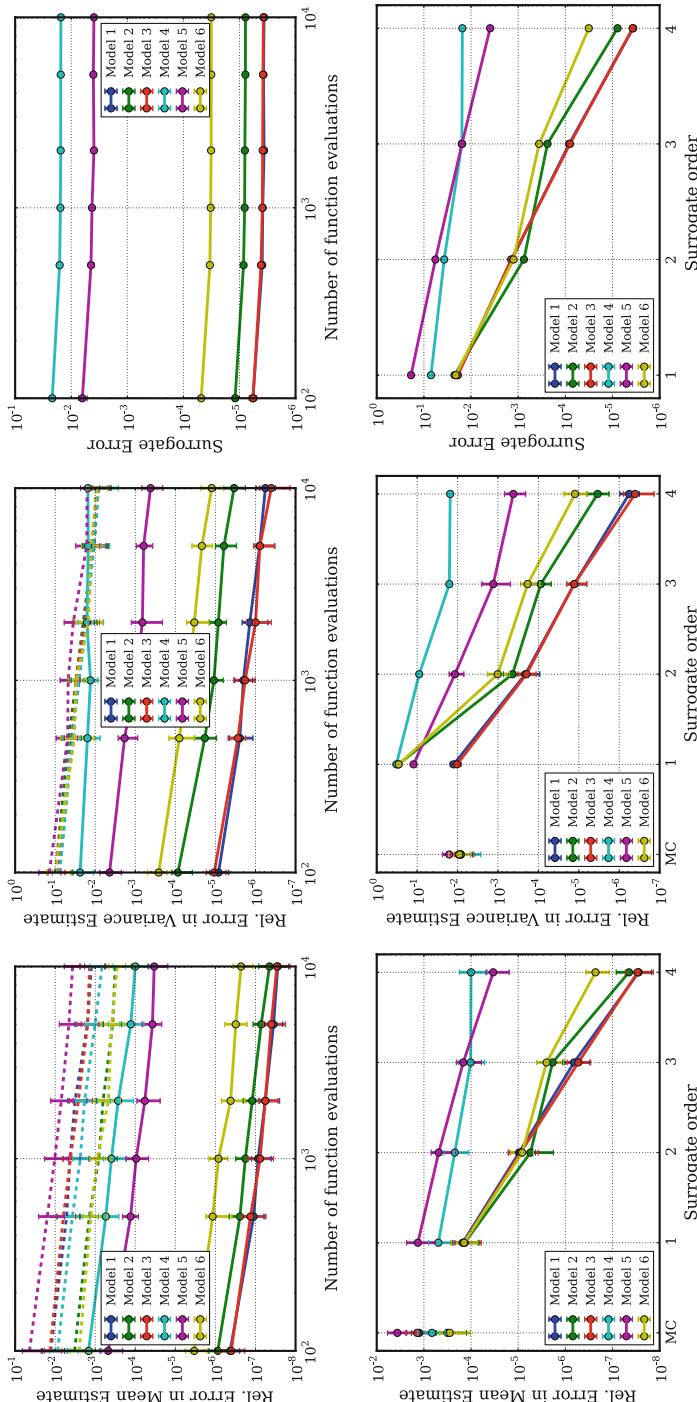

Fig. 19.6 Illustration of the relative error in the estimate of mean (*left column*) and variance (*middle column*), as well as surrogate error (*right column*), i.e., mean-square mismatch of the surrogate and the true model over a separate set of 100 validation samples. The results are illustrated in two ways, with respect to N (*top row*), the number of function evaluations for the PC surrogate order set to $p = 4$, and with respect to the PC surrogate order for $N = 10,000$ (*bottom row*). The corresponding MC estimates are highlighted for comparison with dashed lines or as a separate abscissa value. The error bars indicate 25 % and 75 % quantiles, while the dots correspond to medians over 100 replica simulations. Models are color coded as shown in the legends

is used to compute sensitivity indices in order to compare against the PC surrogate-based approach. These estimates use the sampling set of M points $\xi^{(m)}$ for $m = 1, \dots, M$, the *resampling* set $\bar{\xi}^{(m)}$, and auxiliary points $\tilde{\xi}_{-i}^{(m)}$ that coincide with resampling points except that, at the i -th dimension, the sampling point value is taken, i.e., $\tilde{\xi}_{-i}^{(m)} = (\bar{\xi}_1^{(m)}, \dots, \bar{\xi}_{i-1}^{(m)}, \xi_i^{(m)}, \bar{\xi}_{i+1}^{(m)}, \dots, \bar{\xi}_d^{(m)})$. Note that such an estimate requires $2M$ random samples and, more importantly, $(d + 2)M$ function evaluations. Other estimators for sensitivity indices are also available [27, 56, 58, 66] with similar convergence properties.

When the function $f(\lambda)$ is replaced by a PC surrogate $g_c(\lambda)$, one can compute the sensitivity indices using the orthogonality of the PC basis functions, assuming λ is uniform on the hypercube $\prod_{i=1}^d [a_i, b_i]$ per input PC expansion (19.7),

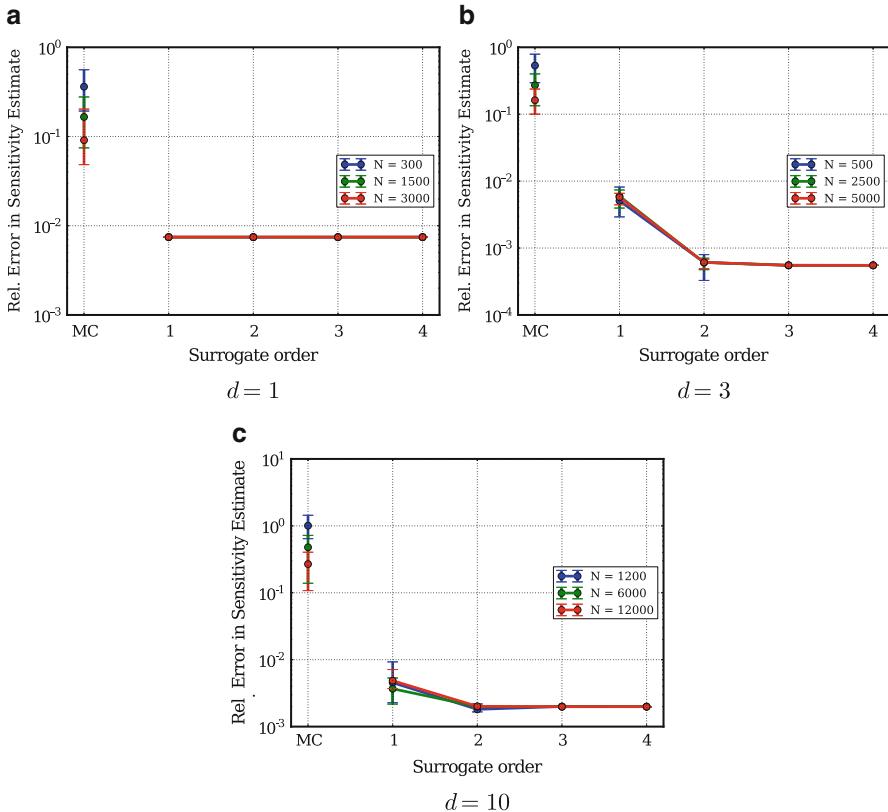

Fig. 19.7 Relative error in estimation of the first main sensitivity index, S_1 , with respect to PC surrogate order with varying number of function evaluations for the oscillatory function for three cases of dimensionality d . The corresponding MC estimates are highlighted for comparison as a separate abscissa value. Presented values of relative errors are based on medians over 100 different training sample sets, while error bars indicate 25 % and 75 % quantiles. (a) $d = 1$. (b) $d = 3$. (c) $d = 10$

$$S_i \approx \frac{\mathbb{V}_{\lambda_i} \mathbb{E}_{\lambda_{-i}} [g_c(\lambda) | \lambda_i]}{\mathbb{V} g_c(\lambda)} = \frac{\sum_{m=1}^{M_i} c_{k_m(i)}^2 \|\Psi_{k_m(i)}\|^2}{\sum_{k=1}^{K-1} c_k^2 \|\Psi_k\|^2}, \quad (19.35)$$

where $(k_1(i), \dots, k_{M_i}(i))$ is the list of indices that correspond to univariate bases in the i -th dimension only, i.e., corresponding to multi-indices of the form $(0, 0, \dots, \alpha_i, \dots, 0, 0)$ with $\alpha_i \neq 0$. Therefore, having constructed the PC surrogate, one can easily compute the sensitivity indices by computing the weighted sum of the squares of appropriately selected PC coefficients.

Figure 19.7 shows convergence with respect to the PC surrogate order for various values of the number of function evaluations, for the oscillatory function, described in the Appendix, with three different dimensionalities. Clearly, a PC surrogate, even the linear one, leads to improved errors compared to an MC-based estimate (19.34). The convergence with order does not reduce below a certain value due to the “true” sensitivity being computed only approximately via the MC formula with a large $M = 10^5$.

4 Conclusions

This chapter has focused on surrogate modeling for computationally expensive forward models. Specifically, polynomial chaos (PC) surrogates have been studied for the purposes of forward propagation and variance-based sensitivity analysis. Among various methods of PC coefficient computation, Bayesian regression has been highlighted as it offers a host of advantages. First of all, it is applicable with noisy function evaluations and allows likelihood or objective function construction stemming from formal probabilistic assumptions. Second, it provides robust answers with an uncertainty certificate with any number of and arbitrarily distributed training function evaluations, which is often very practical for complex physical models, e.g., climate models that are simulated on supercomputers with a single simulation taking hours or days. This is particularly useful for high-dimensional surrogate construction, when one necessarily operates under the condition of sparse training data. Relatedly, high dimensionality or a large number of surrogate parameters often lead to an underdetermined problem in which case Bayesian sparse learning methods such as Bayesian compressive sensing provide an uncertainty-enabled alternative to classical, deterministic regularization methods. Besides, Bayesian methods allow sequential updating of surrogates as new function evaluations arrive by encoding the state of knowledge about the surrogate parameters into a prior distribution. Finally, Bayesian regression allows an efficient solution to the surrogate model selection problem via evidence computation and Bayes factors as demonstrated on toy examples in this chapter. Irrespective of the construction methodology, a PC surrogate enables drastic computational savings when evaluating moments or sensitivity indices of complex models, as illustrated on a select class of functions with tunable dimensionality and a varying degree of smoothness.

Table 19.1 Test functions used in the studies of this section. The shift parameters are set to $u_i = 0.3$ for all dimensions $i = 1, \dots, d$, while the weight parameters are selected as $w_i = C/i$ with normalization constant $C = 1/\sum_{i=1}^d i^{-1}$ to ensure $\sum_{i=1}^d w_i = 1$. The variance formula for the product-peak function is $v(\mathbf{u}, \mathbf{w}) = \prod_{i=1}^d w_i^4 \left(\frac{1-u_i}{2(1+w_i^2(1-u_i)^2)} + \frac{u_i}{2w_i} (\arctan(w_i(1-u_i)) + \arctan(w_i u_i)) \right) - m(\mathbf{u}, \mathbf{w})^2$

Id	Function	Formula $f_{\mathbf{u}, \mathbf{w}}(\lambda)$	Exact mean	Exact variance
			$m(\mathbf{u}, \mathbf{w}) = \int_0^1 f_{\mathbf{u}, \mathbf{w}}(\lambda) d\lambda$	$v(\mathbf{u}, \mathbf{w}) = \int_0^1 (f_{\mathbf{u}, \mathbf{w}}(\lambda) - m(\mathbf{u}, \mathbf{w}))^2 d\lambda$
1	Oscillatory	$\cos \left(2\pi u_1 + \sum_{i=1}^d w_i \lambda_i \right)$	$\left(\cos 2\pi u_1 + \frac{1}{2} \sum_{i=1}^d w_i \right) \prod_{i=1}^d \frac{2 \sin(w_i/2)}{w_i}$	$\frac{1}{2} + \frac{1}{2} m(2\mathbf{u}, 2\mathbf{w}) - m(\mathbf{u}, \mathbf{w})^2$
2	Gaussian	$\exp \left(- \sum_{i=1}^d w_i^2 (\lambda_i - u_i)^2 \right)$	$\prod_{i=1}^d \frac{\sqrt{\pi}}{2w_i} (\text{erf}(w_i(1-u_i)) + \text{erf}(w_i u_i))$	$m(\mathbf{u}, \sqrt{2}\mathbf{w}) - m(\mathbf{u}, \mathbf{w})^2$
3	Exponential	$\exp \left(\sum_{i=1}^d w_i (\lambda_i - u_i) \right)$	$\prod_{i=1}^d \frac{1}{w_i} (\exp(w_i(1-u_i)) - \exp(-w_i u_i))$	$m(\mathbf{u}, 2\mathbf{w}) - m(\mathbf{u}, \mathbf{w})^2$
4	Continuous	$\exp \left(- \sum_{i=1}^d w_i \lambda_i - u_i \right)$	$\prod_{i=1}^d \frac{1}{w_i} (2 - \exp(-w_i u_i) - \exp(w_i(u_i - 1)))$	$m(\mathbf{u}, 2\mathbf{w}) - m(\mathbf{u}, \mathbf{w})^2$
5	Corner peak	$\left(1 + \sum_{i=1}^d w_i \lambda_i \right)^{-(d+1)}$	$\frac{1}{d! \prod_{i=1}^d w_i} \sum_{r \in \{0,1\}^d} \frac{(-1)^{ r _1}}{1 + \sum_{i=1}^d w_i r_i}$	Sampling estimator (19.34) with $M = 10^7$
6	Product peak	$\prod_{i=1}^d \frac{w_i^2}{1 + w_i^2 (\lambda_i - u_i)^2}$	$\prod_{i=1}^d w_i (\arctan(w_i(1-u_i)) + \arctan(w_i u_i))$	See the caption

Appendix

Table 19.1 shows six classes of functions employed in the numerical tests in this chapter. All functions, except the exponential one, are taken from the classical Genz family of test functions [18]. The weight parameters of the test functions are chosen according to a predefined “decay” rate $w_i = C/i$ and a normalization factor $C = 1/\sum_{i=1}^d i^{-1}$ to ensure $\sum_{i=1}^d w_i = 1$. The exact moments are analytically available and are used for reference to compare against, with the exception of the corner-peak function, for which the variance estimator (19.30) with sampling size $M = 10^7$ is used. The “true” reference values ‘true’ reference values for sensitivity indices S_i are also computed via Monte Carlo, using the estimates (19.34) with $M = 10^5$. The functions are defined on $\lambda \in [0, 1]^d$; assuming the inputs are *i.i.d* uniform random variables, the underlying linear input PC expansions are simple linear transformations $\lambda_i = 0.5\xi_i + 0.5$, relating the “physical” model inputs $\lambda_i \in [0, 1]$ to the PC surrogate inputs $\xi_i \in [-1, 1]$, for $i = 1, \dots, d$.

Stochastic Collocation Methods: A Survey

20

Dongbin Xiu

Abstract

Stochastic collocation (SC) has become one of the major computational tools for uncertainty quantification. Its primary advantage lies in its ease of implementation. To carry out SC, one needs only a reliable deterministic simulation code that can be run repetitively at different parameter values. And yet, the modern-day SC methods can retain the high-order accuracy properties enjoyed by most of other methods. This is accomplished by utilizing the large amount of literature in the classical approximation theory. Here we survey the major approaches in SC. In particular, we focus on a few well-established approaches: interpolation, regression, and pseudo projection. We present the basic formulations of these approaches and some of their major variations. Representative examples are also provided to illustrate their major properties.

1 Introduction

Stochastic collocation (SC) is a sampling-based method. The term “collocation” originates from the deterministic numerical methods for differential equations, where one seeks to satisfy the governing continuous equations discretely at a set of *collocation points*. This is to the contrary of Galerkin method, where one seeks to satisfy the governing equation in a weak form. *Stochastic collocation* was first termed in [31], although the idea and its application have existed long before that.

To illustrate the idea, let us consider, for a spatial domain D and time domain $[0, T]$ with $T > 0$, the following partial differential equation (PDE) system:

$$\begin{cases} u_t(x, t, Z) = \mathcal{L}(u), & D \times (0, T] \times I_Z, \\ \mathcal{B}(u) = 0, & \partial D \times [0, T] \times I_Z, \\ u = u_0, & D \times \{t = 0\} \times I_Z, \end{cases} \quad (20.1)$$

where $I_Z \subset \mathbb{R}^d$, $d \geq 1$ is the support of the uncertain parameters $Z = (Z_1, \dots, Z_d)$ and \mathcal{B} is the boundary condition operator. The solution is then a mapping

$$u(x, t, Z) : \bar{D} \times [0, T] \times I_Z \rightarrow \mathbb{R},$$

where for the simplicity of exposition we consider a scalar equation. In UQ computations, we are primarily interested in the solution dependence in the parameter space, that is,

$$u(\cdot, Z) : I_Z \rightarrow \mathbb{R}, \quad (20.2)$$

where the dependence on the spatial and temporal variables (x, t) is suppressed. Hereafter, all statements are made for any fixed x and t .

In stochastic collocation, the system (20.1) is solved in a discrete manner. More specifically, we seek to enforce the equation at a discrete set of nodes – “collocation points.” Let $\Theta_M = \{Z^{(j)}\}_{j=1}^M \subset I_Z$ be a set of (prescribed) nodes in the random space, where $M \geq 1$ is the number of nodes. Then in SC, we enforce (20.1) at the node $Z^{(j)}$, for all $j = 1, \dots, M$, by solving

$$\begin{cases} u_t(x, t, Z^{(j)}) = \mathcal{L}(u), & D \times (0, T], \\ \mathcal{B}(u) = 0, & \partial D \times [0, T], \\ u = u_0, & D \times \{t = 0\}. \end{cases} \quad (20.3)$$

It is easy to see that for each j , (20.3) is a deterministic problem because the value of the random parameter Z is fixed. Therefore, solving the system poses no difficulty provided one has a well-established deterministic algorithm. Let $u^{(j)} = u(\cdot, Z^{(j)})$, $j = 1, \dots, M$, be the solution of the above problem. The result of solving (20.3) is an ensemble of deterministic solutions $\{u^{(j)}\}_{j=1}^M$. And one can apply various post-processing operations to the ensemble to extract useful information about $u(Z)$.

From this point of view, all classical sampling methods belong to the class of collocation methods. For example, in *Monte Carlo sampling*, the nodal set Θ_M is generated randomly according to the distribution of Z , and the ensemble averages are used to estimate the solution statistics, e.g., mean and variance. In *deterministic sampling methods*, the nodal set is typically the nodes of a cubature rule (i.e., quadrature rule in multidimensional space) defined on I_Z such that one can use the integration rule defined by the cubature to estimate the solution statistics.

In SC, the goal is to construct an accurate approximation to the solution response function using the samples. This is a stronger goal than estimating the solution statistics and the major difference between SC and the classical sampling methods. Knowing the function response of the solution allows us to immediately derive all of the statistical information of the solution. It is not the case conversely, as knowing the solution statistics does not allow us to create the solution response. To this end, SC can be classified as *strong approximation* methods, whereas the traditional sampling methods are *weak approximation* methods. (More precise definitions of strong and weak approximations can be found in [30].)

2 Definition of Stochastic Collocation

The goal of SC is to construct a numerical approximation to the solution response (20.2) in the parameter space I_Z , using the deterministic solution ensemble $\{u(\cdot, Z^{(j)})\}$, $j = 1, \dots, M$, of (20.3). Following [30], we give the following formal definition of SC:

Definition 1 (Stochastic collocation). Let $\Theta_M = \{Z^{(j)}\}_{j=1}^M \subset I_Z$ be a set of (prescribed) nodes in the random space I_Z , where $M \geq 1$ is the number of nodes, and $\{u^{(j)}\}_{j=1}^M$ be the solution of the governing equation (20.3). Then find $w(Z) \approx u(Z)$ such that it is an approximation to the true solution $u(Z)$ in the sense that $\|w(Z) - u(Z)\|$ is sufficiently small in a strong norm defined on I_Z .

In this general definition, the norm is left unspecified. In practice, different choices of the norm lead to different SC methods. Typically, we employ L^p -norm ($p \geq 1$), with the L^2 -norm used the most in practice and leading to “mean-square” approximation.

The numerical approximation $w(Z)$ shall be chosen from a class of functions. Mathematically speaking, this implies that $w \in V$, where V is a linear space from which the approximation is sought. In SC, the most widely used choice

is polynomial space, which leads to strong ties of SC methods to generalized polynomial chaos (gPC) approximation ([16, 32]). Here, the space V is

$$\mathbb{P}_n^d = \text{span}\{z^\alpha : |\alpha| = (\alpha_1 + \dots + \alpha_d) \leq n\}, \quad (20.4)$$

where $\alpha = (\alpha_1, \dots, \alpha_d)$ is multi-index. This is the space of polynomials of degree up to n , whose cardinality is $\dim \mathbb{P}_n^d = \binom{n+d}{n}$. Other spaces of polynomials, or other classes of functions, can certainly be chosen.

The construction and properties of SC methods then critically depend on the approximation properties of w and the choice of the collocation nodal set Θ_M . Broadly speaking, the current SC methods fall into the following three categories: interpolation type, regression type, and pseudo projection type.

3 Stochastic Collocation via Interpolation

3.1 Formulation

In interpolation approach, we seek to match the numerical approximation w with the true solution u exactly at the nodal set Θ_M . More specifically, let $w \in V_N$ be constructed from a linear space V_N with cardinality $\dim V_N = N$. Let (b_1, \dots, b_N) be a basis for V_N . Then, we can express w as

$$w(Z) = \sum_{i=1}^N c_i b_i(Z), \quad (20.5)$$

where c_i are the coefficients to be determined. We then enforce the interpolation condition

$$w(Z^{(j)}) = u(Z^{(j)}), \quad \text{for all } j = 1, \dots, M. \quad (20.6)$$

This immediately leads to a linear system of equations for the unknown coefficients

$$\mathbf{A}\mathbf{c} = \mathbf{f}, \quad (20.7)$$

where

$$\mathbf{A} = (a_{ij})_{1 \leq i \leq M, 1 \leq j \leq N}, \quad a_{ij} = b_j(Z^{(i)}), \quad (20.8)$$

and

$$\mathbf{c} = (c_1, \dots, c_N)^T, \quad \mathbf{f} = (u(Z^{(1)}), \dots, u(Z^{(M)}))^T \quad (20.9)$$

are the coefficient vector and solution sample vector, respectively. For example, if one adopts the gPC expansion, then V_N is the polynomial space \mathbb{P}_n^d from (20.4), and the matrix \mathbf{A} becomes the Vandermonde-like matrix with entries

$$a_{ij} = \Phi_j(Z^{(i)}), \quad (20.10)$$

where $\Phi_j(Z)$ are the gPC orthogonal polynomials chosen based on the probability distribution of Z and satisfy

$$\int_{I_Z} \Phi_i(z) \Phi_j(z) \rho(z) dz = \delta_{ij}. \quad (20.11)$$

Here, δ_{ij} is the Kronecker delta function and the polynomials are normalized.

When the number of the collocation points is the same as the number of the basis functions, i.e., $M = N$, the matrix \mathbf{A} is square and can be inverted when it is nonsingular. One then immediately obtains

$$\mathbf{c} = \mathbf{A}^{-1} \mathbf{f}, \quad (20.12)$$

and can construct the approximation $w(Z)$ using (20.5). Although very flexible, this approach is not used widely in practice. The reason is that interpolation is often not very robust and leads to wild behavior in $w(Z)$. This is especially true in multidimensional spaces ($d > 1$). The accuracy of the interpolation is also difficult to assess and control. Even though the interpolation $w(Z)$ has no error at the nodal points, it can incur large errors between the nodes. Rigorous mathematical analysis is also lacking on this front, particularly in high dimensions. Some of these facts are well documented in texts such as [7, 23, 27].

Another approach to accomplish interpolation is to employ the *Lagrange interpolation approach*. That is, we seek

$$w(Z) = \sum_{j=1}^M u(Z^{(j)}) L_j(Z), \quad (20.13)$$

where

$$L_j(Z^{(i)}) = \delta_{ij}, \quad 1 \leq i, j \leq M, \quad (20.14)$$

are the Lagrange interpolating polynomials. By construction, the polynomial $w(Z)$ automatically satisfies the interpolation conditions. We then need to explicitly construct the Lagrange interpolation polynomials $L_j(Z)$. This can be easily done in one dimension $d = 1$, i.e.,

$$L_j(Z) = \prod_{i=1, i \neq j}^M \frac{Z - Z^{(i)}}{Z^{(j)} - Z^{(i)}}, \quad j = 1, \dots, M. \quad (20.15)$$

Much is known about polynomial interpolation in one dimension. It is widely acknowledged that interpolation on equidistance grids is unstable at higher degree

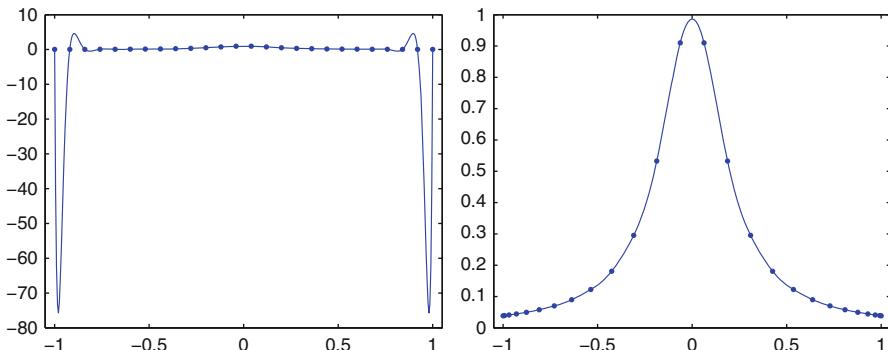

Fig. 20.1 Polynomial interpolation of $f(x) = 1/(1 + 25x^2)$ in $[-1, 1]$, the rescaled Runge function. *Left:* interpolation on uniformly distributed nodes; *Right:* interpolation on nonuniform nodes (the zeros of Chebyshev polynomials)

polynomials. To construct robust and accurate interpolations, one should employ grids that are clustered toward the boundaries of the interval. The well-known example of interpolating the Runge function clearly illustrates this property. The results are shown in Fig. 20.1. Even though both interpolations can faithfully interpolate the function data, the result by the equidistance nodes admits wild oscillations between the nodes, whereas the result by the Chebyshev nodes is well behaved and accurate.

Interpolation in multiple dimensions ($d > 1$) is usually carried out in two different approaches. The first approach is to extend the well-studied one-dimensional interpolation methods to multiple dimensions via a certain tensor product rule. This naturally results in sampling sets that are structured. An immediate consequence is that the growth of the number of samples in high dimensions can be prohibitively fast – courtesy of the “curse of dimensionality.” The second approach is to directly construct interpolations on a set of unstructured nodes. This, however, is a mathematically challenging task and leaves many open issues to study.

3.2 Interpolation SC on Structured Samples

The major difficulty in the interpolation SC is the construction of interpolation polynomials in multiple dimensions. Traditionally, this is carried out by extending the one-dimensional interpolation techniques (20.15) to higher dimensions.

3.2.1 Tensor Nodes

Since univariate interpolation is a well-studied topic, it is straightforward to employ a univariate interpolation and then fill up the multidimensional parameter space dimension by dimension. By doing so, the properties and error estimates of univariate interpolation can be retained as much as possible.

Let

$$\mathcal{Q}_{m_i}[f] = \sum_{j=1}^{m_i} f(Z_i^{(j)}) L_j(Z_i), \quad i = 1, \dots, d, \quad (20.16)$$

be the one-dimensional Lagrange interpolation in the i -th dimension, where L_j are defined in (20.15) and the number of samples is m_i . Let $\Theta_1^{m_i}$ be the interpolation nodal set in this direction. To extend this into the entire d -dimensional space I_Z , we can use tensor product approach and define the multidimensional interpolation operator as

$$\mathcal{Q}_M = \mathcal{Q}_{m_1} \otimes \cdots \otimes \mathcal{Q}_{m_d}, \quad (20.17)$$

and the nodal set is

$$\Theta_M = \Theta_1^{m_1} \times \cdots \times \Theta_1^{m_d}, \quad (20.18)$$

where the total number of nodes is $M = m_1 \times \cdots \times m_d$.

The advantage of this approach is that all the properties of the underlying one-dimensional interpolation scheme can be retained. For example, if one employs the Gauss points as $\Theta_1^{m_i}$, then the interpolation can be highly accurate and robust. The drawback is that the total number of points (20.18) grows too fast in high dimensions. And the desirable properties of the one-dimensional interpolation will be severely offset by this. For example, let us assume one uses the same number of samples in every dimensions, i.e., $m_1 = \cdots = m_d = m$. Then, the total number of points is $M = m^d$. Let us further assume that the one-dimensional interpolation error in each dimension $1 \leq i \leq d$ follows

$$(I - \mathcal{Q}_{m_i})[f] \propto m^{-\alpha},$$

where the constant $\alpha > 0$ depends on the smoothness of the function f . Then, the overall interpolation error also follows the same convergence rate

$$(I - \mathcal{Q}_M)[f] \propto m^{-\alpha}.$$

However, if we measure the convergence in terms of the total number of points, $M = m^d$ in this case, then

$$(I - \mathcal{Q}_M)[f] \propto M^{-\alpha/d}, \quad d \geq 1.$$

For large dimensions $d \gg 1$, the rate of convergence deteriorates drastically and we observe very slow convergence, if there is any, in terms of the total number of collocation points. This is the well known *curse of dimensionality*. For this reason, the tensor product construction is mostly used for low-dimensional problems with d typically less than 5. A detailed theoretical analysis for the tensor interpolation SC for stochastic diffusion equations can be found in [2].

3.2.2 Sparse Grids

An alternative approach is Smolyak sparse grids interpolation. This is based on the original work by Smolyak in [25]. It has been studied extensively in various deterministic settings (cf. the reviews in [3, 4] and the references therein) and was first used in UQ computations in [31]. The Smolyak sparse interpolation also relies on the one-dimensional interpolation (20.16). Instead of taking the full tensor product (20.17), the Smolyak interpolation takes a subset of the full tensor construction in the following manner (cf. [28]),

$$\mathcal{Q}_\ell = \sum_{\ell-d+1 \leq |\mathbf{i}| \leq \ell} (-1)^{\ell-|\mathbf{i}|} \cdot \binom{d-1}{\ell-|\mathbf{i}|} \cdot (\mathcal{Q}_{i_1} \otimes \cdots \otimes \mathcal{Q}_{i_d}), \quad (20.19)$$

where $\ell \geq d$ is an integer denoting the *level* of the construction. Though the expression is rather complex, (20.19) is nevertheless a combination of the subsets of the full tensor construction. The nodal set, the *sparse grids*, is

$$\Theta_M = \bigcup_{\ell-d+1 \leq |\mathbf{i}| \leq \ell} (\Theta_1^{i_1} \times \cdots \times \Theta_1^{i_d}). \quad (20.20)$$

Again it is clear that this is the union of a collection of subsets of the full tensor grids. Unfortunately there is usually no explicit formula to determine the total number of nodes M in terms of d and ℓ .

One popular choice of sparse grids is based on Clenshaw-Curtis nodes, which are the extrema of the Chebyshev polynomials and are defined as, for any $1 \leq i \leq d$,

$$Z_i^{(j)} = -\cos \frac{\pi(j-1)}{m_i^k - 1}, \quad j = 1, \dots, m_i^k, \quad (20.21)$$

where an additional index k is introduced to indicate the *level* of the Clenshaw-Curtis nodes. The number of points doubles with the increasing index $k > 1$, $m_i^k = 2^{k-1} + 1$, where we define $m_i^1 = 1$ and $Z_i^{(1)} = 0$. By doing so, the Clenshaw-Curtis nodes are nested, a property strongly preferred in the Smolyak construction. (For a more detailed discussion on the Clenshaw-Curtis nodes, see [14].) The total number of points satisfies the following estimate

$$M = \#\Theta_k \sim 2^k d^k / k!, \quad d \gg 1. \quad (20.22)$$

It has been shown ([3]) that the interpolation through the Clenshaw-Curtis sparse grid interpolation is exact if the function is in \mathbb{P}_k^d . (In fact, the polynomial space for which the interpolation is exact is slightly bigger than \mathbb{P}_k^d .) For large dimensions $d \gg 1$, $\dim \mathbb{P}_k^d = \binom{d+k}{d} \sim d^k / k!$. Therefore, the number of points from (20.22) is about 2^k more and the factor is *independent* of the dimension d . For this reason, the

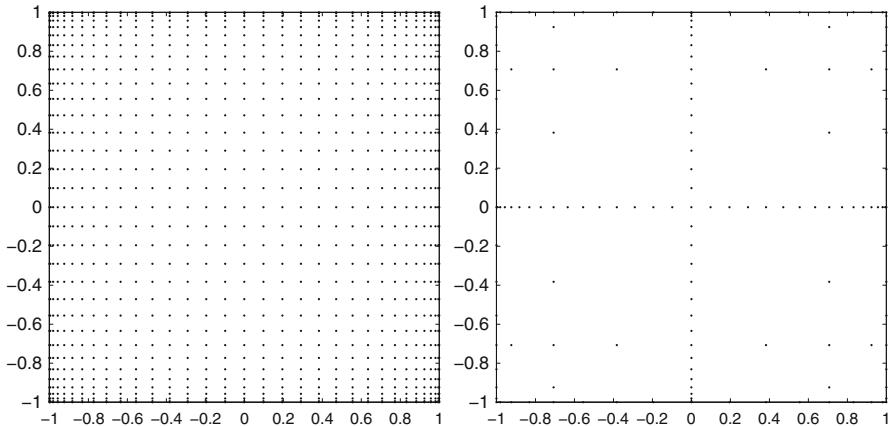

Fig. 20.2 Two-dimensional ($d = 2$) nodes based on the same one-dimensional extrema of Chebyshev polynomials at level $k = 5$. *Left:* Tensor grids. The total number of points is 1,089. *Right:* Smolyak sparse grids. The total number of nodes is 145

Table 20.1 The number of samples of the Smolyak sparse grids using Clenshaw-Curtis nodes, the cardinality of the polynomial space \mathbb{P}_k^d , and the number of samples of the full tensor grids $(k+1)^d$, for various dimensions d and polynomial order k (This is a reproduction of the Table 3.1 from [31])

d	n	Sparse grids	$\dim(\mathbb{P}_n^d)$	Tensor grids
2	1	5	3	4
	2	13	6	9
	3	29	10	16
	4	65	15	25
10	1	21	11	1,024
	2	221	66	59,049
	3	1,581	286	1,048,576
20	1	41	21	1,048,576
	2	841	231	$\approx 3.5 \times 10^9$
50	1	101	51	$\approx 1.1 \times 10^{16}$
	2	5,101	1,326	$\approx 7.2 \times 10^{23}$

Clenshaw-Curtis-based sparse grid construction is sometimes regarded as optimal in high dimensions.

An example of the two-dimensional tensor grids and sparse grids is in Fig. 20.2, where we observe significant reduction of the number of nodes in sparse grids. The reduction becomes more obvious in Table 20.1, where the number of samples of the sparse grids and tensor grids is listed for various dimensions d and polynomial degree k . We clearly see the drastic reduction in the number of samples for sparse grids, compared to that of the tensor grids. We observe the 2^k factor between the number of samples in sparse grids and the cardinality of the polynomial space \mathbb{P}_k^d in high dimensions $d \gg 1$.

Even though the sparse grids enjoy great reduction in the number of sample points, one should be aware that the total number of points can still be exceedingly large at high dimensions. The estimate for Clenshaw-Curtis (20.22) is almost the

best, as all other types of sparse grid constructions have (much) larger number of points. To this end, sparse grid interpolation has been used for moderately high dimensions, say, $d \sim O(10)$.

3.3 Interpolation on Unstructured Samples

From a practical point of view, it is highly desirable to conduct multidimensional interpolation on an arbitrary set of nodes Θ_M . To this end, however, it becomes much less clear what the best approach shall be. Arguably the only existing approach is least interpolation. This was first developed in [10, 11] and later extended to general orthogonal polynomials in [21]. The mathematical theory of this approach is rather involved and technical, although its implementation is straightforward using only numerical linear algebra. The major advantage of this approach is that one can then conduct SC interpolation on nested samples and, more importantly, samples that are arbitrarily distributed. This is especially useful from a practical point of view, for in many applications the samples are collected by practitioners at locations not following certain mathematical theory. Not to mention that in many cases there are restrictions on where one can or cannot collect the samples. Robust interpolation using this approach can be achieved by carefully designed sample sets [22]. An example of its effectiveness can be seen from simple interpolations of the following one-dimensional functions with increasing smoothness:

$$f_0(x) = \begin{cases} -1, & x < \frac{1}{2}, \\ 1, & x \geq \frac{1}{2}, \end{cases} \quad f_s(x) = \int_{-1}^x f_{s-1}(t) dx, \quad s = 1, 2, 3. \quad (20.23)$$

The results are shown in Fig. 20.3. We observe almost the same convergence rate and errors in both the least interpolation and the standard interpolation using Gauss-Legendre nodes. The fundamental difference between the two methods is that the

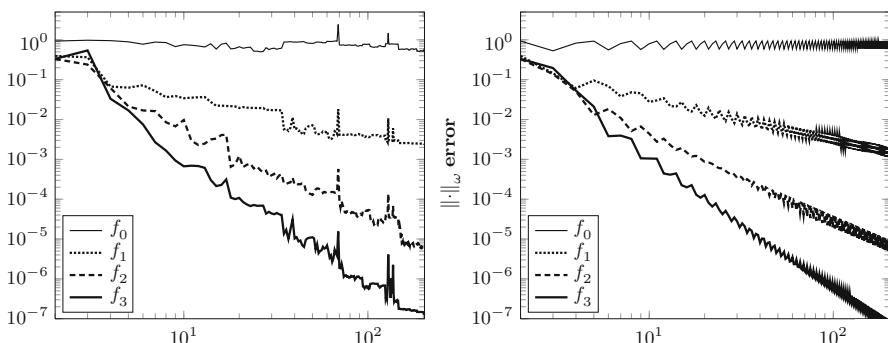

Fig. 20.3 Interpolation accuracy for functions f_0 , f_1 , f_2 , and f_3 in (20.23). Left: errors by least interpolation; Right: errors by interpolation on Legendre-Gauss nodes (Reproduction of Fig. 5.2 in [22])

least interpolation is conducted on completely nested sample nodes, allowing one to progressively add sample points for improved accuracy. On the other hand, the standard Gauss node interpolation is not nested – increasing the accuracy of the interpolation implies sampling at a new set of points.

Again, the theory of the least interpolation is quite involved. We refer the interested readers to [10, 11, 21, 22] for more details.

4 Stochastic Collocation via Regression

In regression type SC, one does not require the approximation $w(Z)$ to precisely match the solution $u(Z)$ at the collocation nodes Θ_M . Instead, one resorts to minimize the error difference

$$\|w(Z) - u(Z)\|_{\Theta}, \quad (20.24)$$

where the norm $\|\cdot\|_{\Theta}$ is a discrete norm defined over the nodal set Θ . By doing so, the numerical errors are more evenly distributed in the entire parameter space I_Z , assuming that the set Θ fills up the space I_Z in a reasonable manner. Thus, the non-robustness of interpolation can be alleviated. The regression approach also becomes a natural choice when the solution samples $u(Z^{(j)})$ are of low accuracy or contaminated by noise, in which case interpolation of the solution samples becomes an unnecessarily strong requirement.

4.1 Over-sampled Case: Least Squares

When the number of samples is larger than the cardinality of the linear space V_N , we have an over-determined system of equations (20.7) with $M > N$. Consequently, the equality cannot hold true in general. The natural approach is to use the least squares method. By doing so, the norm in (20.24) is the vector 2-norm, and we have the well-known least squares solution:

$$\mathbf{c} = \mathbf{A}^{\dagger} \mathbf{f} = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{f}, \quad (20.25)$$

where \mathbf{A}^{\dagger} denotes the pseudo-inverse of \mathbf{A} .

The least squares method is an orthogonal projection onto the range of the matrix \mathbf{A} . Consequently, it is the optimal approximation (in vector 2-norm) over the Hilbert space defined by the vector inner product. Over-sampling is the key to the accuracy and efficiency of the least squares method. A rule of thumb for practical problems is that one should over-sample the system by a linear factor, i.e., $M \approx \alpha N$, where $\alpha \sim O(1)$ and is often chosen to be $\alpha = 1.5 \sim 3$. There are a variety of choices for the nodal set Θ_M . The most commonly used sets include Monte Carlo points (random sampling), quasi-Monte Carlo points, etc. It is also

worthwhile to strategically choose the points to achieve better accuracy. This is the topic of *experimental design*. Interested readers can refer to, for example, [1, 15], and the references therein.

Despite the large amount of literature on least squares methods, a series of more recent studies from the computational mathematics perspective show that the linear over-sampling of Monte Carlo and quasi-Monte Carlo points for polynomial approximation can be asymptotically unstable (cf. [8, 18–20]). Care must be taken if one intends to conduct very high-order polynomial approximations using the least squares method.

4.2 Under-sampled Case: Sparse Approximations

When the number of samples is smaller than the cardinality of the linear space V_N , we have an under-determined system of equation (20.7) with $M < N$. Equation (20.7) then admits an infinite number of solutions. In this case, one can resort to the idea of compressive sensing (CS) and seek a sparse solution:

$$\min \|\mathbf{c}\|_0 \quad \text{subject to } \mathbf{Ac} = \mathbf{f}, \quad (20.26)$$

where the $\|\mathbf{c}\|_0 = \{\#c_i : c_i \neq 0, i = 1, \dots, N\}$ is the number of nonzero entries in the vector \mathbf{c} . The solution of this constrained optimization problem leads to a sparse solution, in the sense that the number of nonzero entries in the solution is minimized. Unfortunately, this optimization is an NP-hard problem and cannot be easily solved. As a compromise, the ℓ_1 norm is often used, leading to the well-known compressive sensing formulation (cf. [5, 6, 12]):

$$\min \|\mathbf{c}\|_1 \quad \text{subject to } \mathbf{Ac} = \mathbf{f}, \quad (20.27)$$

where $\|\mathbf{c}\|_1 = |c_1| + \dots + |c_N|$. The use of the ℓ_1 norm also promotes sparsity. But the optimization problem can be cast into a linear programming and solved easily. The constraint $\mathbf{Ac} = \mathbf{f}$ effectively enforces interpolation. This does not need to be the case, especially when the samples \mathbf{f} contain errors or noises. In this case, the de-noising version of CS [5, 6, 12] can be used.

$$\min \|\mathbf{c}\|_1 \quad \text{subject to } \|\mathbf{Ac} - \mathbf{f}\| \leq \tau, \quad (20.28)$$

where $\tau > 0$ is a real number associated with the noise level in the sample data \mathbf{f} .

The idea of CS was first used in UQ computations in [13], where the gPC-type orthogonal approximations using Legendre polynomials were used. The advantage of this approach lies in the fact that it allows one to construct reliable sparse gPC approximations when the underlying system is (severely) under sampled. Most of the existing studies focus on the use of Legendre polynomials [17, 24, 33].

For example, it was proved in [24] that the Chebyshev-weighted ℓ_1 minimization algorithm using Chebyshev samples has notably higher rate of recovery and should be preferred in practice. That is, instead of (20.27), one solves

$$\min \|\mathbf{c}\|_1 \quad \text{subject to } \mathbf{WAc} = \mathbf{Wf}, \quad (20.29)$$

where \mathbf{W} is a diagonal matrix with entries $w_{j,j} = (\pi/2)^{d/2} \prod_{i=1}^d (1 - (z_i^{(j)})^2)^{1/4}$, $j = 1, \dots, M$. Note that this is the tensor product of the one-dimensional Chebyshev weights. The corresponding de-noising version for (20.28) takes a similar form. On the other hand, it was also proved that in high dimensions $d \gg 1$, the standard non-weighted version (20.27) using uniformly distributed random samples is in fact better than the weighted Chebyshev version (20.29).

The performance of the ℓ_1 minimization methods is typically measured by the recovery probability of the underlying sparse functions. For high rate of recovery, the required number of samples typically follows:

$$M \propto s \log^3(s) \log(N),$$

where s is the sparsity of the underlying function, i.e., s is the number of nonzero terms in the underlying function. A representative result can be seen in Fig. 20.4, where the ℓ_1 minimization is used to recover a $d = 3$ dimensional polynomial

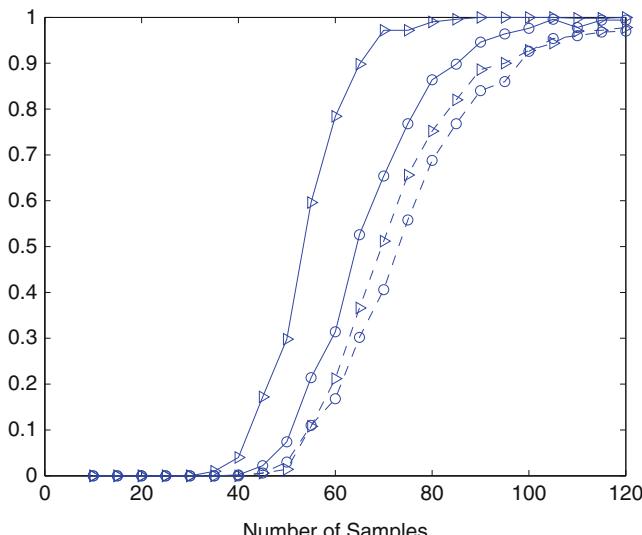

Fig. 20.4 Probability of successful function recovery vs. number of samples. ($d = 3$ and $s = 10$). The degree of polynomial space is $k = 10$ with $\dim \mathbb{P}_k^d = 286$. Line pattern: *dotted-circle*, uniform samples; *dotted-triangle*: Chebyshev samples; *solid-circle*: weighted uniform samples; *solid-triangle*: weighted Chebyshev samples (Reproduction of Fig. 1 in [33])

function with sparsity $s = 10$. Although the different implementations result in variations in the results, we can still see that the methods can recover, with very high probability, the underlying function with $M \sim 100$ samples. This is notably lower than the cardinality of the polynomial space $\dim \mathbb{P}_k^d = 286$. This clearly demonstrates the effectiveness of CS methods. We shall remark that, despite these few works mentioned here, the application of CS in UQ is still in its early stage. There exist many open issues to study.

5 Stochastic Collocation via Pseudo Projection

In the pseudo projection approach (first formally defined in [29]), one seeks to approximate the continuous orthogonal projection using an integration rule. Since the orthogonal projection is the “best approximation,” based on a properly chosen norm, the pseudo projection method allows one to obtain a “near best” approximation whenever the chosen integration is sufficiently accurate. Again, let V_N be a properly chosen linear space, from which an approximation is sought. Then, the orthogonal projection of the solution is

$$u_N := \mathcal{P}_{V_N} u, \quad (20.30)$$

where \mathcal{P} denotes the orthogonal projection operator. The projection operator is often defined via integrals. In the pseudo projection approach, one then approximates the integrals using a quadrature/cubature rule.

To better illustrate the method, let us again use the gPC-based approximation. In this case, $V_N = \mathbb{P}_n^d$, and we seek an approximation

$$w(Z) = \sum_{i=1}^N c_i \Phi_i(Z), \quad N = \dim \mathbb{P}_n^d = \binom{n+d}{n}. \quad (20.31)$$

The orthogonal projection, which is the best approximation in L_ρ^2 norm, takes the following form,

$$u_N(Z) := \sum_{i=1}^N \hat{u}_i \Phi_i(Z), \quad \hat{u}_i = \int u(z) \Phi_i(z) \rho(z) dz. \quad (20.32)$$

In the pseudo projection approach, we then use a cubature rule to approximate the coefficients \hat{u}_i . That is, in (20.31), we seek

$$c_i = \sum_{j=1}^M u(Z^{(j)}) \Phi_i(Z^{(j)}) w_j \approx \hat{u}_i, \quad i = 1, \dots, N. \quad (20.33)$$

This means the collocation nodal set Θ needs to be a quadrature such that integrals over the I_Z can be approximated by a weighted sum. That is,

$$\int_{I_Z} f(z)\rho(z)dz \approx \sum_{j=1}^M f(Z^{(j)})w_j, \quad (20.34)$$

where w_j are the weights.

The pseudo projection method turns out to be remarkably robust and accurate, provided one finds an efficient and accurate quadrature rule. Unlike the other approaches for SC, e.g., interpolation SC and regression SC, where the goal is to approximate the underlying multidimensional function u directly, in the pseudo projection approach, the challenge becomes the approximation of multidimensional integrals. The nodal set Θ should now be a good cubature rule. Depending on the problem at hand and the accuracy requirement, one can choose different cubature sets. The field of multidimensional integration is by itself a big and evolving field, with a large amount of literature. Interested readers should consult the literature on cubature rules (cf. [9, 26]).

It should also be remarked that an “easier” way to construct cubature rules is to extend the one-dimensional quadrature rule to multiple dimensions via tensor products. A construction is very much similar to the tensor product multidimensional interpolation SC, as discussed in Sect. 3.2. Quadrature rules in one dimension are well studied and understood. It is widely accepted that Gauss quadrature, particularly Chebyshev quadrature, is near optimal. One can then extend it into multiple dimensions either via full tensor products or the Smolyak construction (which is a subset of full tensor products). Upon doing so, one obtains tensor cubature or sparse grid cubature, respectively. An example of this is seen in Fig. 20.2.

When pseudo projection is used, one should pay attention to the accuracy of the cubature rule. This is because the integrals to be approximated in (20.32) become progressively more complex, when a higher degree gPC expansion is used. As a general rule of thumb, one should employ a cubature that is accurate with order at least $2n$, where n is the degree of the gPC expansion. This ensures that if the underlying unknown function is an n -degree polynomial (which is almost never the case), then the n -degree gPC expansion can be accurately constructed by the pseudo projection method. When the cubature rule is of low accuracy, then a higher order gPC expansion is pointless. This can be clearly seen in the example in Fig. 20.5. This is an example of approximating a three-dimensional ($d = 3$) nonlinear function, the example 5.1 from [29]. Here, the full tensor product cubature rule based on Gauss-Legendre quadrature is used. The number of Gauss quadrature points in each dimension is q_1 . We observe that when q_1 is small, the gPC approximation error deteriorates at higher order and the expansion fails to converge. It is only when the cubature is of sufficiently high accuracy, $q_1 = 6$ in this case, that the gPC approximation exhibits the expected exponential error convergence for up to order $n = 6$.

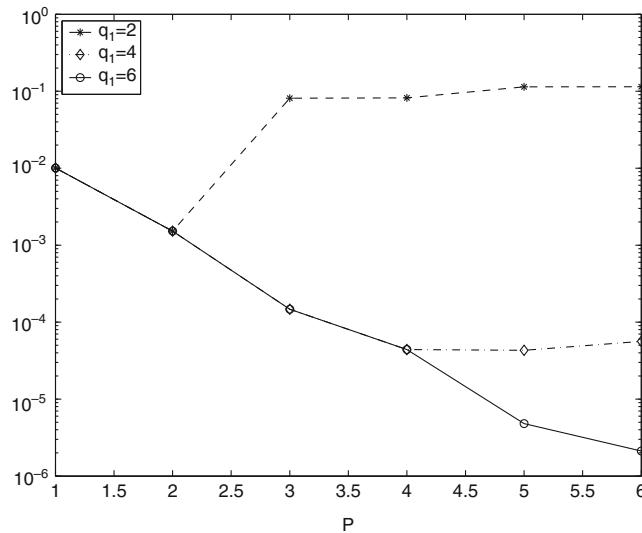

Fig. 20.5 Error convergence of pseudo projection method with different choices of cubature rule. Here the cubature rule is the full tensor quadrature rule with q_1 number of points in each dimension

6 Summary

Here, we briefly reviewed several major numerical approaches for stochastic collocation (SC). Our focus is on the fundamental approximation properties, basic formulations, and major properties of the methods. We reviewed the interpolation type SC, the regression type SC, and the pseudo projection type SC. Most, if not all, of the mainstream SC methods fall into these categories. There exist, however, a large variety of modifications and improvements over the core methods reviewed here. For example, many efforts have been devoted to the development of adaptive SC methods, particularly in conjunction of the sparse grid collocation. There also exist a large amount of works on the improvements of least squares methods. On the other hand, for under-sampled systems, the use of compressive sensing SC is still in its early stage, with many open issues to study. Overall, stochastic collocation has been under rapid development in the last decade, with many new variations emerging. Interested readers should consult the more recent literature for the latest developments.

Sparse Collocation Methods for Stochastic Interpolation and Quadrature

21

Max Gunzburger, Clayton G. Webster, and Guannan Zhang

Abstract

In this chapter, the authors survey the family of sparse stochastic collocation methods (SCMs) for partial differential equations with random input data. The SCMs under consideration can be viewed as a special case of the generalized stochastic finite element method (Gunzburger et al., *Acta Numer.* 23:521–650, 2014), where the approximation of the solution dependences on the random variables is constructed using Lagrange polynomial interpolation. Relying on the “delta property” of the interpolation scheme, the physical and stochastic degrees of freedom can be decoupled, such that the SCMs have the same nonintrusive property as stochastic sampling methods but feature much faster convergence. To define the interpolation schemes or interpolatory quadrature rules, several approaches have been developed, including global sparse polynomial approximation, for which global polynomial subspaces (e.g., sparse Smolyak spaces (Nobile et al., *SIAM J Numer Anal.* 46:2309–2345, 2008) or quasi-optimal subspaces (Tran et al., *Analysis of quasi-optimal polynomial approximations for parameterized PDEs with deterministic and stochastic coefficients. Tech. Rep. ORNL/TM-2015/341*, Oak Ridge National Laboratory, 2015)) are used to exploit the inherent regularity of the PDE solution, and local sparse approximation, for which hierarchical polynomial bases (Ma and Zabaras, *J Comput Phys.* 228:3084–3113, 2009; Bungartz and Griebel, *Acta Numer.* 13:1–123, 2004) or wavelet bases (Gunzburger et al., *Lect Notes Comput Sci Eng.* 97:137–170, Springer, 2014) are used to accurately capture irregular behaviors of the PDE solution. All these method classes are surveyed in this chapter, including

1 Introduction

Many applications in engineering and science are affected by uncertainty in input data, including model coefficients, forcing terms, boundary condition data, media properties, source and interaction terms, as well as geometry. The presence of random input uncertainties can be incorporated into a system of partial differential equations (PDEs) by formulating the governing equations as PDEs with random inputs. In practice, such PDEs may depend on a set of distinct random parameters with the uncertainties represented by a given joint probability distribution. In other situations, the input data varies randomly from one point of the physical domain to another and/or from one time instant to another; in these cases, uncertainties in the inputs are instead described in terms of *random fields* that can be expressed as an expansion containing an infinite number of random variables. For example, for correlated random fields, one has Karhunen-Loëve (KL) expansions [49, 50], Fourier-Karhunen-Loëve expansions [48], or expansions in terms of global orthogonal polynomials [35, 70, 72]. However, in a large number of applications, it is reasonable to limit the analysis to just a finite number of random variables, either because the problem input itself can be described in that way (e.g., the random parameter case) or because the input random field can be approximated

by truncating an infinite expansion [30] (e.g., the correlated random field case). As such, a crucial, yet often complicated, ingredient that all numerical approaches to UQ must incorporate is an accurate and efficient numerical approximation technique for solving PDEs with random inputs. In some circles, although the nomenclature “stochastic partial differential equations (SPDEs)” is reserved for a specific class of PDEs having random inputs, here, for the sake of economy of notation, this terminology is used to refer to any PDE having random inputs.

Currently, there are several types of numerical methods available for solving SPDEs. Monte Carlo methods (MCMs) [29], quasi MCMs [46, 47], multilevel MCMs [4, 20, 36] stochastic Galerkin methods (SGMs) [2, 3, 35, 55], and stochastic collocation methods (SCMs) [1, 51, 57, 58, 71, 73]. In this chapter, the authors provide an overview of the family of stochastic collocation methods for SPDEs. Recently, SCMs based on either full or sparse tensor-product approximation spaces [1, 32, 54, 57, 58, 62, 71] have gained considerable attention. As shown in [1], SCMs can essentially match the fast convergence of intrusive polynomial chaos methods, even coinciding with them in particular cases. The major difference between the two approaches is that stochastic collocation methods are ensemble-based, *nonintrusive* approaches that achieve fast convergence rates by exploiting the inherent regularity of PDE solutions with respect to parameters. Compared to nonintrusive polynomial chaos methods, they also require fewer assumptions about the underlying SPDE. SCMs can also be viewed as stochastic Galerkin methods in which one employs an interpolatory basis built from the zeros of orthogonal polynomials with respect to the joint probability density function of the input random variables. For additional details about the relations between polynomial chaos methods and stochastic collocation methods, see [41], and for computational comparisons between the two approaches, see [5, 25, 28, 41].

To achieve increased rates of convergence, most SCMs described above are based on global polynomial approximations that take advantage of smooth behavior of the solution in the multidimensional parameter space. Hence, when there are steep gradients, sharp transitions, bifurcations, or finite discontinuities (e.g., piecewise processes) in stochastic space, these methods converge very slowly or even fail to converge. Such problems often arise in scientific and engineering problems due to the highly complex nature of most physical or biological phenomena. To be effective, refinement strategies must be guided by accurate estimations of errors while not expending significant computational effort approximating an output of interest within each random dimension. The papers [27, 45, 51, 52, 74] apply an adaptive sparse grid stochastic collocation strategy that follows the work of [14, 37]. This approach utilizes the hierarchical surplus as an error indicator to automatically detect regions of importance (e.g., discontinuities) in the stochastic parameter space and adaptively refine the collocation points in this region. To this end, grids are constructed in an adaptation process steered by the indicator in such a way that a prescribed global error tolerance is attained. This goal, however, might be achieved using more points than necessary due to the instability of this multi-scale basis.

The outline of this chapter is as follows. In Sect. 2, a generalized mathematical description of SPDEs is provided, together with the notations that are used

throughout. In Sect. 3, the general framework of stochastic finite element methods is discussed, followed by the notions of semi-discrete and fully discrete stochastic approximation, as well as several choices of multivariate polynomial subspaces. In Sect. 4, all discussions are based on the fact that the solution of the SPDE has very smooth dependence on the input random variables. Thus, SCMs approximate solutions using global approximations in parameter space. A generalized sparse grid interpolatory approximation is presented, followed by a detailed convergence analysis with respect to the total number of collocation points. In Sect. 5, it is assumed that the solution of the SPDE may have irregular dependence on the input random variables, as a result of which the global approximations are usually not appropriate. As an alternative, SCMs approximate the solutions using locally supported piecewise polynomial spaces for both spatial and stochastic discretization. We then extend this concept to include adaptive hierarchical stochastic collocation methods. Two comments about the content of this article are important to point out. First, the temporal dependence of solutions of SPDEs is ignored, i.e., it is assumed that coefficients, forcing functions, etc., and therefore solutions, only depend on spatial variables and random parameters. This is merely for economizing notation. Almost all discussions extend to problems that also involve temporal dependences. Second, only finite element methods are considered for effecting the spatial discretization of SPDEs, but most of the discussions also apply to finite difference, finite volume, and spectral methods for spatial discretization.

2 Problem Setting

This chapter considers a relevant model of boundary value problems, involving the simultaneous solution of a family of equations, parameterized by a vector $\mathbf{y} = (y_1, \dots, y_N) \in \Gamma = \prod_{i=1}^N \Gamma_i \subset \mathbb{R}^N$, on a bounded Lipschitz domain $D \subset \mathbb{R}^d$, $d \in \{1, 2, 3\}$. In particular, let \mathcal{L} denote a differential operator defined on D , and let $a(\mathbf{x}, \mathbf{y})$, with $\mathbf{x} \in D$ and $\mathbf{y} \in \Gamma$, represent the input coefficient associated with the operator \mathcal{L} . The forcing term $f = f(\mathbf{x}, \mathbf{y})$ is also assumed to be a parameterized field in $D \times \Gamma$. This chapter concentrates on the following parameterized boundary value problem: for all $\mathbf{y} \in \Gamma$, find $u(\cdot, \mathbf{y}) : \overline{D} \rightarrow \mathbb{R}$, such that the following equation holds

$$\mathcal{L}(a(\cdot, \mathbf{y})) [u(\cdot, \mathbf{y})] = f(\cdot, \mathbf{y}) \quad \text{in } D, \quad (21.1)$$

subject to suitable (possibly parameterized) boundary conditions. Such a problem arises in both contexts of deterministic and stochastic modeling. In the first case, the parameter vector \mathbf{y} is known or controlled by the user, and a typical goal is to study the dependence of u with respect to these parameters, e.g., optimizing an output of the equation with respect to \mathbf{y} (see [13, 56] for more details). In the second case, the parameters $\{y_n\}_{n=1}^N$ are random variables, and $\mathbf{y}(\omega) : \Omega \rightarrow \Gamma$ is a random vector. Here, $(\Omega, \mathcal{F}, \mathbb{P})$ is a complete probability space, Ω being the set of outcomes, $\mathcal{F} \subset 2^\Omega$ the σ -algebra of events, and $\mathbb{P} : \mathcal{F} \rightarrow [0, 1]$ a probability measure. Moreover, the

components of $\mathbf{y}(\omega)$ have a joint probability density function (PDF) $\rho : \Gamma \rightarrow \mathbb{R}_+$, with $\rho \in L^\infty(\Gamma)$. In this setting, $(\Omega, \mathcal{F}, \mathbb{P})$ is mapped to $(\Gamma, \mathcal{B}(\Gamma), \rho(\mathbf{y})d\mathbf{y})$, where $\mathcal{B}(\Gamma)$ denotes the Borel σ -algebra on Γ and $\rho(\mathbf{y})d\mathbf{y}$ is the probability measure of \mathbf{y} .

Let $W(D)$ denote a Banach space of functions $v : D \rightarrow \mathbb{R}$ and define the following stochastic Banach spaces

$$L_\rho^q(\Gamma; W(D)) := \left\{ v : \Gamma \rightarrow W(D) \mid v \text{ is strongly measurable and} \right. \\ \left. \int_{\Gamma} \|v(\cdot, \mathbf{y})\|_{W(D)}^q \rho(\mathbf{y}) d\mathbf{y} < +\infty \right\}. \quad (21.2)$$

To guarantee the well posedness of the system (21.1) in a Banach space, the following assumptions are needed:

Assumption 1. (a) The solution to (21.1) has realizations in the Banach space $W(D)$, i.e., $u(\cdot, \mathbf{y}) \in W(D)$ ρ -almost surely satisfies that

$$\|u(\cdot, \mathbf{y})\|_{W(D)} \leq C \|f(\cdot, \mathbf{y})\|_{W^*(D)},$$

where $W^*(D)$ denotes the dual space of $W(D)$ and C denotes a constant having value independent of the realization $\mathbf{y} \in \Gamma$.

(b) The forcing term $f \in L_\rho^2(\Gamma; W^*(D))$ is such that the solution u is unique and bounded in $L_\rho^2(\Gamma; W(D))$.

Two examples of problems posed in this setting are as follows.

Example 1. The linear second-order elliptic problem

$$\begin{cases} -\nabla \cdot (a(\mathbf{x}, \mathbf{y}) \nabla u(\mathbf{x}, \mathbf{y})) = f(\mathbf{x}, \mathbf{y}) & \text{in } D \times \Gamma \\ u(\mathbf{x}, \mathbf{y}) = 0 & \text{on } \partial D \times \Gamma \end{cases} \quad (21.3)$$

with $a(\mathbf{x}, \mathbf{y})$ uniformly bounded from above and below, i.e.,

there exist $a_{\min}, a_{\max} \in (0, \infty)$ such that

$$\mathbb{P}\left(\mathbf{y} \in \Gamma : a(\mathbf{x}, \mathbf{y}) \in [a_{\min}, a_{\max}] \quad \forall \mathbf{x} \in \overline{D}\right) = 1$$

and $f(\mathbf{x}, \mathbf{y})$ square integrable with respect to $\rho(\mathbf{y})d\mathbf{y}$, i.e.,

$$\int_D \mathbb{E}[f^2] d\mathbf{x} = \int_D \int_{\Gamma} f^2(\mathbf{x}, \mathbf{y}) \rho(\mathbf{y}) d\mathbf{y} d\mathbf{x} < \infty,$$

such that Assumptions 1(a-b) are satisfied with $W(D) = H_0^1(D)$; see [1].

Example 2. Similarly, for $s \in \mathbb{N}_+$, the *nonlinear* second-order elliptic problem

$$\begin{cases} -\nabla \cdot (a(\mathbf{x}, \mathbf{y}) \nabla u(\mathbf{x}, \mathbf{y})) + u(\mathbf{x}, \mathbf{y})|u(\mathbf{x}, \mathbf{y})|^s = f(\mathbf{x}, \mathbf{y}) & \text{in } D \times \Gamma \\ u(\mathbf{x}, \mathbf{y}) = 0 & \text{on } \partial D \times \Gamma \end{cases} \quad (21.4)$$

with $a(\mathbf{x}, \mathbf{y})$ uniformly bounded from above and below and $f(\mathbf{x}, \mathbf{y})$ square integrable with respect to the probability measure such that Assumptions 1(a–b) are satisfied with $W(D) = H_0^1(D) \cap L^{s+2}(D)$; see [69].

In many applications, the stochastic input data may have a simple piecewise random representation, whereas, in other applications, the coefficients a and the right-hand side f in (21.1) may have spatial variation that can be modeled as a correlated random field, making them amenable to description by a Karhunen-Loëve (KL) expansion [37, 38]. In practice, one has to truncate such expansions according to the degree of correlation and the desired accuracy of the simulation. Examples of both types of random input data are given next.

Example 3 (Piecewise constant random fields). Assume that the spatial domain D is the union of non-overlapping subdomains D_n , $n = 1, \dots, N$. Then, consider a coefficient $a(\mathbf{x}, \mathbf{y})$ that is a random constant in each subdomain D_n , i.e., $a(\mathbf{x}, \mathbf{y})$ is the piecewise constant function

$$a(\mathbf{x}, \mathbf{y}) := a_0 + \sum_{n=1}^N a_n \mathbf{1}_{D_n}(\mathbf{x}),$$

where a_n , $n = 0, \dots, N$, denote constants, $\mathbf{1}_{D_n}(\mathbf{x})$ denotes the indicator function of the set $D_n \subset D$, and the random variables $y_n(\omega)$, $n = 1, \dots, N$ are bounded and independent.

Example 4 (Karhunen-Loëve expansions). According to Mercer's theorem [49], any second-order correlated random field with a continuous covariance function can be represented as an infinite sum of random variables. A commonly used example is the Karhunen-Loëve expansion. In this case, $a(\mathbf{x}, \mathbf{y})$ in (21.1) can be defined as a truncated Karhunen-Loëve expansion having the form

$$a(\mathbf{x}, \mathbf{y}) := \bar{a}(\mathbf{x}) + \sum_{n=1}^N \sqrt{\lambda_n} b_n(\mathbf{x}) y_n(\omega),$$

where λ_n and $b_n(\mathbf{x})$ for $n = 1, \dots, N$ are the dominant eigenvalues and corresponding eigenfunctions for the covariance function and $y_n(\omega)$ for $n = 1, \dots, N$ denote uncorrelated real-valued random variables. In addition, for the purpose of keeping

the property that a is bounded away from function zero, the logarithm of the random field is instead expanded so that $a(\mathbf{x}, \mathbf{y})$ has the form

$$a(\mathbf{x}, \mathbf{y}) := a_{\min} + \exp \left\{ \bar{a}(\mathbf{x}) + \sum_{n=1}^N \sqrt{\lambda_n} b_n(\mathbf{x}) y_n(\omega) \right\}, \quad (21.5)$$

where $a_{\min} > 0$ is the lower bound of a .

3 Stochastic Finite Element Method

Since the solution u of the SPDE in (21.1) can be expressed as $u(\mathbf{x}, y_1, \dots, y_N)$, it is natural to treat $u(\mathbf{x}, \mathbf{y})$, a function of d spatial variables and N random parameters, as a function of $d + N$ variables. This leads one to consider a *Galerkin weak formulation* of the SPDE, with respect to both physical and parameter space, of the form: seek $u \in W(D) \otimes L_\rho^q(\Gamma)$ such that

$$\begin{aligned} & \sum_{k=1}^K \int_{\Gamma} \int_D S_k(u; \mathbf{y}) T_k(v) \rho(\mathbf{y}) d\mathbf{x} d\mathbf{y} \\ &= \int_{\Gamma} \int_D v f(\mathbf{x}, \mathbf{y}) \rho(\mathbf{y}) d\mathbf{x} d\mathbf{y} \quad \forall v \in W(D) \otimes L_\rho^q(\Gamma), \end{aligned} \quad (21.6)$$

where $S_k(\cdot; \cdot)$, $k = 1, \dots, K$ are in general nonlinear operators and $T_k(\cdot, \cdot)$, $k = 1, \dots, K$ are linear operators.

Example 5. A weak formulation of the stochastic PDE in (21.4) is given by

$$\begin{aligned} & \int_{\Gamma} \int_D (a(\mathbf{y}) \nabla u) \cdot \nabla v \rho(\mathbf{y}) d\mathbf{x} d\mathbf{y} + \int_{\Gamma} \int_D (u(\mathbf{y}) |u(\mathbf{y})|^s) v \rho(\mathbf{y}) d\mathbf{x} d\mathbf{y} \\ &= \int_{\Gamma} \int_D f(\mathbf{y}) v \rho(\mathbf{y}) d\mathbf{x} d\mathbf{y} \quad \forall v \in H_0^1(D) \otimes L_\rho^q(\Gamma), \end{aligned}$$

where reference to the dependence of a , f , u , and v on the spatial variable \mathbf{x} is omitted for notational simplicity. For the first term on the left-hand side, the operators $S_1(u, \mathbf{y}) = a(\mathbf{y}) \nabla u$ and $T_1(v) = \nabla v$ are linear; for the second term, the operator $S_2(u, \mathbf{y}) = u(\mathbf{y}) |u(\mathbf{y})|^s$ is nonlinear and the operator $T_2(v) = v$ is linear.

Without loss of generality, it suffices to consider the single term form of (21.6), i.e.,

$$\int_{\Gamma} \int_D S(u; \mathbf{y}) T(v) \rho(\mathbf{y}) d\mathbf{x} d\mathbf{y} = \int_{\Gamma} \int_D v f(\mathbf{y}) \rho(\mathbf{y}) d\mathbf{x} d\mathbf{y} \quad \forall v \in W(D) \otimes L_\rho^q(\Gamma), \quad (21.7)$$

where $T(\cdot)$ is a linear operator and, in general, $S(\cdot)$ is a nonlinear operator and where again the explicit reference to dependences on the spatial variable \mathbf{x} is suppressed.

3.1 Spatial Finite Element Semi-discretization

Let \mathcal{T}_h denote a conforming triangulation of D with maximum mesh size $h > 0$, and let $W_h(D) \subset W(D)$ denote a finite element space, parameterized by $h \rightarrow 0$, constructed using the triangulation \mathcal{T}_h . Let $\{\phi_j(\mathbf{x})\}_{j=1}^{J_h}$ denote a basis for $W_h(D)$ so that J_h denotes the dimension of $W_h(D)$. The *semi-discrete* approximation $u_{J_h}(\mathbf{x}, \mathbf{y}) \in W_h(D) \otimes L_\rho^q(\Gamma)$ has the form

$$u_{J_h}(\mathbf{x}, \mathbf{y}) := \sum_{j=1}^{J_h} c_j(\mathbf{y}) \phi_j(\mathbf{x}). \quad (21.8)$$

At each point in $\mathbf{y} \in \Gamma$, the coefficients $c_j(\mathbf{y})$ and thus u_{J_h} are determined by solving the problem

$$\int_D S\left(\sum_{j=1}^{J_h} c_j(\mathbf{y}) \phi_j(\mathbf{x}); \mathbf{y}\right) T(\phi_{j'}) d\mathbf{x} = \int_D \phi_{j'} f(\mathbf{y}) d\mathbf{x} \quad \text{for } j' = 1, \dots, J_h. \quad (21.9)$$

What this means is that *to obtain the semi-discrete approximation $u_{J_h}(\mathbf{x}, \mathbf{y})$ at any specific point $\mathbf{y}_0 \in \Gamma$, one only has to solve a deterministic finite element problem by fixing $\mathbf{y} = \mathbf{y}_0$ in (21.9)*. The subset of Γ in which (21.9) has no solution has zero measure with respect to $\rho d\mathbf{y}$. For convenience, it is assumed that the coefficient a and the forcing term f in (21.1) admit a smooth extension on $\rho d\mathbf{y}$ -zero measure sets. Then, (21.9) can be extended a.e. in Γ with respect to the Lebesgue measure, instead of the measure $\rho d\mathbf{y}$.

3.2 Stochastic Fully Discrete Approximation

Let $\mathcal{P}(\Gamma) \subset L_\rho^q(\Gamma)$ denote a global/local polynomial subspace, and let $\{\psi_m(\mathbf{y})\}_{m=1}^M$ denote a basis for $\mathcal{P}(\Gamma)$ with M being the dimension of $\mathcal{P}(\Gamma)$. A *fully discrete* approximation of the solution $u(\mathbf{x}, \mathbf{y})$ of (21.7) has the form

$$u_{J_h, M}(\mathbf{x}, \mathbf{y}) := \sum_{m=1}^M \sum_{j=1}^{J_h} c_{jm} \phi_j(\mathbf{x}) \psi_m(\mathbf{y}) \in W_h(D) \times \mathcal{P}(\Gamma), \quad (21.10)$$

where the coefficients c_{jm} and thus $u_{J_h, M}$ are determined by solving the problem

$$\int_\Gamma \int_D S(u_{J_h, M}; \mathbf{y}) T(v) \rho(\mathbf{y}) d\mathbf{x} d\mathbf{y} = \int_\Gamma \int_D v f(\mathbf{y}) \rho(\mathbf{y}) d\mathbf{x} d\mathbf{y} \quad \forall v \in W_h(D) \times \mathcal{P}(\Gamma) \quad (21.11)$$

In general, the integrals in (21.11) cannot be evaluated exactly so that quadrature rules must be invoked to effect the approximate evaluation of both the integrals over Γ and D . However, by assuming that all methods discussed treat all aspects of the spatial discretization in the same manner, the quadrature rules for the integral over D will not be written out explicitly. As such, for some choice of quadrature points $\{\hat{\mathbf{y}}_r\}_{r=1}^R$ in Γ and quadrature weights $\{w_r\}_{r=1}^R$, (21.11) is further discretized, resulting in

$$\begin{aligned} & \sum_{r=1}^R w_r \rho(\hat{\mathbf{y}}_r) \psi_{m'}(\hat{\mathbf{y}}_r) \cdot \int_D S \left(\sum_{m=1}^M \sum_{j=1}^{J_h} c_{jm} \phi_j(\mathbf{x}) \psi_m(\hat{\mathbf{y}}_r), \hat{\mathbf{y}}_r \right) T(\phi_{j'}(\mathbf{x})) d\mathbf{x} \\ &= \sum_{r=1}^R w_r \rho(\hat{\mathbf{y}}_r) \psi_{m'}(\hat{\mathbf{y}}_r) \int_D \phi_{j'}(\mathbf{x}) f(\mathbf{x}, \hat{\mathbf{y}}_r) d\mathbf{x} \\ & \quad \text{for } j' \in \{1, \dots, J_h\} \text{ and } m' \in \{1, \dots, M\}. \end{aligned} \tag{21.12}$$

The discrete problem (21.12) is generally a fully coupled system of $J_h M$ equations in $J_h M$ degrees of freedom c_{jm} , $j = 1, \dots, J_h$ and $m = 1, \dots, M$. Both intrusive, e.g., stochastic Galerkin, and nonintrusive methods, e.g., MC sampling and stochastic collocation, can be viewed as being special cases of the problems in (21.12). They differ in the choices made for the stochastic polynomial subspace $\mathcal{P}(\Gamma)$, for the basis $\{\psi_m(\mathbf{y})\}_{m=1}^M$, and for the quadrature rule $\{\hat{\mathbf{y}}_r, \omega_r\}_{r=1}^R$. For example, in the context of stochastic Galerkin methods with $\{\psi_m(\mathbf{y})\}_{m=1}^M$ being an orthogonal polynomial basis, the fully discrete approximation $u_{J_h, M}(\mathbf{x}, \mathbf{y})$ of the solution $u(\mathbf{x}, \mathbf{y})$ of the SPDE can be obtained by solving the *single deterministic problem* (21.12). For stochastic collocation methods with the use of global Lagrange basis, set $R = M$ and choose $\{\hat{\mathbf{y}}_r, \omega_r\}_{r=1}^R$ to be the point set for interpolation. Then, the basis $\psi_m(\mathbf{y})$ satisfies the “delta property,” i.e., $\psi_m(\hat{\mathbf{y}}_r) = \delta_{mr}$ for $m = 1, \dots, M$, $r = 1, \dots, R$, so that the discrete problem of size $J_h M \times J_h M$ in (21.12) can be decoupled into M systems at each point $\hat{\mathbf{y}}_r$, each of size $J_h \times J_h$.

3.3 Stochastic Polynomial Subspaces

In this section, several choices of the stochastic polynomial subspace $\mathcal{P}(\Gamma)$ are discussed for constructing the fully discrete approximation in (21.10).

3.3.1 Standard Sparse Global Polynomial Subspaces

Let $\mathcal{S} := \{\mathbf{v} = (v_n)_{1 \leq n \leq N} : v_n \in \mathbb{N}\}$ denote an infinite multi-index set, where N is the dimension of \mathbf{y} . Let $p \in \mathbb{N}$ denote a single index denoting the polynomial order of the associated approximation and consider a sequence of increasing finite multi-index sets $\mathcal{J}(p) \subset \mathcal{S}$ such that $\mathcal{J}(0) = \{(0, \dots, 0)\}$ and $\mathcal{J}(p) \subseteq \mathcal{J}(p+1)$.

Let $\mathcal{P}(\Gamma) := \mathcal{P}_{\mathcal{J}(p)}(\Gamma) \subset L^2_\rho(\Gamma)$ denote the multivariate polynomial space over Γ corresponding to the index set $\mathcal{J}(p)$, defined by

$$\mathcal{P}_{\mathcal{J}(p)}(\Gamma) = \text{span} \left\{ \prod_{n=1}^N y_n^{v_n} \mid \mathbf{v} := (v_1, \dots, v_N) \in \mathcal{J}(p), y_n \in \Gamma_n \right\}, \quad (21.13)$$

where $M := \dim(\mathcal{P}_{\mathcal{J}(p)})$ is the dimension of the polynomial subspace.

Several choices for the index set and the corresponding polynomial spaces are available [5, 22, 30, 65]. The most obvious one is the tensor-product (TP) polynomial space, defined by choosing $\mathcal{J}(p) = \{\mathbf{v} \in \mathbb{N}^N \mid \max_n v_n \leq p\}$. In this case, $M = (p+1)^N$ which results in an explosion in computational effort for higher dimensions. For the same value of p , the same nominal rate of convergence is achieved at a substantially lower costs by the total degree (TD) polynomial spaces for which $\mathcal{J}(p) = \{\mathbf{v} \in \mathbb{N}^N \mid \sum_{n=1}^N v_n \leq p\}$ and $M = (N+p)!/(N!p!)$. Other subspaces having dimension smaller than the TP subspace include hyperbolic cross (HC) polynomial spaces for which $\mathcal{J}(p) = \{\mathbf{v} \in \mathbb{N}^N \mid \sum_{n=1}^N \log_2(v_n + 1) \leq \log_2(p+1)\}$ and sparse Smolyak (SS) polynomial spaces for which

$$\mathcal{J}(p) = \left\{ \mathbf{v} \in \mathbb{N}^N \mid \sum_{n=1}^N \gamma(v_n) \leq \gamma(p) \right\} \quad \text{with } \gamma(p) = \begin{cases} 0 & \text{for } p = 0 \\ 1 & \text{for } p = 1 \\ \lceil \log_2(p) \rceil & \text{for } p \geq 2. \end{cases} \quad (21.14)$$

As illustrated by Example 4, it is often the case that the stochastic input data exhibits anisotropic behavior with respect to the “directions” y_n , $n = 1, \dots, N$. To exploit this effect, it is necessary to approximate u_{J_h} in an anisotropic polynomial space. Following [57], the vector $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_N) \in \mathbb{R}_+^N$ of positive weights is introduced with $\alpha_{\min} = \min_{n=1, \dots, N} \alpha_n$. The anisotropic versions $\mathcal{J}_{\boldsymbol{\alpha}}(p)$ of the aforementioned polynomial spaces are described in [5]. Here, the anisotropic SS polynomial space is given by

$$\mathcal{J}_{\boldsymbol{\alpha}}(p) = \left\{ \mathbf{v} \in \mathbb{N}^N \mid \sum_{n=1}^N \alpha_n \gamma(v_n) \leq \alpha_{\min} \gamma(p) \right\}.$$

For $N = 2$ dimensions, in Fig. 21.1 examples are provided of both isotropic and anisotropic TP, TD, HC, and SS polynomial spaces, where $p = 8$ and $\boldsymbol{\alpha} = (2, 1)$.

3.3.2 Best M -Term Polynomial Subspaces

The construction of the fully discrete approximation in (21.10) combats the curse of dimensionality by imposing a sparse polynomial space $\mathcal{P}_{\mathcal{J}(p)}(\Gamma)$ a priori (e.g., total degree) and then adaptively selecting a set of polynomial indices (e.g., anisotropic refinement and/or coefficient thresholding). This results in methods with increased

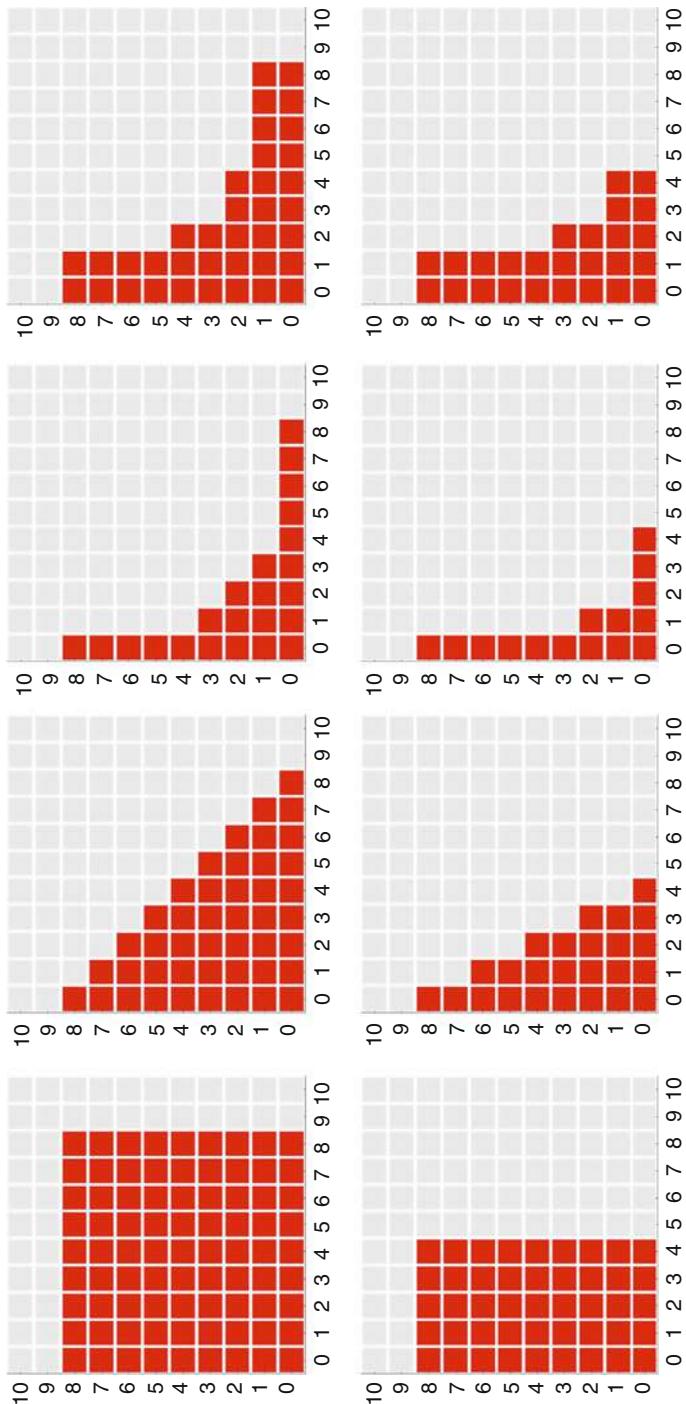

Fig. 21.1 For a finite dimensional Γ with $N = 2$ and a fixed polynomial index $p = 8$, *top row*: the indices $(p_1, p_2) \in \mathcal{J}(8)$ corresponding to the isotropic TP, TD, HC, and SS polynomial spaces. *Bottom row*: the indices $(p_1, p_2) \in \mathcal{J}_a(8)$ with $\alpha_1/\alpha_2 = 2$ corresponding to the anisotropic TP, TD, HC, and SS polynomial spaces

rates of convergence; however, the error estimates depend on the cardinality of the polynomial space, which can grow quickly with respect to the dimension N . Therefore, it is critical to construct a set of the most effective indices for approximation (21.10), which provides maximum accuracy for a given cardinality. In other words, one searches for an index set $\mathcal{J}_M^{\text{opt}}$ with cardinality $M = \#(\mathcal{J}_M^{\text{opt}})$ which minimizes the error $u_{J_h} - u_{J_h, M}$. This practice is known as best M -term approximations. In this case, the fully discrete approximation in (21.10) can be rewritten as

$$u_{J_h, M}(\mathbf{x}, \mathbf{y}) := \sum_{\nu \in \mathcal{J}_M^{\text{opt}}} t_\nu(\mathbf{x}) \psi_\nu(\mathbf{y}) := \sum_{\nu \in \mathcal{J}_M^{\text{opt}}} \left(\sum_{j=1}^{J_h} c_{j,\nu} \phi_j(\mathbf{x}) \right) \psi_\nu(\mathbf{y}), \quad (21.15)$$

where the basis functions of the best M -term subspace $\mathcal{P}_{\mathcal{J}_M^{\text{opt}}}(\Gamma)$ are indexed by $\nu \in \mathcal{J}_M^{\text{opt}}$ and the coefficient $t_\nu(\mathbf{x})$ is defined by $t_\nu(\mathbf{x}) := \sum_{j=1}^{J_h} c_{j,\nu} \phi_j(\mathbf{x})$.

The literature on the best M -term Taylor and Galerkin approximations has been growing fast recently; see [6, 7, 10, 15, 16, 21, 22, 42–44]. In the benchmark work [22], the analytical dependence of the solutions of stochastic elliptic PDEs on the parameters was proved under mild assumptions on the input coefficients, and convergence analysis of the best M -term Taylor and Legendre approximations was established subsequently. Consider, for example, the Taylor expansion of the semi-discrete solution $u_{J_h}(\mathbf{x}, \mathbf{y})$ with respect to \mathbf{y} on $\Gamma = [-1, 1]^N$. Application of the triangle inequality gives

$$\sup_{\mathbf{y} \in \Gamma} \left\| u_{J_h}(\mathbf{y}) - \sum_{\nu \in \mathcal{J}_M^{\text{opt}}} t_\nu \psi_\nu(\mathbf{y}) \right\|_{W(D)} \leq \sum_{\nu \notin \mathcal{J}_M^{\text{opt}}} \|t_\nu\|_{W(D)},$$

which suggests determining optimal index set $\mathcal{J}_M^{\text{opt}}$ by choosing for it the set of indices ν corresponding to M largest $\|t_\nu\|_{W(D)}$. In [22], the error of such approximation was estimated due to Stechkin inequality (see, e.g., [23]):

$$\sum_{\nu \notin \mathcal{J}_M^{\text{opt}}} \|t_\nu\|_{W(D)} \leq \|(\|t_\nu\|_{W(D)})\|_{\ell^q(\mathcal{S})} M^{1-\frac{1}{q}}, \quad (21.16)$$

where $q \in (0, 1)$ such that $(\|t_\nu\|_{W(D)})_{\nu \in \mathcal{S}}$ is ℓ^q -summable. It should be noted that the convergence rate (21.16) does not depend on the dimension of the parameter domain Γ (which is possibly countably infinite therein). This error estimate, however, has some limitations. First, sharp, explicit evaluation of coefficient $\|(\|t_\nu\|_{W(D)})\|_{\ell^q(\mathcal{S})}$ is inaccessible in general (thus so is the total estimate). Secondly, (21.16) often occurs with infinitely many values of q , and stronger rates, corresponding to smaller q , are also attached to bigger coefficients. For a specific range of M , the effective rate of convergence is unclear. In [66], the estimate (21.16) has been improved to a sharp sub-exponential convergence rates of the form

$M \exp(-(\kappa M)^{1/N})$, where κ is a constant depending on the shape and cardinality of multi-index sets. On the other hand, in implementation, finding the best index set and polynomial space is an infeasible task, since this requires computation of all of the t_ν . As a strategy to circumvent this challenge, adaptive algorithms which generate the index set in a near-optimal, greedy procedure were developed in [15]. This method gives the optimal rates; however, it comes with a high cost of exploring the polynomial space, which may be daunting in high-dimensional problems.

3.3.3 Quasi-optimal Polynomial Subspaces

Instead of building the index set based on exact values of polynomial coefficients t_ν , an attractive alternative approach (referred to as *quasi-optimal approximation*) is to establish sharp upper bounds of t_ν (by a priori or a posteriori methods) and then construct $\mathcal{J}_{M^{q\text{-opt}}}$ corresponding to M largest such bounds. For this strategy, the main computational work for the selection of the (near) best terms reduces to determining sharp coefficient estimates, which is expected to be significantly cheaper than exact calculations. Quasi-optimal polynomial approximation has been performed for some parametric elliptic models with optimistic results: while the upper bounds of $\|t_\nu\|_{V(D)}$, denoted by $B(\nu)$, were computed with a negligible cost, the method was comparably as accurate as best M -term approach; see [6, 7]. The first rigorous numerical analysis of quasi-optimal approximation was presented in [6] for $B(\nu) = \mathbf{r}^{-\nu}$ with \mathbf{r} being a vector $(r_n)_{1 \leq n \leq N}$ with $r_n > 1 \forall i$ (see Assumption 2). In that work, the asymptotic sub-exponential convergence rate was proved based on optimizing the Stechkin estimation. Briefly, the analysis applied Stechkin inequality to get

$$\sum_{\nu \notin \mathcal{J}_M^{q\text{-opt}}} B(\nu) \leq \|B(\nu)\|_{\ell^p(S)} M^{1-\frac{1}{q}} \quad (21.17)$$

and then took advantage of the formula of $B(\nu)$ to compute $q \in (0, 1)$ depending on M which minimizes $\|B(\nu)\|_{\ell^p(S)} M^{1-\frac{1}{q}}$.

Although known as an essential tool to study the convergence rate of best M -term approximations, the Stechkin inequality is probably less efficient for quasi-optimal methods. As a generic estimate, it does not fully exploit the available information of the decay of coefficient bounds. In this setting, a direct estimate of $\sum_{\nu \notin \mathcal{J}_M^{q\text{-opt}}} B(\nu)$ may be viable and advantageous to give a sharper result. On the other hand, the process of solving the minimization problem $q^* = \operatorname{argmin}_{q \in (0,1)} \|B(\nu)\|_{\ell^p(S)} M^{1-\frac{1}{q}}$ needs to be tailored to $B(\nu)$, making this approach not ideal for generalization. Currently, the minimization has been limited for some quite simple types of upper bounds. In many scenarios, the sharp estimates of the coefficients may involve complicated bounds which are not even explicitly computable, such as those proposed in [22]. The extension of this approach to such cases seems to be challenging.

In [66], a generalized methodology was proposed for convergence analysis of quasi-optimal polynomial approximations for parameterized elliptic PDEs, where the input coefficient depends affinely and non-affinely on the random parameters. However, since the error analysis only depends on the upper bounds of polynomial coefficients, it is expected that the presented results in [66] can be applied for other, more general model problems with finite parametric dimension, including nonlinear elliptic PDEs, initial value problems, and parabolic equations [16, 42–44]. The key idea of the effort in [66] is to seek for a direct estimate of $\sum_{\nu \notin \mathcal{J}_M^{\text{q-opt}}} B(\nu)$ without using Stechkin inequality. It involves a partition of $B(\mathcal{S} \setminus \mathcal{J}_M^{\text{q-opt}})$ into a family of small positive real intervals $(\mathcal{I}_k)_{k \in \mathcal{K}}$ and the corresponding splitting of $\mathcal{S} \setminus \mathcal{J}_M^{\text{q-opt}}$ into disjoint subsets \mathcal{Q}_k of indices ν such that $B(\nu) \in \mathcal{I}_k$. Under this process, the truncation error can be bounded as

$$\sum_{\nu \notin \mathcal{J}_M^{\text{q-opt}}} B(\nu) = \sum_{k \in \mathcal{K}} \sum_{\nu \in \mathcal{Q}_k} B(\nu) \leq \sum_{k \in \mathcal{K}} \#(\mathcal{Q}_k) \cdot \max(\mathcal{I}_k),$$

thus the quality of the error estimate mainly depends on the approximation of cardinality of \mathcal{Q}_k . To tackle this problem, the authors of [66] developed a strategy which extends \mathcal{Q}_k into continuous domain and, through relating the number of N -dimensional lattice points to continuous volume (Lebesgue measure), established a sharp estimate of the cardinality $\#(\mathcal{Q}_k)$ up to any prescribed accuracy. The development includes the utilization and extension of several results on lattice point enumeration; see [8, 38] for a survey. Under some weak assumptions on $B(\nu)$, an asymptotic sub-exponential convergence rate of truncation error of the form $M \exp(-(\kappa M)^{1/N})$ was achieved, where κ is a constant depending on the shape and size of quasi-optimal index sets. Through several examples, the authors explicitly derived κ and demonstrated the optimality of the estimate both theoretically (by proving a lower bound) and computationally (via comparison with exact calculation of truncation error). The advantage of the analysis framework is therefore twofold. First, it applies to a general class of quasi-optimal approximations; further, it gives sharp estimates for their asymptotic convergence rates.

3.3.4 Local Piecewise Polynomial Subspaces

The use of global polynomials discussed requires high regularity of the solution $u(\mathbf{x}, \mathbf{y})$ with respect to the random parameters $\{y_n\}_{n=1}^N$. They are therefore ineffective for the approximation of solutions that have irregular dependence with respect to those parameters. Motivated by finite element methods (FEMs) for spatial approximation, an alternate and potentially more effective approach for approximating irregular solutions is to use *locally supported piecewise polynomial* approaches for approximating the solution dependence on the random parameters. To achieve greater accuracy, global polynomial approaches increase the polynomial degree; piecewise polynomial approaches instead keep the polynomial degree fixed but refine the grid used to define the approximation space.

4 Global Stochastic Collocation Methods

This section focuses on the construction of the fully discrete approximation (21.10) in the subspace $W_h(D) \otimes \mathcal{P}_{\mathcal{J}(p)}(\Gamma)$. Rather than making use of a Galerkin projection in both the deterministic and stochastic domains, the semi-discrete approximation $u_{J_h}(\cdot, \mathbf{y})$ given in (21.8) is instead collocated on an appropriate set of points $\{\mathbf{y}_m\}_{m=1}^M \in \Gamma$ to determine $M := \dim(\mathcal{P}_{\mathcal{J}(p)})$ solutions $\{u_{J_h}(\cdot, \mathbf{y}_m)\}_{m=1}^M$. One can then use these solutions to construct a global, possibly interpolatory, polynomial to define the fully discrete approximation $u_{J_h, M}(\mathbf{x}, \mathbf{y}) := u_{J_h, M}^{\text{gSC}}(\mathbf{x}, \mathbf{y})$. This process is referred to as global stochastic collocation methods (gSCMs). Clearly, gSCMs are *nonintrusive* in the sense that the solution of (21.10) naturally decouples into a series of M deterministic solves, each of size $J_h \times J_h$.

In general, throughout this section, the following assumption is made about the regularity of the solution to (21.7).

Assumption 2. For $0 < \delta < a_{\min}$, there exists \mathbf{r} , with $(r_n)_{1 \leq n \leq N}$ and $r_n > 1 \ \forall i$, such that the complex extension of u to the (δ, \mathbf{r}) -polyellipse $\mathcal{E}_{\mathbf{r}}$, i.e., $u^* : \mathcal{E}_{\mathbf{r}} \rightarrow W(D)$ is well-defined and analytic in an open neighborhood of $\mathcal{E}_{\mathbf{r}}$, given by

$$\mathcal{E}_{\mathbf{r}} = \bigotimes_{1 \leq n \leq N} \left\{ z_n \in \mathbb{C} : \Re(z_n) = \frac{r_n + r_n^{-1}}{2} \cos \phi, \Im(z_n) = \frac{r_n - r_n^{-1}}{2} \sin \phi, \phi \in [0, 2\pi] \right\},$$

for all $x \in \overline{D}$ and all $\mathbf{z} = (z_n)_{1 \leq n \leq N}$ contained in the polyellipse.

4.1 Lagrange Global Polynomial Interpolation in Parameter Space

Interpolatory approximations in parameter space start with the selection of a set of distinct points $\{\mathbf{y}_m\}_{m=1}^M \in \Gamma$ and a set of basis functions $\{\psi_m(\mathbf{y})\}_{m=1}^M \subset \mathcal{P}_{\mathcal{J}(p)}(\Gamma)$. Then, an approximation $u_{J_h, M}^{\text{gSC}} \in W_h(D) \otimes \mathcal{P}_{\mathcal{J}(p)}(\Gamma)$ of the form

$$u_{J_h, M}^{\text{gSC}}(\mathbf{x}, \mathbf{y}) := \sum_{m=1}^M c_m(\mathbf{x}) \psi_m(\mathbf{y}). \quad (21.18)$$

The Lagrange interpolant is defined by first obtaining M realizations $u_{J_h}(\mathbf{x}, \mathbf{y}_m)$ of the finite element approximation of the solution $u(\mathbf{x}, \mathbf{y}_m)$ of the problem (21.1), i.e., one solves for the finite element approximation for each of the interpolation points in the set $\{\mathbf{y}_m\}_{m=1}^M$. Then, the coefficient functions $\{c_m(\mathbf{x})\}_{m=1}^M$ are determined by imposing the interpolation conditions

$$\sum_{m=1}^M c_m(\mathbf{x}) \psi_m(\mathbf{y}_{m'}) = u_{J_h}(\mathbf{x}, \mathbf{y}_{m'}) \quad \text{for } m' = 1, \dots, M. \quad (21.19)$$

Thus, each of the coefficient functions $\{c_m(\mathbf{x})\}_{m=1}^M$ is a linear combination of the finite element data $\{u_{J_h}(\mathbf{x}, \mathbf{y}_m)\}_{m=1}^M$; the specific linear combinations are determined in the usual manner from the entries of the inverse of the $M \times M$ interpolation matrix \mathbf{L} having entries $L_{m',m} = \psi_m(\mathbf{y}_{m'})$, $m, m' = 1, \dots, M$. The sparsity and conditioning of \mathbf{L} heavily depend on the choice of basis; that choice could result in matrices that range from fully dense to diagonal and from highly ill conditioned to perfectly well conditioned.

The main attraction of interpolatory approximations of parameter dependences is that it effects a complete decoupling of the spatial and probabilistic degrees of freedom. Clearly, once the interpolation points $\{\mathbf{y}_m\}_{m=1}^M$ are chosen, one can solve M deterministic finite element problems, one for each parameter point \mathbf{y}_m , with total disregard to what basis $\{\psi_m(\mathbf{y})\}_{m=1}^M$ one choose to use. Then, the coefficients $\{c_m(\mathbf{x})\}_{m=1}^M$ defining the approximation (21.18) are found from the interpolation conditions in (21.19); it is only in this last step that the choice of stochastic basis enters into the picture. Note that this decoupling property makes the implementation of Lagrange interpolatory approximations of parameter dependences almost as trivial as it is for Monte Carlo sampling. However, if that dependence is smooth, because of the higher accuracy of global polynomial approximations in the space $\mathcal{P}_{\mathcal{J}(p)}(\Gamma)$, interpolatory approximations require substantially fewer sampling points to achieve a desired error tolerance.

Given a set of interpolation points, to complete the setup of a Lagrange interpolation problem, one has to choose a basis. The simplest and most popular choices are the Lagrange fundamental polynomials, i.e., polynomials that have the *delta property* $\psi_{m'}(\mathbf{y}_m) = \delta_{m'm}$, where $\delta_{m'm}$ denotes the Kronecker delta. In this case, the interpolating conditions (21.19) reduce to $c_m(\mathbf{x}) = u_{J_h}(\mathbf{x}, \mathbf{y}_m)$ for $m = 1, \dots, M$, i.e., the interpolation matrix \mathbf{L} is simply the $M \times M$ identity matrix. In this sense, the use of Lagrange polynomial bases can be viewed as resulting in pure sampling methods, much the same as Monte Carlo methods, but instead of randomly sampling in the parameter space Γ , the sample points are deterministically structured. Mathematically, using the Lagrange fundamental polynomial basis $\{\psi_m\}_{m=1}^M$, this ensemble-based approach results in a fully discrete approximation of the solution $u(\mathbf{x}, \mathbf{y})$ of the form

$$u_{J_h M}^{gSC}(\mathbf{x}, \mathbf{y}) = \sum_{m=1}^M u_{J_h}(\mathbf{x}, \mathbf{y}_m) \psi_m(\mathbf{y}). \quad (21.20)$$

The construction of multivariate Lagrange fundamental polynomials for a general set of interpolation points is not an easy matter. Fortunately, there exist means for so doing; see [59].

4.2 Generalized Sparse Grid Construction

By following [5, 57, 58, 61], a generalized version of the Smolyak sparse grid gSCM is described for interpolation and quadrature. For each $n = 1, \dots, N$, let $l_n \in \mathbb{N}_+$ denote the one-dimensional level of approximation, and let $\{y_{n,k}^{(l_n)}\}_{k=1}^{m(l_n)} \subset \Gamma_n$ denote

a sequence of one-dimensional interpolation points in Γ_n . Here, $m(l) : \mathbb{N}_+ \rightarrow \mathbb{N}_+$ is such that $m(0) = 0$, $m(1) = 1$, and $m(l) < m(l + 1)$ for $l = 2, 3, \dots$ so that $m(l)$ strictly increases with l ; $m(l_n)$ defines the total number of collocation points at level l_n . For a univariate function $v \in C^0(\Gamma_n)$, a sequence of one-dimensional Lagrange interpolation operators $\mathcal{U}_n^{m(l_n)} : C^0(\Gamma_n) \rightarrow \mathcal{P}_{m(l_n)-1}(\Gamma_n)$ is defined by

$$\mathcal{U}_n^{m(l_n)}[v](y_n) = \sum_{k=1}^{m(l_n)} v\left(y_{n,k}^{(l_n)}\right) \psi_{n,k}^{(l_n)}(y_n) \quad \text{for } l_n = 1, 2, \dots, \quad (21.21)$$

where $\psi_{n,k}^{(l_n)} \in \mathcal{P}_{m(l_n)-1}(\Gamma_n)$, $k = 1, \dots, m(l_n)$ are Lagrange fundamental polynomials of degree $p_{l_n} = m(l_n) - 1$ such that

$$\psi_{n,k}^{(l_n)}(y_n) = \prod_{\substack{k'=1 \\ k' \neq k}}^{\min(l_n)} \frac{\left(y_n - y_{n,k'}^{(l_n)}\right)}{\left(y_{n,k}^{(l_n)} - y_{n,k'}^{(l_n)}\right)}.$$

Using the convention that $\mathcal{U}_n^{m_0} = 0$, the difference operator can be defined by

$$\Delta_n^{m(l_n)} = \mathcal{U}_n^{m(l_n)} - \mathcal{U}_n^{m(l_n-1)}. \quad (21.22)$$

For the multivariate case, let $\mathbf{l} = (l_1, \dots, l_N) \in \mathbb{N}_+^N$ denote a multi-index and $L \in \mathbb{N}_+$ denote the total level of the sparse grid approximation. Then, for each $n = 1, \dots, N$, the N -dimensional hierarchical surplus operator can be defined by

$$\Delta^m = \bigotimes_{n=1}^N \Delta_n^{m(l_n)}, \quad (21.23)$$

and, from (21.22) and (21.23), the L -th level generalized sparse grid operator given by

$$\mathcal{I}_L^{m,g} = \sum_{g(\mathbf{l}) \leq L} \bigotimes_{n=1}^N \Delta_n^{m(l_n)}, \quad (21.24)$$

where $g : \mathbb{N}_+^N \rightarrow \mathbb{N}$ is another strictly increasing function that defines the mapping between the multi-index \mathbf{l} and the level L used to construct the sparse grid. Finally, given the functions m and g and a level L , the generalized sparse grid approximation of u_{J_h} can be constructed by

$$u_{J_h M_L}^{\text{gSC}} = \mathcal{I}_L^{m,g}[u_{J_h}] = \sum_{L-N+1 \leq g(\mathbf{l}) \leq L} \sum_{\substack{\mathbf{k} \in \{0,1\}^N \\ g(\mathbf{l+k}) \leq L}} (-1)^{|\mathbf{k}|} \bigotimes_{n=1}^N \mathcal{U}_n^{m(l_n)}[u_{J_h}]. \quad (21.25)$$

The fully discrete gSCM (21.25) requires the independent evaluation of the finite element approximation $u_{J_h}(\mathbf{x}, \mathbf{y})$ on a deterministic set of *distinct collocation points* given by

$$\mathcal{H}_L^{m,g} = \bigcup_{g(\mathbf{l}) \leq L} \bigotimes_{n=1}^N \left\{ y_{n,k}^{(l_n)} \right\}_{k=1}^{m(l_n)}$$

having cardinality M_L , i.e., $M = M_L$ in (21.10). Moreover, the construction of the sparse grid approximation naturally enables the evaluation of moments through simple sparse grid quadrature formulas, i.e.,

$$\mathbb{E}[u_{J_h M_L}^{\text{gSC}}](\mathbf{x}) = \sum_{m=1}^{M_L} u_{J_h}(\mathbf{x}, \mathbf{y}_m) \underbrace{\int_{\Gamma} \psi_m(\mathbf{y}) \rho(\mathbf{y}) d\mathbf{y}}_{\text{precomputed weights}} = \sum_{m=1}^{M_L} u_{J_h}(\mathbf{x}, \mathbf{y}_m) w_m$$

and

$$\mathbb{V}[u_{J_h M_L}^{\text{gSC}}](\mathbf{x}) = \sum_{m=1}^{M_L} \tilde{w}_m u_{J_h}^2(\mathbf{x}, \mathbf{y}_m) - \mathbb{E}[u_{J_h M_L}^{\text{gSC}}]^2(\mathbf{x}),$$

where $\tilde{w}_m = \mathbb{V}[\psi_m(\mathbf{y})]$, $m = 1, \dots, M_L$.

The work [5] constructs the underlying polynomial space associated with the approximation (21.25) for particular choices of m , g , and L . Let $m^{-1}(k) = \min\{l \in \mathbb{N}_+ \mid m(l) \geq k\}$ denote the left inverse of m such that $m^{-1}(m(l)) = l$ and $m(m^{-1}(k)) \geq k$. Then, let $\mathbf{s}(\mathbf{l}) = (m(l_1), \dots, m(l_N))$ and define the polynomial index set

$$\mathcal{J}^{m,g}(L) = \{ \mathbf{v} \in \mathbb{N}^N : g(\mathbf{m}^{-1}(\mathbf{v} + \mathbf{1})) \leq L \}.$$

With this definition in hand, the following proposition, whose proof can be found in [5, Proposition 1], characterizes the underlying polynomial space of the sparse grid approximation $\mathcal{I}_L^{m,g}[u_{J_h}]$.

Proposition 1. *Let $m : \mathbb{N}_+ \rightarrow \mathbb{N}_+$ and $g(\mathbf{l}) : \mathbb{N}_+^N \rightarrow \mathbb{N}$ denote strictly increasing functions, as described above, and $\{y_{n,k}^{(l)}\}_{k=1}^{m(l)} \subset \mathbb{C}_n$ denote arbitrary distinct points used in (21.21) to determine $\mathcal{U}_n^{m(l)}$, $l = 1, 2, \dots$. Then,*

- (1) *For any function $v \in C^0(\Gamma)$, the approximation $\mathcal{I}_L^{m,g}[v] \in \mathcal{P}_{\mathcal{J}^{m,g}(L)}(\Gamma)$.*
- (2) *For all $v \in \mathcal{P}_{\mathcal{J}^{m,g}(p)}(\Gamma)$, it holds that $\mathcal{I}_L^{m,g}[v] = v$.*

With Proposition 1 in hand, the sparse grid approximation $\mathcal{I}_L^{m,g}$ can be related with the corresponding polynomial subspaces, i.e., $\mathcal{P}_{\mathcal{J}^{m,g}(L)}(\Gamma)$ with $m(l) = l$ and $g(\mathbf{l}) = \max_{n=1,\dots,N} (l_n - 1) \leq L$, $g(\mathbf{l}) = \sum_{n=1}^N (l_n - 1) \leq L$, and

$g(\mathbf{l}) = \sum_{n=1}^N \log_2(l_n) \leq \log_2(L + 1)$ for the tensor-product, total degree, and hyperbolic cross polynomial subspaces, respectively. However, the most widely used polynomial subspace is the sparse Smolyak given by (21.14), which, in the context of the sparse grid approximation, is defined by

$$m(1) = 1, \quad m(l) = 2^{l-1} + 1, \quad \text{and} \quad g(\mathbf{l}) = \sum_{n=1}^N (l_n - 1). \quad (21.26)$$

Moreover, similar to the anisotropic polynomial spaces, the generalized gSCM enables anisotropic refinement with respect to the direction y_n by incorporating a weight vector $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_N) \in \mathbb{R}_+^N$ into the mapping $g : \mathbb{N}_+^N \rightarrow \mathbb{N}$, e.g., $g(\mathbf{l}) = \sum_{n=1}^N \alpha_n (l_n - 1) \leq \alpha_{\min} L$ in (21.26). Anisotropic refinement will be discussed further in the sections that follow, but first, two choices of points used for (21.25) are introduced, namely, the Clenshaw-Curtis and Gaussian points. See [68] for an insightful comparison of quadrature formulas based on these points.

4.2.1 Clenshaw-Curtis Points on Bounded Hypercubes

Without loss of generality, assume that $\Gamma_n = [-1, 1]$. The Clenshaw-Curtis points are the extrema of Chebyshev polynomials (CC) (see [19]) given by, for any choice of $m(l) > 1$,

$$y_k^{(l)} = -\cos\left(\frac{\pi(k-1)}{m(l)-1}\right) \quad \text{for } k = 1, \dots, M_l. \quad (21.27)$$

In addition, one sets $y_1^{(l)} = 0$ if $m(l) = 1$ and chooses the multi-index map g as well as the number of points $m(l)$, $l > 1$, at each level as in (21.26). Note that this particular choice corresponds to the most used sparse grid approximation because it leads to nested sequences of points, i.e., $\{y_k^{(l)}\}_{k=1}^{m(l)} \subset \{y_k^{(l+1)}\}_{k=1}^{m(l+1)}$ so that the sparse grids are also nested, i.e., $\mathcal{H}_L^{m,g} \subset \mathcal{H}_{L+1}^{m,g}$.

However, even though the CC choice of points results in a significantly reduced number of points used by $\mathcal{I}_L^{m,g}$, that number of points eventually increases exponentially fast with N . With this in mind, an alternative to the standard Clenshaw-Curtis (CC) family of rules is considered which attempts to retain the advantages of nestedness while reducing the excessive growth described above. To achieve this, it is necessary to exploit the fact that the CC interpolant is exact in the polynomial space $\mathcal{P}_{m(l)-1}$ to drop, in each direction, the requirement that the function m be strictly increasing. Instead, a new mapping $\tilde{m}(l) : \mathbb{N}_+ \rightarrow \mathbb{N}_+$ is defined such that $\tilde{m}(l) \leq \tilde{m}(l+1)$ and $\tilde{m}(l) = \tilde{m}(k)$, where $k = \operatorname{argmin}\{k' | 2^{k'-1} \geq L\}$. In other words, the current rule are reused for as many levels as possible, until the total degree subspace is properly included. Figure 21.2 shows the difference between the standard CC sparse grid and the “slow growth” CC (sCC) sparse grid for $l = 1, 2, 3, 4$. Figure 21.3 shows the corresponding polynomial accuracy of the CC and sCC sparse grids when used in a quadrature rule approximation (as opposed

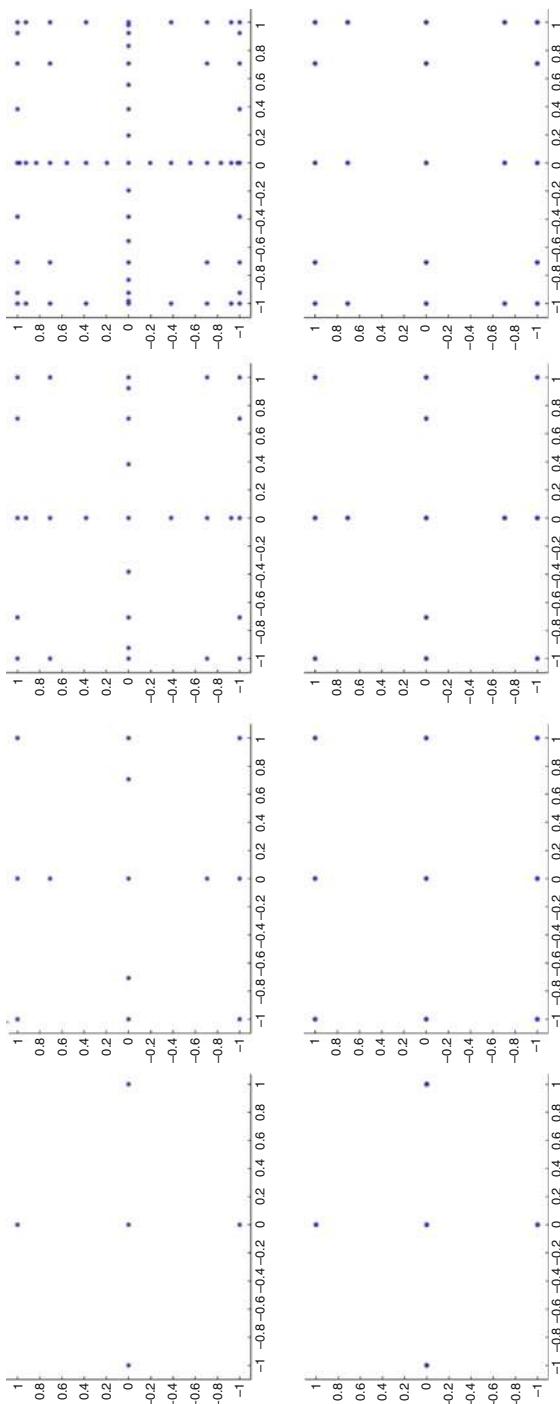

Fig. 21.2 For $\Gamma = [-1, 1]^2$, the sparse grids corresponding to levels $L = 1, 2, 3, 4$, using standard Clenshaw-Curtis points (*top*) and slow-growth Clenshaw-Curtis points (*bottom*)

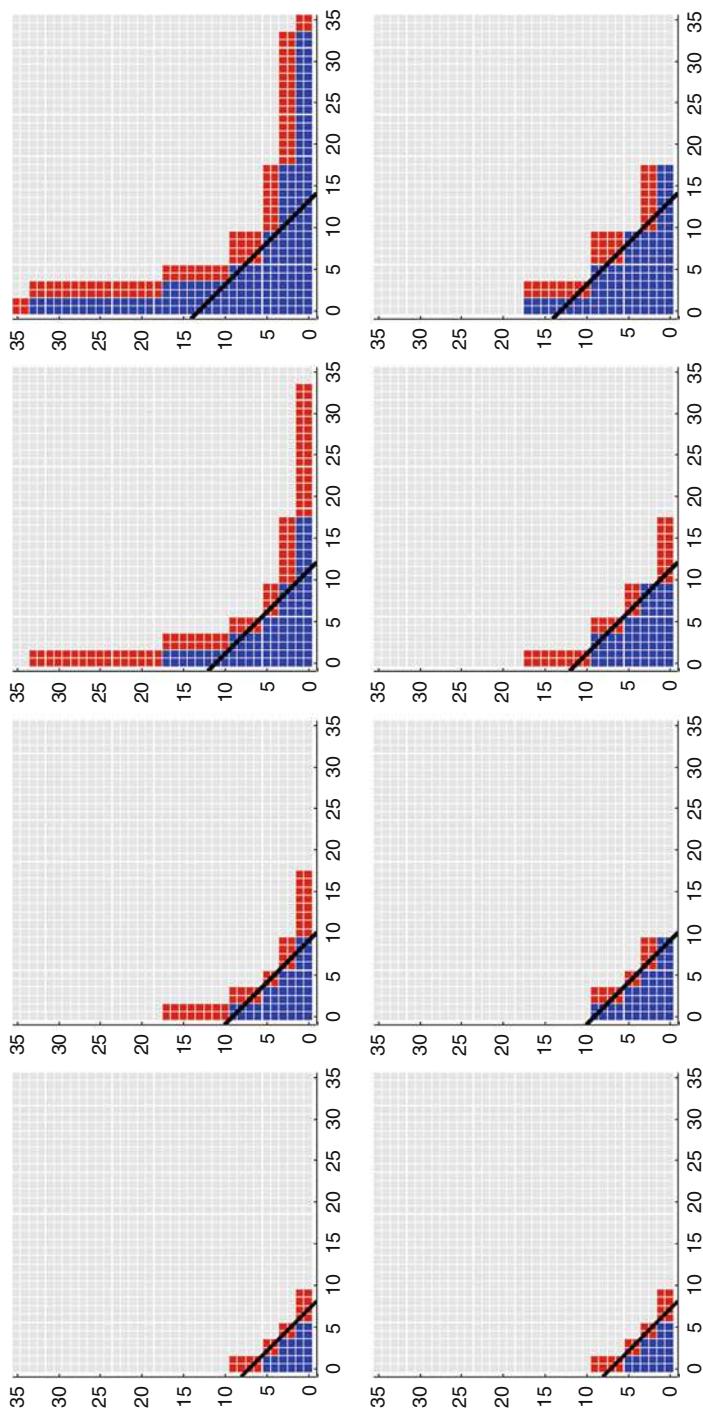

Fig. 21.3 For $\Gamma = [-1, 1]^2$, the polynomial subspaces associated with integrating a function $u \in C^0(\Gamma)$, using sparse grids corresponding to levels $L = 3, 4, 5, 6$ using standard Clenshaw-Curtis points (*top*) and slow-growth Clenshaw-Curtis points (*bottom*)

to an interpolant) of the integral a function in $C^0(\Gamma)$. Note that the concept of “slow growth” can also be applied to other nested one-dimensional rules, including, e.g., the Gauss-Patterson points [34].

4.2.2 Gaussian Points in Bounded or Unbounded Hypercubes

The Gaussian points $\{y_{n,k}^{(l_n)}\}_{k=1}^{m(l_n)} \subset \Gamma_n$ are the zeros of the orthogonal polynomials with respect to some positive weight function. In general, they are not nested. The natural choice for the weight function is the PDF $\rho(\mathbf{y})$ of the random variables \mathbf{y} . However, in the general multivariate case, if the random variables y_n are not independent, the PDF $\rho(\mathbf{y})$ does not factorize, i.e., $\rho(\mathbf{y}) \neq \prod_{n=1}^N \rho_n(y_n)$. As a result, an auxiliary probability density function $\widehat{\rho}(\mathbf{y}) : \Gamma \rightarrow \mathbb{R}^+$ is defined by

$$\widehat{\rho}(\mathbf{y}) = \prod_{n=1}^N \widehat{\rho}_n(y_n) \quad \forall \mathbf{y} \in \Gamma \quad \text{and such that} \quad \left\| \frac{\rho}{\widehat{\rho}} \right\|_{L^\infty(\Gamma)} < \infty.$$

Note that $\widehat{\rho}(\mathbf{y})$ factorizes so that it can be viewed as a joint PDF for N independent random variables.

For each parameter dimension $n = 1, \dots, N$, let the $m(l_n)$ Gaussian points be the roots of the $m(l_n)$ degree polynomial that is $\widehat{\rho}_n$ -orthogonal to all polynomials of degree $m(l_n - 1)$ on the interval Γ_n . The auxiliary density $\widehat{\rho}$ should be chosen as close as possible to the true density ρ so that the quotient $\rho/\widehat{\rho}$ is not too large.

4.2.3 Selection of the Anisotropic Weights for Example 3

In the special case of Example 3, the analytic dependence with respect to each of the random variables, i.e., Assumption 2, reduces to the following: for $n = 1, \dots, N$, let $\Gamma_n^* = \prod_{\substack{j=1 \\ j \neq n}}^N \Gamma_j$, and let \mathbf{y}_n^* denote an arbitrary element of Γ_n^* . Then there exist constants λ and $\tau_n \geq 0$ and regions $\Sigma_n \equiv \{z \in \mathbb{C}, \text{ dist}(z, \Gamma_n) \leq \tau_n\}$ in the complex plane for which

$$\max_{\mathbf{y}_n^* \in \Gamma_n^*} \max_{z \in \Sigma_n} \|u(\cdot, \mathbf{y}_n^*, z)\|_{W(D)} \leq \lambda,$$

such that, the solution $u(\mathbf{x}, \mathbf{y}_n^*, y_n)$ admits an analytic extension $u(\mathbf{x}, \mathbf{y}_n^*, z)$, $z \in \Sigma_n \subset \mathbb{C}$. The ability to treat the stochastic dimensions differently is a necessity because many practical problems exhibit highly anisotropic behavior, e.g., the size τ_n of the analyticity region associated to each random variable y_n increases with n .

In such a case, it is known that if the dependence on each random variable is approximated with polynomials, the best approximation error decays exponentially fast with respect to the polynomial degree. More precisely, for a bounded region Γ_n and a univariate analytic function, recall the following Lemma, whose proof can be found in [1, Lemma 7] and which is an immediate extension of the result given in [24, Chapter 7, Section 8].

Lemma 1. Given a function $v \in C^0(\Gamma_n; W(D))$, which admits an analytic extension in the region of the complex plane $\Sigma(\Gamma_n; \tau_n) = \{z \in \mathbb{C}, \text{dist}(z, \Gamma_n) \leq \tau_n\}$ for some $\tau_n > 0$, then

$$E_{m(l_n)} \equiv \min_{w \in \mathcal{P}_{m(l_n)}} \|v - w\|_{C_n^0} \leq \frac{2}{e^{2r_n} - 1} e^{-2M_{l_n}r_n} \max_{z \in \Sigma(\Gamma_n; \tau_n)} \|v(z)\|_{W(D)}$$

with

$$0 < r_n = \frac{1}{2} \log \left(\frac{2\tau_n}{|\Gamma_n|} + \sqrt{1 + \frac{4\tau_n^2}{|\Gamma_n|^2}} \right). \quad (21.28)$$

A related result with weighted norms holds for unbounded random variables whose probability density decays as the Gaussian density at infinity; see [1].

In the multivariate case, the size τ_n of the analyticity region depends, in general, on the direction n . As a consequence, the decay coefficient r_n will also depend on the direction. The key idea of the anisotropic sparse gSCM in [58] is to place more points in directions having slower convergence rate, i.e., with smaller value for r_n . In particular, the weights α_n can be linked with the rate of exponential convergence in the corresponding direction by

$$\alpha_n = r_n \quad \text{for all } n = 1, 2, \dots, N. \quad (21.29)$$

Let

$$\underline{\alpha} = \underline{r} = \min_{n=0,1,\dots,N} \{r_n\} \quad \text{and} \quad \mathcal{R}(N) = \sum_{n=1}^N r_n. \quad (21.30)$$

As observed in Remark 4, the choice $\alpha = \mathbf{r}$ is optimal with respect to the error bound derived in Theorem 1. Now, the problem of choosing α is transformed into the one of estimating the decay coefficients $\mathbf{r} = (r_1, \dots, r_N)$. In [58, Section 2.2], two rigorous estimation strategies are given. The first uses a priori knowledge about the error decay in each direction, whereas the second approach uses a posteriori information obtained from computations and fits the values of \mathbf{r} .

An illustration of the salubrious effect on the resulting sparse grid resulting from accounting for anisotropy is given in Fig. 21.4.

4.2.4 Sparse Grid gSCM Error Estimates for Example 3

Global sparse grid Lagrange interpolation gSCMs can be used to approximate the solution $u \in C^0(\Gamma; W(D))$ using finitely many function values. By Assumption 2, u admits an analytic extension. Furthermore, each function value is computed by means of a finite element technique. Recall that the fully discrete approximation is

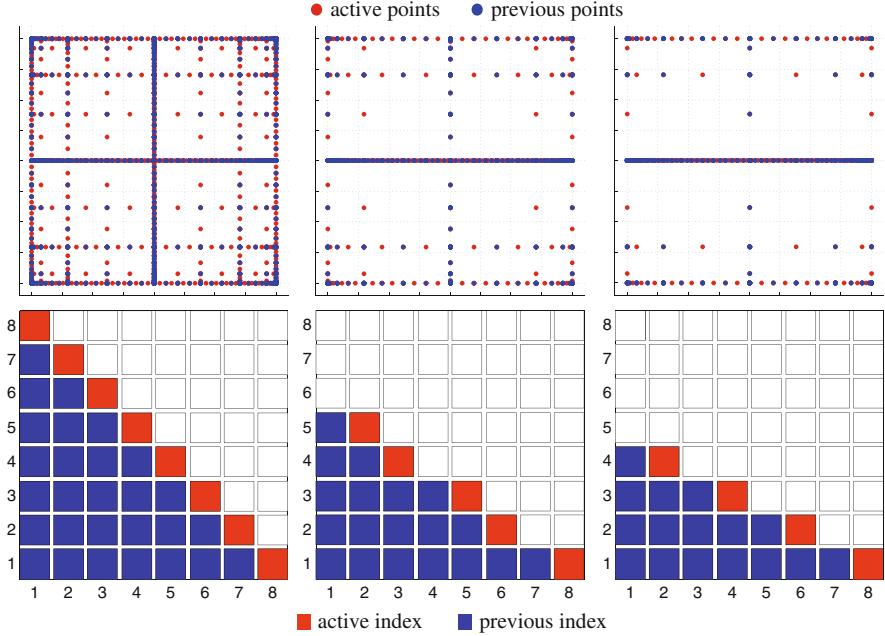

Fig. 21.4 For $\Gamma = [0, 1]^2$ and $L = 7$: the anisotropic sparse grids with $\alpha_2/\alpha_1 = 1$ (isotropic), $\alpha_2/\alpha_1 = 3/2$, and $\alpha_2/\alpha_1 = 2$ utilizing the Clenshaw-Curtis points (top row) and the corresponding indices (l_1, l_2) such that $\alpha_1(l_1 - 1) + \alpha_2(l_2 - 1) \leq \alpha_{\min} L$ (bottom row)

defined as $u_{J_h M_p}^{\text{gSC}} = \mathcal{I}_L^{m,g}[u_{J_h}]$, where the operator $\mathcal{I}_L^{m,g}$ is defined in (21.24). The aim is to provide an a priori estimates for the total error

$$\epsilon = u - \mathcal{I}_L^{m,g}[u_{J_h}].$$

The goal is to investigate the error

$$\|u - \mathcal{I}_L^{m,g}[u_{J_h}]\| \leq \underbrace{\|u - u_{J_h}\|}_{(I)} + \underbrace{\|u_{J_h} - \mathcal{I}_L^{m,g}[u_{J_h}]\|}_{(II)} \quad (21.31)$$

evaluated in the natural norm $L_\rho^2(\Gamma; W(D))$. Note that if the stochastic data, i.e., a and/or f , are not an exact representation but are instead an approximation in terms of N random variables, e.g., arising from a suitable truncation of infinite representations of random fields, then there would be an additional error $\|u - u_N\|$ to consider. This contribution to the total error was considered in [57, Section 4.2]. By controlling the error in this natural norm, the error can also be controlled in the expected value of the solution, e.g.,

$$\|\mathbb{E}[\epsilon]\|_{W(D)} \leq \mathbb{E}[\|\epsilon\|_{W(D)}] \leq \|\epsilon\|_{L_\rho^2(\Gamma; W(D))}.$$

The quantity (I) accounts for the error with respect to the spatial grid size h , i.e., the finite element error; it is estimated using standard approximability properties of the finite element space $W_h(D)$ and the spatial regularity of the solution u ; see, e.g., [11, 18]. Specifically,

$$\|u - u_{J_h}\|_{L^2_\rho(\Gamma; W(D))} \leq h^s \left(\int_\Gamma C_\pi(\mathbf{y}) C(s; u(\mathbf{y}))^2 \rho(\mathbf{y}) d\mathbf{y} \right)^{1/2}.$$

The primary concern will be to analyze the approximation error (II) , i.e.,

$$\|u_{J_h} - \mathcal{I}_L^{m,g}[u_{J_h}]\|_{L^2_\rho(\Gamma; W(D))}, \quad (21.32)$$

for the Clenshaw-Curtis points using the anisotropic sparse grid approximation with $m(l)$ and g defined as follows:

$$m(1) = 1, \quad m(l) = 2^{l-1} + 1, \quad \text{and} \quad g(l) = \sum_{n=1}^N \alpha_n (l_n - 1) \leq \alpha_{\min} L. \quad (21.33)$$

Error analysis of the sparse grid approximation with other isotropic or anisotropic choices of $m(l)$ and g can be found in [57, 58].

Under the very reasonable assumption that the semi-discrete finite element solution u_{J_h} admits an analytic extension as described in Assumption 2 with the same analyticity region as for u , the behavior of the error (21.32) will be analogous to $\|u - \mathcal{I}_L^{m,g}[u]\|_{L^2_\rho(\Gamma; W(D))}$. For this reason, the analysis presented next considers the latter.

Recall that even though in the global estimate (21.31) it is enough to bound the approximation error (II) in the $L^2_\rho(\Gamma; W(D))$ norm, we consider the more stringent $L^\infty(\Gamma; W(D))$ norm. In this chapter, the norm $\|\cdot\|_{\infty,n}$ is shorthand for $\|\cdot\|_{L^\infty(\Gamma_n; W(D))}$ and similarly, $\|\cdot\|_{\infty,N}$ is shorthand for $\|\cdot\|_{L^\infty(\Gamma; W(D))}$.

The multidimensional error estimate $\|u - \mathcal{I}_L^{m,g}[u]\|$ is constructed from a sequence of one-dimensional estimates and a tight bound on the number of distinct nodes on the sparse grid $\mathcal{H}_L^{m,g}$. To begin, let E_m denote the best approximation error, as in Lemma 1, to functions $u \in C^0(\Gamma_n; W(D))$ by polynomial functions $w \in \mathcal{P}_M$. Because the interpolation formula $\mathcal{U}_n^{M_{l_n}}$, $n = 1, \dots, N$ is exact for polynomials in $\mathcal{P}_{m(l_n)-1}$, the general formula can be applied

$$\|u - \mathcal{U}^{m(l_n)}[u]\|_{\infty,n} \leq (1 + \Lambda_{m(l_n)}) E_{m(l_n)-1}(u), \quad (21.34)$$

where Λ_m denotes the Lebesgue constant corresponding to the points (21.27). In this case, it is known that

$$\Lambda_m \leq \frac{2}{\pi} \log(m-1) + 1 \quad (21.35)$$

for $M_{l_n} \geq 2$; see [26]. On the other hand, using Lemma 1, the best approximation to functions $u \in C^0(\Gamma_n; W(D))$ that admit an analytic extension as described by Assumption 2 is bounded by

$$E_{m(l_n)}(u) \leq \frac{2}{e^{2r_n} - 1} e^{-2m(l_n)r_n} \theta(u), \quad (21.36)$$

where $\theta(u) = \max_{1 \leq n \leq N} \max_{y_n^* \in \Gamma_n^*} \max_{z \in \Sigma(\Gamma_n; \tau_n)} \|u(z)\|_{W(D)}$. For $n = 1, 2, \dots, N$, denote the one-dimensional identity operator by $I_n : C^0(\Gamma_n; W(D)) \rightarrow C^0(\Gamma_n; W(D))$ and use (21.34)–(21.36) to obtain the estimates

$$\|u - \mathcal{U}_n^{m(l_n)}[u]\|_{\infty,n} \leq \frac{4}{e^{2r_n} - 1} l_n e^{-r_n 2^{l_n}} \theta(u)$$

and

$$\|\Delta_n^{m(l_n)}[u]\|_{\infty,n} \leq \frac{8}{e^{2r_n} - 1} l_n e^{-r_n 2^{l_n} - 1} \theta(u). \quad (21.37)$$

Because the value $\theta(u)$ affects the error estimates as a multiplicative constant, from here on, it is assumed to be one without any loss of generality.

The next Theorem provides an error bound in terms of the total number M_L of Clenshaw-Curtis collocation points. The details of the proof can be found in [58, Section 3.1.1] and is therefore omitted. A similar result holds for the sparse grid $\mathcal{I}_L^{m,g}$ using Gaussian points and can be found in [58, Section 3.1.2].

Theorem 1. *Let $u \in L_p^2(\Gamma; W(D))$ and let the functions m and g satisfy (21.33) with weights $\alpha_n = r_n$. Then for the gSCM approximation based on the Clenshaw-Curtis points, the following estimates hold.*

- Algebraic convergence $(0 \leq L \leq \frac{\mathcal{R}(N)}{\underline{r} \log(2)})$.

$$\|u - \mathcal{I}_L^{m,g}[u]\|_{L^\infty(\Gamma^N; W(D))} \leq \widehat{C}(\mathbf{r}, N) M_L^{-\mu_1}$$

with $\mu_1 = \frac{\underline{r}(\log(2)e - 1/2)}{\log(2) + \sum_{n=1}^N \underline{r}/g(n)}.$ (21.38)

- Sub-exponential convergence $(L > \frac{\mathcal{R}(N)}{\underline{r} \log(2)})$

$$\|u - \mathcal{I}_L^{m,g}[u]\|_{L^\infty(\Gamma^N; W(D))} \leq \widehat{C}(\mathbf{r}, N) M_L^{\frac{\mu_2}{2}} \exp\left(-\mathcal{R}(N) M_L^{\frac{\log(2)}{\mathcal{R}(N)} \mu_2}\right)$$

with $\mu_2 = \frac{\underline{r}}{\left(\log(2) + \sum_{n=1}^N \underline{r}/g(n)\right)},$ (21.39)

where the constant $\widehat{C}(\mathbf{r}, N)$, defined in [58, (3.14)], is independent of M_L .

Remark 1. The estimate (21.39) may be improved when $L \rightarrow \infty$. Such an asymptotic estimate is obtained using the better counting result described in [58, Remark 3.7].

Remark 2. Observe that sub-exponential rate of convergence is always faster than the algebraic one when $L > \mathcal{R}(N)/(\underline{r} \log(2))$. Yet, this estimate is of little practical relevance since in practical computations, such a high level L is seldom reached.

Remark 3 (On the curse of dimensionality). Suppose that the stochastic input data are truncated expansions of random fields and that the values $\{r_n\}_{n=1}^\infty$ can be estimated. Whenever the sum $\sum_{n=1}^\infty r/r_n$ is finite, the algebraic exponent in (21.38) does not deteriorate as the truncation dimension N increases. This condition is satisfied. This is a clear advantage compared to the isotropic Smolyak method studied in [57] because $r_n \rightarrow +\infty$ is available and $\widehat{C}(\mathbf{r}, N)$ does not deteriorate with N , i.e., it is bounded, and therefore *the method does not suffer from the curse of dimensionality*. In fact, in such a case, the anisotropic Smolyak formula can be extended to infinite dimensions, i.e., $\sum_{n=1}^\infty (l_n - 1)r_n \leq L\underline{r}$.

The condition $\sum_{n=1}^\infty r/r_n < \infty$ is clearly sufficient to break the curse of dimensionality. In that case, even an anisotropic full tensor approximation also breaks the curse of dimensionality.

The algebraic exponent for the convergence of the anisotropic full tensor approximation again deteriorates with the value of $\sum_{n=1}^\infty r/r_n$, but the constant for such convergence is $\sum_{n=1}^N \frac{2}{e^{2r_n} - 1}$. This constant is worse than the one corresponding to the anisotropic Smolyak approximation $\widehat{C}(\mathbf{r}, N)$.

On the other hand, by considering the case where all r_n are equal and the results derived in [57], it can be seen that the algebraic convergence exponent has not be estimated sharply. It is expected that the anisotropic Smolyak method to break the curse of dimensionality for a wider set of problems, i.e., the condition $\sum_{n=1}^\infty r/r_n < \infty$, seems to be unnecessary to break the curse of dimensionality. This is in agreement with Remark 1.

Remark 4 (Optimal choice of weights α). Looking at the exponential term $e^{-h(\mathbf{l}, d)}$, where $h(\mathbf{l}, d) = \sum_{n=1}^N r_n 2^{l_n - 1}$ determining the rate of convergence, the weight α can be chosen as the solution to the optimization problem

$$\max_{\substack{\alpha \in \mathbb{R}_+^N \\ |\alpha|=1}} \min_{\tilde{g}(\mathbf{l}) \leq \alpha L} h(\mathbf{l}, N),$$

where $\tilde{g}(\mathbf{l}) = \sum_{n=1}^N \alpha_n (l_n - 1)$. This problem has the solution $\alpha = \mathbf{r}$, and hence, the choice of weights (21.29) is optimal.

4.3 Nonintrusive Sparse Interpolation in Quasi-optimal Subspaces

The anisotropic sparse grid gSCMs discussed above is an effective approach to alleviate the curse of dimensionality, by adaptively selecting the anisotropic weights based on the size of the analyticity region associated to each random parameter. However, to cover the best M -term polynomial subspace $\mathcal{P}_{\mathcal{J}_M^{\text{opt}}}(\Gamma)$, it is easy to see that the number of degrees of freedom of the sparse grid polynomial subspace $\mathcal{P}_{\mathcal{J}^{m,g}(L)}(\Gamma)$ is much larger than that of the quasi-optimal subspace $\mathcal{P}_{\mathcal{J}_M^{\text{q-opt}}}(\Gamma)$. Therefore, a sparse interpolation approach can be constructed for approximating the solution map $\mathbf{y} \mapsto u_{J_h}(\mathbf{y})$ in the quasi-optimal polynomial subspace $\mathcal{P}_{\mathcal{J}_M^{\text{q-opt}}}(\Gamma)$, by constructing a *nonintrusive* hierarchical interpolant $\mathcal{I}_{\mathcal{J}_M^{\text{q-opt}}}[u]$ on a set of *distinct collocation points* $\mathcal{H}_{\mathcal{J}_M^{\text{q-opt}}}$ given by

$$\mathcal{I}_{\mathcal{J}_M^{\text{q-opt}}}[u] = \sum_{v \in \mathcal{J}_M^{\text{q-opt}}} \bigotimes_{n=1}^N \Delta^{m(v_n)}[u] = \sum_{v \in \mathcal{J}_M^{\text{q-opt}}} \bigotimes_{n=1}^N (\mathcal{U}^{m(v_n)} - \mathcal{U}^{m(v_n-1)})[u] \quad (21.40)$$

and

$$\mathcal{H}_{\mathcal{J}_M^{\text{q-opt}}} = \bigcup_{v \in \mathcal{J}_M^{\text{q-opt}}} \bigotimes_{n=1}^N \{y_{n,k}\}_{k=1}^{m(v_n)}, \quad (21.41)$$

respectively. Here, for $n = 1, \dots, N$, $\mathcal{U}^{m(v_n)} : C^0(\Gamma_n) \rightarrow \mathcal{P}_{m(v_n)-1}(\Gamma_n)$ is a sequence of one-dimensional Lagrange interpolation operators using abscissas $\{y_{n,k}\}_{k=1}^{m(v_n)} \subset \Gamma_n$, with $m(v) : \mathbb{N}_+ \rightarrow \mathbb{N}_+$ a strictly increasing function such that $m(0) = 0$ and $m(v) < m(v+1)$. It is straightforward to construct a multidimensional interpolant that approximates u in the *quasi-optimal* subspace described above, i.e., $\mathcal{I}_{\mathcal{J}_M^{\text{q-opt}}}[u] \in \mathcal{P}_{\mathcal{J}_M^{\text{q-opt}}}(\Gamma)$; however, there are two difficult challenges that must be addressed in order to guarantee that the interpolation error recovers the convergence rate of the quasi-optimal approximation. First, the number of grid points must equal the dimension of the polynomial space, i.e., $\#(\mathcal{H}_{\mathcal{J}_M^{\text{q-opt}}}) = \dim(\mathcal{P}_{\mathcal{J}_M^{\text{q-opt}}}(\Gamma)) = M$, which implies the one-dimensional abscissas must be nested and increase linearly, i.e., $\{y_{n,k}\}_{k=1}^{m(v_n-1)} \subset \{y_{n,k}\}_{k=1}^{m(v_n)}$ for all $n = 1, \dots, N$ and $m(v) = v + 1$. Second, the Lebesgue constant $\mathbb{L}_{\mathcal{J}_M^{\text{q-opt}}}$ must grow slowly with respect to the total number of collocation points, so as to guarantee the accuracy of the interpolation operator $\mathcal{I}_{\mathcal{J}_M^{\text{q-opt}}}$, dictated by the inequality [12, 24, 60]:

$$\begin{aligned} \|u - \mathcal{I}_{\mathcal{J}_M^{\text{q-opt}}}[u]\|_{L^\infty(\Gamma)} &\leq \left(1 + \mathbb{L}_{\mathcal{J}_M^{\text{q-opt}}}\right) \inf_{v \in \mathcal{P}_{\mathcal{J}_M^{\text{q-opt}}}(\Gamma)} \|u - v\|_{L^\infty(\Gamma)} \\ &\leq \left(1 + \mathbb{L}_{\mathcal{J}_M^{\text{q-opt}}}\right) \|u - u_{\mathcal{J}_M^{\text{q-opt}}}\|_{L^\infty(\Gamma)}. \end{aligned} \quad (21.42)$$

Therefore, let $K = m(v_n)$ by suppressing n . Several choices of one-dimensional collocation points $\{y_k\}_{k=1}^K$ can be constructed that satisfy the criteria above. It is worth noting that the Lebesgue constant for the extrema points of the Chebyshev polynomials exhibits slow logarithmic growth, i.e., $\mathcal{O}(\log(K))$; however, evaluating Δ^K requires $2K + 1$ samples, resulting in $\#(\mathcal{H}_{\mathcal{J}_M^{q\text{-opt}}}) \gg M$. Even the nested version of the Chebyshev points, known as the Clenshaw-Curtis abscissas [19, 33, 68], requires $m(l) = 2^{l-1} + 1$, and hence capturing a general polynomial space requires excess interpolation points [41, 57, 58]. Instead, to ensure the sequence of one-dimensional abscissas is nested and grows linearly, greedy search approaches can be exploited, wherein, given the sequence $\{y_k\}_{k=1}^{K-1} = \mathcal{Z}_{K-1}$, the next abscissa is chosen as the extrema of some functional, e.g.,

$$\begin{aligned} \text{(i)} \quad & y_K = \underset{\xi \in \Gamma}{\operatorname{argmax}} \mathcal{R}_{\mathcal{Z}_{K-1}}(\xi), \\ \text{(ii)} \quad & y_K = \underset{\xi \in \Gamma}{\operatorname{argmax}} \mathcal{L}_{\mathcal{Z}_{K-1}}(\xi), \\ \text{(iii)} \quad & y_K = \underset{\xi \in \Gamma}{\operatorname{argmin}} \left[\max_{y \in \Gamma} \mathcal{L}_{\mathcal{Z}_{K-1}, \xi}(y) \right], \end{aligned} \quad (21.43)$$

where (i) is also known as the Leja sequence [9, 17], $\mathcal{R}_{\mathcal{Z}_{K-1}}(\xi) = \prod_{k=1}^{K-1} |\xi - y_k|$ is the residual function, and $\mathcal{L}_{\mathcal{Z}_{K-1}}(\xi)$ is the well-known Lebesgue function [12, 60]. The three separate one-dimensional optimization problems are referred to as (i) ‘‘Leja,’’ (ii) ‘‘Max-Lebesgue,’’ and (iii) ‘‘Min-Lebesgue.’’ Preliminary comparisons of the growth of the Lebesgue constants in $N = 1$ and $N = 2$ dimensions (using the sparse interpolant $\mathcal{I}_{\mathcal{J}_M^{q\text{-opt}}}$ in a total degree polynomial subspace) are given in Fig. 21.5. All three cases exhibit moderate growth of the Lebesgue constant, but theoretical estimates of growth of the Lebesgue constants are still open questions. Finally, it should be noted that the approach of constructing the

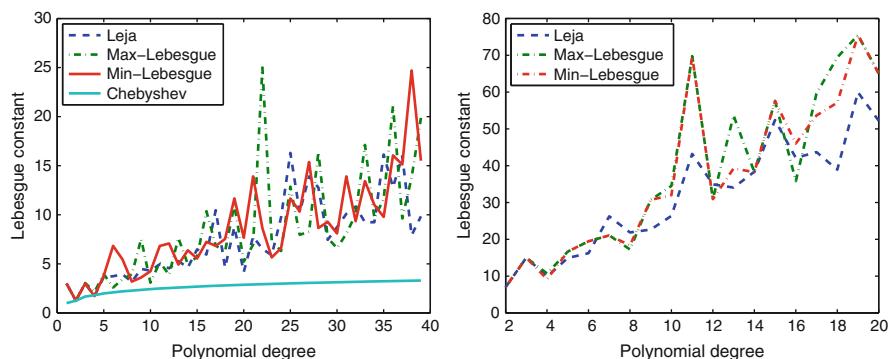

Fig. 21.5 (Left) Comparison between Lebesgue constants for one-dimensional interpolation rules; (right) comparison between Lebesgue constants for two-dimensional interpolation rules constructed by virtue of the quasi-optimal interpolant $\mathcal{I}_{\mathcal{J}_M^{q\text{-opt}}}[\mathbf{u}]$

interpolant $\mathcal{I}_{\mathcal{J}_M^{q,\text{opt}}}[u]$ using sparse tensor products of the one-dimensional abscissas is completely generalizable to N dimensions, whereas extensions of the greedy optimization procedures (i)–(iii) in multidimensions, e.g., the so-called *Magic points* [53], are typically complex, ill-conditioned, and computationally impractical for more than $N = 2$.

5 Local Stochastic Collocation Methods

To realize their high accuracy, the stochastic collocation methods based on the use of global polynomials discussed require high regularity of the solution $u(\mathbf{x}, \mathbf{y})$ with respect to the random parameters $\{y_n\}_{n=1}^N$. They are therefore ineffective for the approximation of solutions that have irregular dependence with respect to those parameters. Motivated by finite element methods (FEMs) for spatial approximation, an alternate and potentially more effective approach for approximating irregular solutions is to use *locally supported piecewise polynomial* approaches for approximating the solution dependence on the random parameters. To achieve greater accuracy, global polynomial approaches increase the polynomial degree; piecewise polynomial approaches instead keep the polynomial degree fixed but refine the grid used to define the approximation space.

5.1 Hierarchical Stochastic Collocation Methods

Several types of one-dimensional piecewise hierarchical polynomial bases [14] are first introduced, which are the foundation of hierarchical sparse grid stochastic collocation methods.

5.1.1 One-Dimensional Piecewise Linear Hierarchical Interpolation

The one-dimensional hat function having support $[-1, 1]$ is defined by

$$\psi(y) = \max\{0, 1 - |y|\}$$

from which an arbitrary hat function with support $(y_{l,i} - \tilde{h}_l, y_{l,i} + \tilde{h}_l)$ can be generated by dilation and translation, i.e.,

$$\psi_{l,i}(y) := \psi\left(\frac{y + 1 - i\tilde{h}_l}{\tilde{h}_l}\right),$$

where l denotes the resolution level, $\tilde{h}_l = 2^{-l+1}$ for $l = 0, 1, \dots$ denotes the grid size of the level l grid for the interval $[-1, 1]$, and $y_{l,i} = i\tilde{h}_l - 1$ for $i = 0, 1, \dots, 2^l$ denotes the grid points of that grid. The basis function $\psi_{l,i}(y)$ has local support and is centered at the grid point $y_{l,i}$; the number of grid points in the level l grid is $2^l + 1$.

With $Z = L^2_\rho(\Gamma)$, a sequence of subspaces $\{Z_l\}_{l=0}^\infty$ of Z of increasing dimension $2^l + 1$ can be defined as

$$Z_l = \text{span}\{\psi_{l,i}(y) \mid i = 0, 1, \dots, 2^l\} \quad \text{for } l = 0, 1, \dots$$

The sequence is dense in Z , i.e., $\cup_{l=0}^\infty Z_l = Z$, and nested, i.e.,

$$Z_0 \subset Z_1 \subset \dots \subset Z_l \subset Z_{l+1} \subset \dots \subset Z.$$

Each of the subspaces $\{Z_l\}_{l=0}^\infty$ is the standard finite element subspace of continuous piecewise linear polynomial functions on $[-1, 1]$ that is defined with respect to the grid having grid size \tilde{h}_l . The set $\{\psi_{l,i}(y)\}_{i=0}^{2^l}$ is the standard nodal basis for the space Z_l .

An alternative to the nodal basis $\{\psi_{l,i}(y)\}_{i=0}^{2^l}$ for Z_l is a *hierarchical* basis, the construction of which starts with the hierarchical index sets

$$B_l = \{i \in \mathbb{N} \mid i = 1, 3, 5, \dots, 2^l - 1\} \quad \text{for } l = 1, 2, \dots$$

and the sequence of hierarchical subspaces defined by

$$W_l = \text{span}\{\psi_{l,i}(y) \mid i \in B_l\} \quad \text{for } l = 1, 2, \dots$$

Due to the nesting property of $\{Z_l\}_{l=0}^\infty$, it is easy to see that $Z_l = Z_{l-1} \oplus W_l$ and $W_l = Z_l / \bigoplus_{l'=0}^{l-1} Z_{l'}$ for $l = 1, 2, \dots$. Then, the hierarchical subspace splitting of Z_l is given by

$$Z_l = Z_0 \oplus W_1 \oplus \dots \oplus W_l \quad \text{for } l = 1, 2, \dots$$

Then, the *hierarchical basis* for Z_l is given by

$$\{\psi_{0,0}(y), \psi_{0,1}(y)\} \cup \left(\cup_{l'=1}^l \{\psi_{l',i}(y)\}_{i \in B_{l'}} \right). \quad (21.44)$$

It is easy to verify that, for each l , the subspaces spanned by the hierarchical and the nodal basis bases are the same, i.e., they are both bases for Z_l .

The nodal basis $\{\psi_{L,i}(y)\}_{i=0}^{2^L}$ for Z_L possesses the delta property, i.e., $\psi_{L,i}(y_{L,i'}) = \delta_{i,i'}$ for $i, i' \in \{0, \dots, 2^L\}$. The hierarchical basis (21.44) for Z_L possesses only a partial delta property; specifically, the basis functions corresponding to a specific level possess the delta property with respect to its own level and coarser levels, but not with respect to finer levels, i.e., for $l = 0, 1, \dots, L$ and $i \in B_L$,

$$\begin{aligned} \text{for } 0 \leq l' < l, \quad & \psi_{l,i}(y_{l',i'}) = 0 && \text{for all } i' \in B_{l'} \\ \text{for } l' = l, \quad & \psi_{l,i}(y_{l,i'}) = \delta_{i,i'} && \text{for all } i' \in B_{l'} \\ \text{for } l < l' \leq L, \quad & \psi_{l,i}(y_{l',i'}) \neq 0 && \text{for all } i' \in B_{l'} \end{aligned} \quad (21.45)$$

A comparison between the linear hierarchical polynomial basis and the corresponding nodal basis for $L = 3$ is given in Fig. 21.6.

For each grid level l , the interpolant of a function $g(y)$ in the subspace Z_l in terms of its nodal basis $\{\psi_{l,i}(y)\}_{i=0}^{2^l}$ is given by

$$\mathcal{I}_l(g(y)) = \sum_{i=0}^{2^l} g(y_{l,i}) \psi_{l,i}(y). \quad (21.46)$$

Due to the nesting property $Z_l = Z_{l-1} \oplus W_l$, it is easy to see that $\mathcal{I}_{l-1}(g) = \mathcal{I}_l(\mathcal{I}_{l-1}(g))$, based on which the incremental interpolation operator is defined by

$$\begin{aligned} \Delta_l(g) &= \mathcal{I}_l(g) - \mathcal{I}_{l-1}(g) = \mathcal{I}_l(g - \mathcal{I}_{l-1}(g)) \\ &= \sum_{i=0}^{2^l} [g(y_{l,i}) - \mathcal{I}_{l-1}(g)(y_{l,i})] \psi_{l,i}(y) \\ &= \sum_{i \in B_l} [g(y_{l,i}) - \mathcal{I}_{l-1}(g)(y_{l,i})] \psi_{l,i}(y) = \sum_{i \in B_l} c_{l,i} \psi_{l,i}(y), \end{aligned} \quad (21.47)$$

where $c_{l,i} = g(y_{l,i}) - \mathcal{I}_{l-1}(g)(y_{l,i})$. Note that $\Delta_l(g)$ only involves the basis functions for W_l for $l \geq 1$. Because $\Delta_l(g)$ essentially approximates the difference between g and the interpolant $\mathcal{I}_{l-1}(g)$ on level $l-1$, the coefficients $\{c_{l,i}\}_{i \in B_l}$ are referred to as the *surpluses* on level l .

The interpolant $\mathcal{I}_l(g)$ for any level $l > 0$ can be decomposed in the form

$$\mathcal{I}_l(g) = \mathcal{I}_{l-1}(g) + \Delta_l(g) = \dots = \mathcal{I}_0(g) + \sum_{l'=1}^l \Delta_{l'}(g). \quad (21.48)$$

The delta property of the nodal basis implies that the interpolation matrix is diagonal. The interpolation matrix for the hierarchical basis is not diagonal, but the partial delta property (21.45) implies that it is triangular so that the coefficients in the interpolant can be solved for explicitly. This also can be seen from the definition (21.47) for $\Delta_l(\cdot)$ and the recursive form of $\mathcal{I}_l(\cdot)$ in (21.48) for which the surpluses can be computed explicitly.

5.1.2 Multidimensional Hierarchical Sparse Grid Interpolation

The interpolation of a multivariate function $g(\mathbf{y})$ is defined, again without loss of generality, over the unit hypercube $\Gamma = [-1, 1]^N \subset \mathbb{R}^N$. The one-dimensional hierarchical polynomial basis (21.44) can be extended to the N -dimensional parameter domain Γ using tensorization. Specifically, the N -variate basis function $\psi_{\mathbf{l},\mathbf{i}}(\mathbf{y})$ associated with the point $\mathbf{y}_{\mathbf{l},\mathbf{i}} = (y_{l_1,i_1}, \dots, y_{l_N,i_N})$ is defined using tensor products, i.e.,

$$\psi_{\mathbf{l},\mathbf{i}}(\mathbf{y}) := \prod_{n=1}^N \psi_{l_n,i_n}(y_n),$$

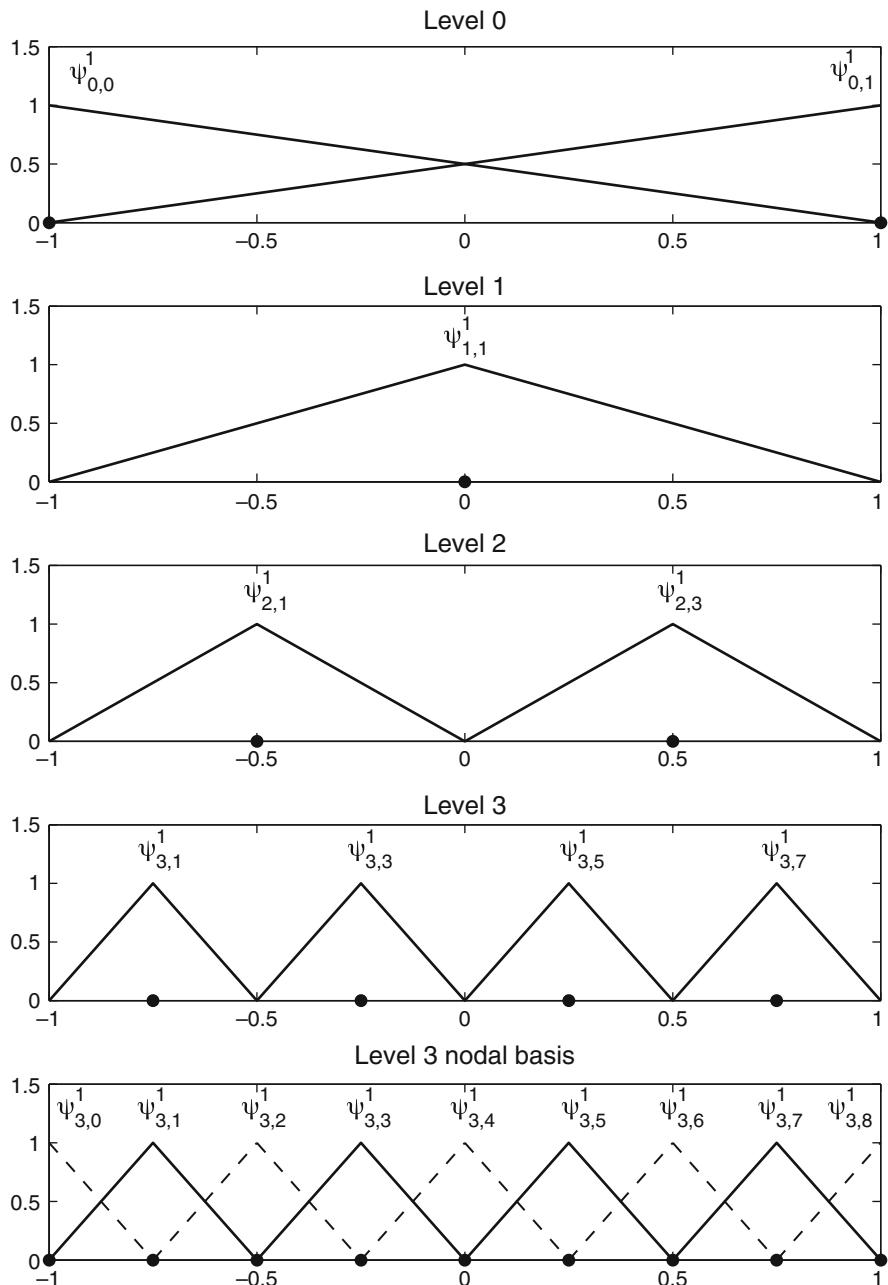

Fig. 21.6 Piecewise linear polynomial bases for $L = 3$. Top four rows: the basis functions for Z_0 , W_1 , W_2 , and W_3 , respectively; the hierarchical basis for Z_3 is the union of the functions in the top four rows. Bottom row: the nodal basis for Z_3

where $\{\psi_{l_n, i_n}(y_n)\}_{n=1}^N$ are the one-dimensional hierarchical polynomials associated with the point $y_{l_n, i_n} = i_n \tilde{h}_{l_n} - 1$ with $\tilde{h}_{l_n} = 2^{-l_n+1}$ and $\mathbf{l} = (l_1, \dots, l_N)$ is a multi-index indicating the resolution level of the basis function. The N -dimensional hierarchical incremental subspace $W_{\mathbf{l}}$ is defined by

$$W_{\mathbf{l}} = \bigotimes_{n=1}^N W_{l_n} = \text{span} \{ \psi_{\mathbf{l}, \mathbf{i}}(\mathbf{y}) \mid \mathbf{i} \in B_{\mathbf{l}} \},$$

where the multi-index set $B_{\mathbf{l}}$ is given by

$$B_{\mathbf{l}} := \left\{ \mathbf{i} \in \mathbb{N}^N \mid \begin{array}{ll} i_n \in \{1, 3, 5, \dots, 2^{l_n} - 1\} & \text{for } n = 1, \dots, N \quad \text{if } l_n > 0 \\ i_n \in \{0, 1\} & \text{for } n = 1, \dots, N \quad \text{if } l_n = 0 \end{array} \right\}.$$

Similar to the one-dimensional case, a sequence of subspaces, again denoted by $\{Z_l\}_{l=0}^{\infty}$, of the space $Z := L^2(\Gamma)$, can be constructed as

$$Z_l = \bigoplus_{l'=0}^l W_{l'} = \bigoplus_{l'=0}^l \bigoplus_{\alpha(\mathbf{l}')=l'} W_{l'},$$

where the key is how the mapping $\alpha(\mathbf{l})$ is defined because it defines the incremental subspaces $W_{l'} = \bigoplus_{\alpha(\mathbf{l}')=l'} W_{l'}$. For example, $\alpha(\mathbf{l}) = \max_{n=1, \dots, N} l_n$ leads to a full tensor-product space, whereas $\alpha(\mathbf{l}) = |\mathbf{l}| = l_1 + \dots + l_N$ leads to a sparse polynomial space. As the full tensor-product space especially suffers from the curse of dimensionality as N increases, this choice is not feasible for even moderately high-dimensional problems. Thus, it is only considered the case that the sparse polynomial space obtained by setting $\alpha(\mathbf{l}) = |\mathbf{l}|$.

The level l hierarchical sparse grid interpolant of the multivariate function $g(\mathbf{y})$ is then given by

$$\begin{aligned} g_l(\mathbf{y}) &:= \sum_{l'=0}^l \sum_{|\mathbf{l}'|=l'} (\Delta_{l'_1} \otimes \dots \otimes \Delta_{l'_N}) g(\mathbf{y}) \\ &= g_{l-1}(\mathbf{y}) + \sum_{|\mathbf{l}'|=l} (\Delta_{l'_1} \otimes \dots \otimes \Delta_{l'_N}) g(\mathbf{y}) \\ &= g_{l-1}(\mathbf{y}) + \sum_{|\mathbf{l}'|=l} \sum_{\mathbf{i} \in B_{\mathbf{l}'}} [g(\mathbf{y}_{\mathbf{l}', \mathbf{i}}) - g_{l'-1}(\mathbf{y}_{\mathbf{l}', \mathbf{i}})] \psi_{\mathbf{l}', \mathbf{i}}(\mathbf{y}) \\ &= g_{l-1}(\mathbf{y}) + \sum_{|\mathbf{l}'|=l} \sum_{\mathbf{i} \in B_{\mathbf{l}'}} c_{\mathbf{l}', \mathbf{i}} \psi_{\mathbf{l}', \mathbf{i}}(\mathbf{y}), \end{aligned} \tag{21.49}$$

where $c_{\mathbf{l}', \mathbf{i}} = g(\mathbf{y}_{\mathbf{l}', \mathbf{i}}) - g_{l'-1}(\mathbf{y}_{\mathbf{l}', \mathbf{i}})$ is the multidimensional hierarchical surplus. This interpolant is a direct extension, via the Smolyak algorithm, of the one-dimensional

hierarchical interpolant. Analogous to (21.47), the definition of the surplus $c_{\mathbf{l}', \mathbf{i}}$ is based on the facts that $g_l(g_{l-1}(\mathbf{y})) = g_{l-1}(\mathbf{y})$ and $g_{l-1}(\mathbf{y}_{\mathbf{l}', \mathbf{i}}) - g(\mathbf{y}_{\mathbf{l}', \mathbf{i}}) = 0$ for $|\mathbf{l}'| = l$. In this case, $\mathcal{H}_{\mathbf{l}}(\Gamma) = \{\mathbf{y}_{\mathbf{l}, \mathbf{i}} \mid \mathbf{i} \in B_{\mathbf{l}}\}$ denotes the set of sparse grid points corresponding to subspace $W_{\mathbf{l}}$. Then, the sparse grid corresponding to the interpolant g_l is given by

$$\mathcal{H}_l^N(\Gamma) = \cup_{l'=0}^l \cup_{|\mathbf{l}'|=l'} \mathcal{H}_{\mathbf{l}'}(\Gamma),$$

and $\mathcal{H}_l^N(\Gamma)$ is also nested, i.e., $\mathcal{H}_{l-1}^N(\Gamma) \subset \mathcal{H}_l^N(\Gamma)$. In Fig. 21.7, the structure of a level $l = 2$ sparse grid is plotted in $N = 2$ dimensions, without consideration of boundary points. The left nine sub-grids $\mathcal{H}_{\mathbf{l}'}(\Gamma)$ correspond to the nine multi-index sets $B_{\mathbf{l}'}$, where

$$\mathbf{l}' \in \{(0, 0), (0, 1), (0, 2), (1, 0), (1, 1), (1, 2), (2, 0), (2, 1), (2, 2)\}.$$

The level $l = 2$ sparse grid $\mathcal{H}_2^2(\Gamma)$ shown on the right-top includes only six of the nine sub-grids, with the three sub-grids depicted in gray not included because they fail the criterion $|\mathbf{l}'| \leq l' = 2$. Moreover, due to the nesting property of the

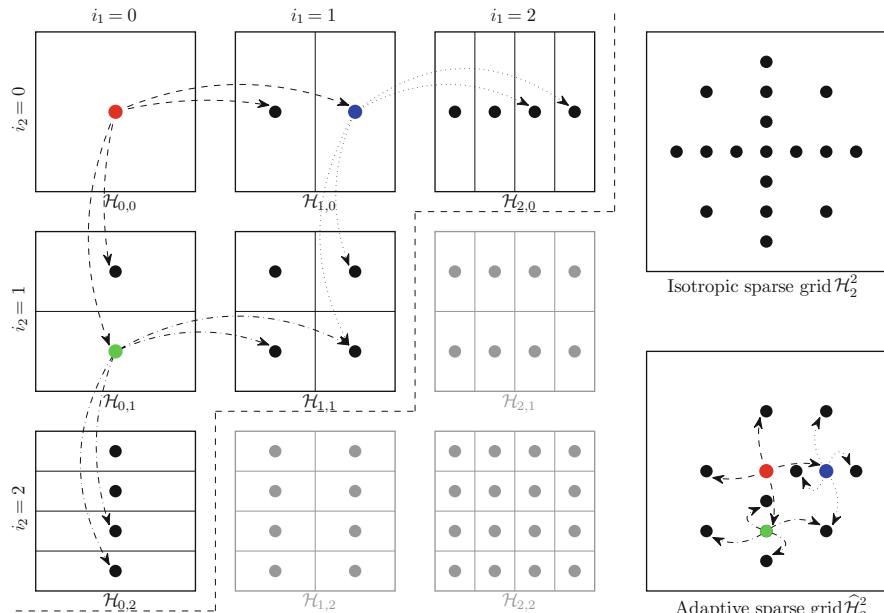

Fig. 21.7 Nine tensor-product sub-grids (left) for level $l = 0, 1, 2$ of which only the 6 sub-grids for which $l'_1 + l'_2 \leq l = 2$ are chosen to appear in the level $l = 2$ isotropic sparse grid $\mathcal{H}_2^2(\Gamma)$ (right-top) containing 17 points. With adaptivity, only points that correspond to a large surplus, i.e., the points in red, blue, and green, lead to 2 children points added in each direction resulting in the adaptive sparse grid $\tilde{\mathcal{H}}_2^2(\Gamma)$ (right-bottom) containing 12 points

hierarchical basis, $\mathcal{H}_2^2(\Gamma)$ has only 17 points, as opposed to the 49 points of the full tensor-product grid.

5.1.3 Hierarchical Sparse Grid Stochastic Collocation

Now the hierarchical sparse grid interpolation is used to approximate the parameter dependence of the solution $u(\mathbf{x}, \mathbf{y})$ of an SPDE. Specifically, the basis $\{\psi_m(\mathbf{y})\}_{m=1}^M$ entering into the fully discrete approximation (21.10) is chosen to be the hierarchical basis. In this case, the fully discrete approximate solution takes the form

$$u_{J_h M_L}(\mathbf{x}, \mathbf{y}) = \sum_{l=0}^L \sum_{|\mathbf{l}|=l} \sum_{\mathbf{i} \in B_l} c_{\mathbf{l}, \mathbf{i}}(\mathbf{x}) \psi_{\mathbf{l}, \mathbf{i}}(\mathbf{y}), \quad (21.50)$$

where now the coefficients are functions of \mathbf{x} to reflect that dependence of the function $u_{J_h M_L}(\mathbf{x}, \mathbf{y})$. In the usual manner, those coefficients are given in terms of the spatial finite element basis $\{\phi_j(\mathbf{x})\}_{j=1}^{J_h}$ by $c_{\mathbf{l}, \mathbf{i}}(\mathbf{x}) = \sum_{j=1}^{J_h} c_{j, \mathbf{l}, \mathbf{i}} \phi_j(\mathbf{x})$ so that, from (21.50), it can be obtained that

$$\begin{aligned} u_{J_h M_L}(\mathbf{x}, \mathbf{y}) &= \sum_{l=0}^L \sum_{|\mathbf{l}|=l} \sum_{\mathbf{i} \in B_l} \left(\sum_{j=1}^{J_h} c_{j, \mathbf{l}, \mathbf{i}} \phi_j(\mathbf{x}) \right) \psi_{\mathbf{l}, \mathbf{i}}(\mathbf{y}) \\ &= \sum_{j=1}^{J_h} \left(\sum_{l=0}^L \sum_{|\mathbf{l}|=l} \sum_{\mathbf{i} \in B_l} c_{j, \mathbf{l}, \mathbf{i}} \psi_{\mathbf{l}, \mathbf{i}}(\mathbf{y}) \right) \phi_j(\mathbf{x}). \end{aligned} \quad (21.51)$$

The number of parameter degrees of freedom M_L of $u_{J_h M_L}$ is equal to the number of the grid points of the sparse grid $\mathcal{H}_L^N(\Gamma)$.

The next step is to introduce how the coefficients $c_{j, \mathbf{l}, \mathbf{i}}$ in (21.51) are determined. In general, after running the deterministic FEM solver for all the sparse grid points, the dataset are obtained

$$u_h(\mathbf{x}_j, \mathbf{y}_{\mathbf{l}, \mathbf{i}}) \quad \text{for } j = 1, \dots, J_h \text{ and } |\mathbf{l}| \leq L, \mathbf{i} \in B_l.$$

Then, it is easy to see from (21.51) that, for fixed j , $\{c_{j, \mathbf{l}, \mathbf{i}}\}_{|\mathbf{l}| \leq L, \mathbf{i} \in B_l}$ can be obtained by solving the linear system

$$\begin{aligned} u_{J_h M_L}(\mathbf{x}_j, \mathbf{y}_{\mathbf{l}', \mathbf{i}'}) &= \sum_{l=0}^L \sum_{|\mathbf{l}|=l} \sum_{\mathbf{i} \in B_l} c_{j, \mathbf{l}, \mathbf{i}} \psi_{\mathbf{l}, \mathbf{i}}(\mathbf{y}_{\mathbf{l}', \mathbf{i}'}) \\ &= u_{N_h}(\mathbf{x}_j, \mathbf{y}_{\mathbf{l}', \mathbf{i}'}) \quad \text{for } |\mathbf{l}'| \leq L, \mathbf{i}' \in B_l. \end{aligned} \quad (21.52)$$

Thus, the approximation $u_{J_h M_L}(\mathbf{x}, \mathbf{y})$ can be obtained by solving J_h linear systems. However, because the hierarchical bases $\psi_{\mathbf{l}, \mathbf{i}}(\mathbf{y})$ satisfies $\psi_{\mathbf{l}, \mathbf{i}}(\mathbf{y}_{\mathbf{l}', \mathbf{i}'}) = 0$ if $l' \leq l$ (this is a consequence of the one-dimensional partialdelta property), the coefficient

$c_{j,\mathbf{l}',\mathbf{i}'}$ in the system (21.52) corresponding to the sparse grid point $\mathbf{y}_{\mathbf{l}',\mathbf{i}'}$ on level L , i.e., for $|\mathbf{l}'| = L$, reduces to

$$\begin{aligned} c_{j,\mathbf{l}',\mathbf{i}'} &= u_{N_h}(\mathbf{x}_j, \mathbf{y}_{\mathbf{l}',\mathbf{i}'}) - \sum_{l=0}^{L-1} \sum_{|\mathbf{l}|=l} \sum_{\mathbf{i} \in B_l} c_{j,\mathbf{l},\mathbf{i}} \psi_{\mathbf{l},\mathbf{i}}(\mathbf{y}_{\mathbf{l}',\mathbf{i}'}) \\ &= u_{N_h}(\mathbf{x}_j, \mathbf{y}_{\mathbf{l}',\mathbf{i}'}) - u_{J_h M_{L-1}}(\mathbf{x}_j, \mathbf{y}_{\mathbf{l}',\mathbf{i}'}), \end{aligned} \quad (21.53)$$

so that linear system becomes a triangular system and all the coefficients can be computed explicitly by recursively using the (21.53). Note that (21.53) is consistent with the definition of the $c_{\mathbf{l},\mathbf{i}}(\mathbf{x})$ given in (21.49).

5.2 Adaptive Hierarchical Stochastic Collocation Methods

By virtue of the hierarchical surpluses $c_{j,\mathbf{l},\mathbf{i}}$, the approximation in (21.51) can be represented in a hierarchical manner, i.e.,

$$u_{J_h M_L}(\mathbf{x}, \mathbf{y}) = u_{J_h M_{L-1}}(\mathbf{x}, \mathbf{y}) + \Delta u_{J_h M_L}(\mathbf{x}, \mathbf{y}), \quad (21.54)$$

where $u_{J_h M_{L-1}}(\mathbf{x}, \mathbf{y})$ is the sparse grid approximation in Z_{L-1} and $\Delta u_{J_h M_L}(\mathbf{x}, \mathbf{y})$ is the hierarchical surplus interpolant in the subspace W_L . According to the analysis in [14], for smooth functions, the surpluses $c_{j,\mathbf{l},\mathbf{i}}$ of the sparse grid interpolant $u_{J_h M_L}$ in (21.51) tend to zero as the interpolation level l goes to infinity. For example, in the context of using piecewise linear hierarchical bases and assuming the spatial approximation $u_{N_h}(\mathbf{x}, \mathbf{y})$ of the solution has bounded second-order weak derivatives with respect to \mathbf{y} , i.e., $u_{N_h}(\mathbf{x}, \mathbf{y}) \in W_h(D) \otimes H_\rho^2(\Gamma)$, then the surplus $c_{j,\mathbf{l},\mathbf{i}}$ can be bounded as

$$|c_{j,\mathbf{l},\mathbf{i}}| \leq C 2^{-2|\mathbf{l}|} \quad \text{for } \mathbf{i} \in B_l \text{ and } j = 1, \dots, J_h, \quad (21.55)$$

where the constant C is independent of the level l . Furthermore, the smoother the target function is, the faster the surplus decays. This provides a good avenue for constructing adaptive sparse grid interpolants using the magnitude of the surplus as an error indicator, especially for irregular functions having, e.g., steep slopes or jump discontinuities.

The construction of one-dimensional adaptive grids is first introduced, and then such strategy for adaptivity will be extended to multidimensional sparse grids. As shown in Fig. 21.8, the one-dimensional hierarchical grid points have a treelike structure. In general, a grid point $y_{l,i}$ on level l has two children, namely, $y_{l+1,2i-1}$ and $y_{l+1,2i+1}$ on level $l+1$. Special treatment is required when moving from level 0 to level 1, where only one single child $y_{1,1}$ is added on level 1. On each successive interpolation level, the basic idea of adaptivity is to use the hierarchical surplus as an error indicator to detect the smoothness of the target function and refine

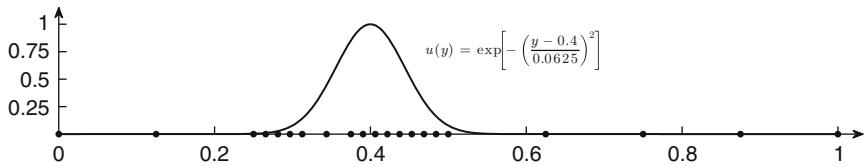

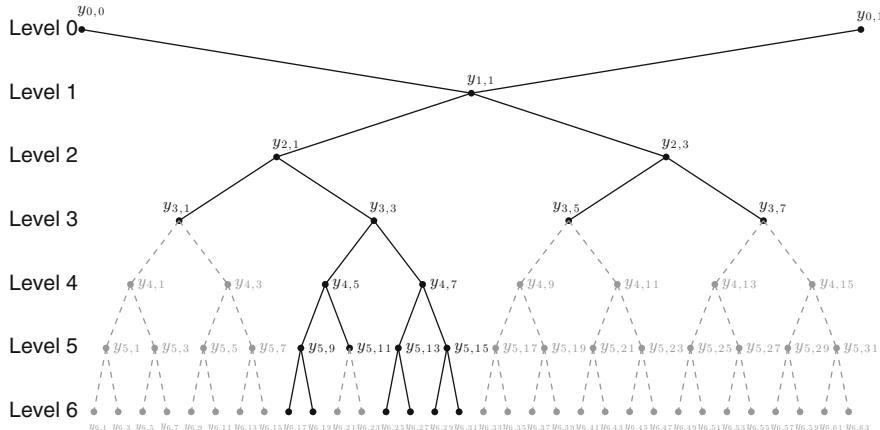

Fig. 21.8 A 6-level adaptive sparse grid for interpolating the one-dimensional function $g(y) = \exp[-(y - 0.4)^2 / 0.0625^2]$ on $[0, 1]$ with the error tolerance of 0.01. The resulting adaptive sparse grid has only 21 points (the black points), whereas the full grid has 65 points (the black and gray points)

the grid by adding two new points on the next level for each point for which the magnitude of the surplus is larger than the prescribed error tolerance. For example, in Fig. 21.8, the 6-level adaptive grid is illustrated for interpolating the function $g(y) = \exp[-(y - 0.4)^2 / 0.0625^2]$ on $[0, 1]$ with error tolerance 0.01. From level 0 to level 2, because the magnitude of every surplus is larger than 0.01, two points are added for each grid point on levels 0 and 2; as mentioned above, only one point is added for each grid point on level 1. However, on level 3, there is only 1 point, namely, $y_{3,3}$, whose surplus has a magnitude larger than 0.01, so only two new points are added on level 4. After adding levels 5 and 6, it ends up with the 6-level adaptive grid with only 21 points (points in black in Fig. 21.8), whereas the 6-level nonadaptive grid has a total of 65 points (points in black and gray in Fig. 21.8).

It is trivial to extend this adaptive approach from one-dimension to a multidimensional adaptive sparse grid. In general, as shown in Fig. 21.7, in N -dimensions a grid point has $2N$ children which are also its neighbor points. However, note that the children of a parent point correspond to hierarchical basis functions on the next interpolation level, so that the interpolant $u_{J_h M_L}$ in (21.51) can be built from level $L - 1$ to level L by only adding those points on level L whose parents have surpluses greater than the prescribed tolerance. At each sparse grid point $\mathbf{y}_{l,i}$,

the error indicator is set to the maximum magnitude of the j surpluses, i.e., to $\max_{j=1,\dots,J_h} |c_{j,l,i}|$. In this way, the sparse grid can be refined locally, resulting in an adaptive sparse grid which is a sub-grid of the corresponding isotropic sparse grid, as illustrated by the right-bottom plot in Fig. 21.7. The solution of the corresponding adaptive hSGSC approach is represented by

$$u_{J_h M_L}^\varepsilon(\mathbf{x}, \mathbf{y}) = \sum_{l=0}^L \sum_{|\mathbf{i}|=l} \sum_{\mathbf{i} \in B_1^\varepsilon} \left(\sum_{j=1}^{J_h} c_{j,l,i} \phi_j(\mathbf{x}) \right) \psi_{l,i}(\mathbf{y}), \quad (21.56)$$

where the multi-index set $B_1^\varepsilon \subset B_1$ is defined by

$$B_1^\varepsilon = \left\{ \mathbf{i} \in B_1 \mid \max_{j=1,\dots,J_h} |c_{j,l,i}| \geq \varepsilon \right\}.$$

Note that B_1^ε is an optimal multi-index set that contains only the indices of the basis functions with surplus magnitudes larger than the tolerance ε . However, in practice, the deterministic FEM solver needs to be executed at a certain number of grid points $y_{l,i}$ with $\max_{j=1,\dots,J_h} |c_{j,l,i}| < \varepsilon$ in order to detect when mesh refinement can stop. For example, in Fig. 21.8, the points $y_{3,1}$, $y_{3,5}$, $y_{3,7}$, and $y_{5,11}$ are this type of points. In this case, the numbers of degrees of freedom in (21.56) is usually smaller than the necessary number of executions of the deterministic FEM solver.

5.2.1 Other Choices of Hierarchical Basis

High-Order Hierarchical Polynomial Basis

One can generalize the piecewise linear hierarchical polynomials to high-order hierarchical polynomials [14]. The goal is to construct polynomial basis functions of order p , denoted by $\psi_{l,i}^p(y)$, without enlarging the support $[y_{l,i} - \tilde{h}_l, y_{l,i} + \tilde{h}_l]$ or increasing the degrees of freedom in the support. As shown in Fig. 21.6, for $l \geq 0$, a piecewise linear polynomial $\psi_{l,i}(y)$ is defined based on 3 supporting points, i.e., $\tilde{y}_{l,i}$ and its two ancestors that are also the endpoints of the support $[y_{l,i} - \tilde{h}_l, y_{l,i} + \tilde{h}_l]$. For $p \geq 2$, it is well known that $p+1$ supporting points are needed to define a Lagrange interpolating polynomial of order p . To achieve the goal, at each grid point $y_{l,i}$, additional ancestors outside of $[y_{l,i} - \tilde{h}_l, y_{l,i} + \tilde{h}_l]$ are borrowed to help build a higher-order Lagrange polynomial; then, the desired polynomial $\psi_{l,i}^p(y)$ is defined by restricting the resulting polynomial to the support $[y_{l,i} - \tilde{h}_l, y_{l,i} + \tilde{h}_l]$. The constructions of the cubic polynomial $\psi_{2,3}^3(y)$ and the quartic polynomial $\psi_{3,1}^4(y)$ are illustrated in Fig. 21.9 (right). For the cubic polynomial associated with $y_{2,3}$, the additional ancestor $y_{0,0}$ is needed to define a cubic Lagrange polynomial; for the quartic polynomial associated with $y_{3,1}$, two more ancestors $y_{1,1}$ and $y_{0,1}$ are added. After the construction of the cubic and quartic polynomials, the part within the support (solid curves) is retained, and the parts outside the support (dashed curves) are cut off. Using this strategy, high-order bases can be constructed, while

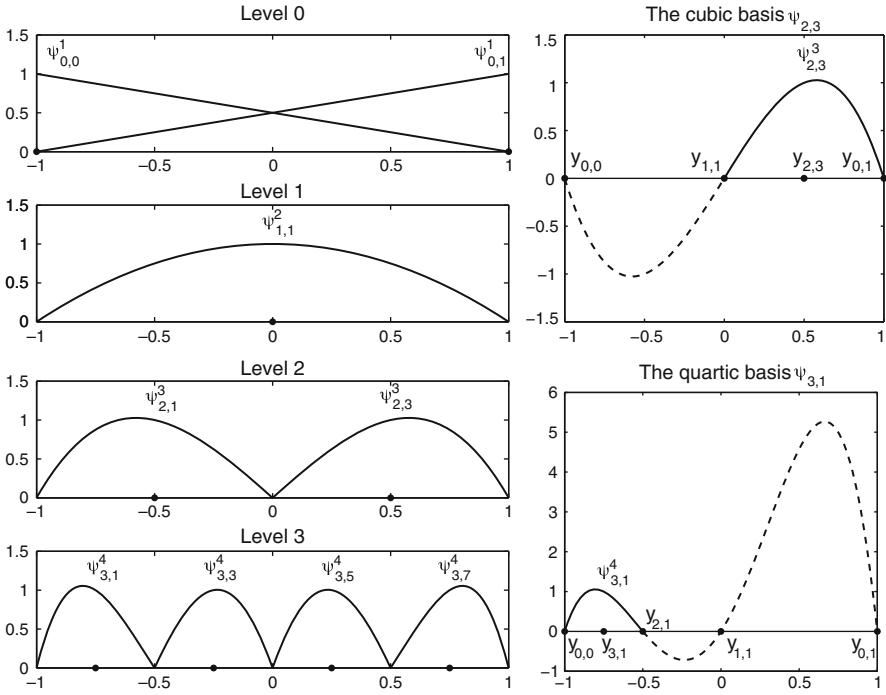

Fig. 21.9 Left: quartic hierarchical basis functions, where linear, quadratic, and cubic basis functions are used on levels 0, 1, and 2, respectively. Quartic basis functions appear beginning with level 3. Right: the construction of a cubic hierarchical basis function and a quartic hierarchical basis function, respectively

the hierarchical structure can be retained. It should be noted that because a total of p ancestors are needed, a polynomial of order p cannot be defined earlier than level $p - 1$. In other words, at level L , the maximum order of polynomials is $p = L + 1$. For example, a quartic polynomial basis of level 3 is plotted in Fig. 21.9 (left) where linear, quadratic, and cubic polynomials are used on levels 0, 1, and 2 due to the lack of ancestors. It is observed that there are multiple types of basis functions on each level when $p \geq 3$ because of the different distributions of supporting points for different grid points. In general, the hierarchical basis of order $p > 1$ contains 2^{p-2} types of p -th order polynomials. In Table 21.1, the supporting points used to define the hierarchical polynomial bases of order $p = 2, 3, 4$ are listed.

Wavelet Basis

Besides the hierarchical bases discussed above, wavelets form another important family of basis functions which can provide a stable subspace splitting because of their Riesz property. The second-generation wavelets, constructed using the lifting scheme discussed in [63, 64], will be briefly introduced in the following. Second-generation wavelets are a generalization of biorthogonal wavelets that are easier

Table 21.1 Supporting points for high-order hierarchical bases ($p = 2, 3, 4$)

Order	Grid point $y_{l,i}$	Supporting points of $\psi_{l,i}^p(y)$
$p = 2$	$l \geq 1, \text{ mod } (i, 2) = 1$	$y_{l,i} - \tilde{h}_l, y_{l,i}, y_{l,i} + \tilde{h}_l$
	$l \geq 2, \text{ mod } (i, 4) = 1$	$y_{l,i} - \tilde{h}_l, y_{l,i}, y_{l,i} + \tilde{h}_l, y_{l,i} + 3\tilde{h}_l$
$p = 3$	$l \geq 2, \text{ mod } (i, 4) = 3$	$y_{l,i} - 3\tilde{h}_l, y_{l,i} - \tilde{h}_l, y_{l,i}, y_{l,i} + \tilde{h}_l$
	$l \geq 3, \text{ mod } (i, 8) = 1$	$y_{l,i} - \tilde{h}_l, y_{l,i}, y_{l,i} + \tilde{h}_l, y_{l,i} + 3\tilde{h}_l, y_{l,i} + 7\tilde{h}_l$
	$l \geq 3, \text{ mod } (i, 8) = 3$	$y_{l,i} - 3\tilde{h}_l, y_{l,i} - \tilde{h}_l, y_{l,i}, y_{l,i} + \tilde{h}_l, y_{l,i} + 5\tilde{h}_l$
$p = 4$	$l \geq 3, \text{ mod } (i, 8) = 5$	$y_{l,i} - 5\tilde{h}_l, y_{l,i} - \tilde{h}_l, y_{l,i}, y_{l,i} + \tilde{h}_l, y_{l,i} + 3\tilde{h}_l$
	$l \geq 3, \text{ mod } (i, 8) = 7$	$y_{l,i} - 7\tilde{h}_l, y_{l,i} - 3\tilde{h}_l, y_{l,i} - \tilde{h}_l, y_{l,i}, y_{l,i} + \tilde{h}_l$

to apply for functions defined on bounded domains. The lifting scheme [63, 64] is a tool for constructing second-generation wavelets that are no longer dilates and translates of a single scaling function. The basic idea behind lifting is to start with simple multi-resolution analysis and gradually build a multi-resolution analysis with specific, a priori defined properties. The lifting scheme can be viewed as a process of taking an existing wavelet and modifying it by adding linear combinations of the scaling function at the coarse level. In the context of the piecewise linear basis, the second-generation wavelet on level $l \geq 1$, denoted by $\psi_{l,i}^w(y)$, is constructed by “lifting” the piecewise linear basis $\psi_{l,i}(y)$ as

$$\psi_{l,i}^w(y) := \psi_{l,i}(y) + \sum_{i'=0}^{2^l-1} \beta_{l,i}^{i'} \psi_{l-1,i'}(y),$$

where, for $i = 0, \dots, 2^l-1$, $\psi_{l-1,i}(y)$ are the nodal polynomials on level $l-1$ and the weights $\beta_{l,i}^{i'}$ in the linear combination are chosen in such a way that the wavelet $\psi_{l,i}^w(y)$ has more vanishing moments than $\psi_{l,i}(y)$ and thus provides a stabilization effect. Specifically, in the bounded domain $[-1, 1]$, there are three types of linear lifting wavelets:

$$\begin{aligned} \psi_{l,i}^w &:= \psi_{l,i} - \frac{1}{4}\psi_{l-1,\frac{i-1}{2}} - \frac{1}{4}\psi_{l-1,\frac{i+1}{2}} & \text{for } 1 < i < 2^l - 1, \text{ } i \text{ odd} \\ \psi_{l,i}^w &:= \psi_{l,i} - \frac{3}{4}\psi_{l-1,\frac{i-1}{2}} - \frac{1}{8}\psi_{l-1,\frac{i+1}{2}} & \text{for } i = 1 \\ \psi_{l,i}^w &:= \psi_{l,i} - \frac{1}{8}\psi_{l-1,\frac{i-1}{2}} - \frac{3}{4}\psi_{l-1,\frac{i+1}{2}} & \text{for } i = 2^l - 1, \end{aligned} \quad (21.57)$$

where the three equations define the central “mother” wavelet, the left-boundary wavelet, and the right-boundary wavelet, respectively. The three lifting wavelets are plotted in Fig. 21.10. For additional details, see [63].

Note that the property given in (21.45) is not valid for the lifting wavelets in (21.57) because neighboring wavelets at the same level have overlapping support. As a result, the coefficient matrix of the linear system (21.52) is no longer triangular.

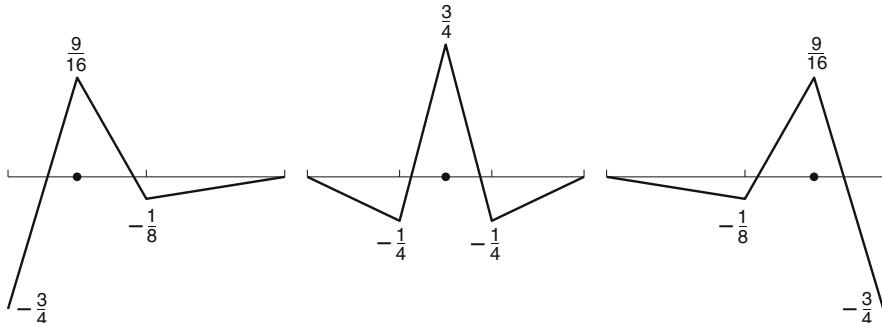

Fig. 21.10 Left-boundary wavelet (*left*), central wavelet (*middle*), right-boundary wavelet (*right*)

Thus, J_h linear systems, each of size $M_L \times M_L$, need be solved to obtain the surpluses in (21.51). However, note that for the second-generation wavelet defined in (21.57), the interpolation matrix is well conditioned. See [40] for details.

6 Conclusion

This chapter provides an overview of the stochastic collocation methods for PDEs with random input data. To alleviate the curse of dimensionality, sparse global polynomial subspaces and local hierarchical polynomial subspaces are incorporated into the framework of SCMs. By exploiting the inherent regularity of PDE solutions with respect to random parameters, the global SCMs can essentially match the fast convergence of the intrusive stochastic Galerkin methods and retain the nonintrusive nature that leads to massively parallel implementation. There are a variety of global sparse polynomial subspaces for the SCMs as alternatives to the standard isotropic full tensor-product space, in order to obtain better approximations to the best M -term polynomial subspace. For instance, the generalized sparse grid SCMs can efficiently approximate PDE solutions with anisotropic behavior by exploiting the size of the analyticity region associated to each random parameter and assigning an appropriate weight to each stochastic dimension. The nonintrusive sparse interpolation in quasi-optimal subspaces can provide more accurate approximations to the best M -term polynomial expansion by building the subspaces based on sharp upper bounds of the coefficients of the polynomial expansion of the PDE solutions.

In addition, there are many works on reducing complexity of implementing SCMs. For example, in [67], a multilevel version of the stochastic collocation method was proposed, which uses hierarchies of spatial approximations to reduce the overall computational complexity. In addition, this approach utilizes, for approximation in stochastic space, a sequence of multidimensional interpolants of increasing fidelity which can then be used for approximating statistics of the solution. With the use of interpolating polynomials, the multilevel SCM [39] can provide us with high-order surrogates featuring faster convergence rates, compared

to standard single-level SCMs as well as multilevel Monte Carlo methods. In [31], an acceleration technique was proposed to reduce the computational burden of hierarchical SCMs. Similar to the way multilevel methods take advantage of hierarchies of spatial approximation to reduce computational cost, our approach exploits the hierarchical structure of the sparse grid construction to seed the linear or nonlinear iterative solvers with improved initial guesses. Specifically, at each newly added sample point on the current level of a sparse grid, the solution of the SPDE is predicted using the sparse grid interpolant on the previous level, and then that prediction is used as the starting point of the chosen iterative solver. This approach can be applied to all the SCMs discussed in this effort, as well as to other hierarchically structured nonintrusive methods, e.g., nonintrusive generalized polynomial chaos, discrete least squares projection, multilevel methods, etc.

Abstract

Parametric uncertainty, considered broadly to include uncertainty in system parameters and driving forces (source terms and initial and boundary conditions), is ubiquitous in mathematical modeling. The method of distributions, which comprises PDF and CDF methods, quantifies parametric uncertainty by deriving deterministic equations for either probability density function (PDF) or cumulative distribution function (CDF) of model outputs. Since it does not rely on finite-term approximations (e.g., a truncated Karhunen-Loëve transformation) of random parameter fields, the method of distributions does not suffer from the “curse of dimensionality.” On the contrary, it is exact for a class of nonlinear hyperbolic equations whose coefficients lack spatiotemporal correlation, i.e., exhibit an infinite number of random dimensions.

1 Introduction

Probabilistic representations of uncertain parameters and forcings (e.g., initial and boundary conditions) are routinely used both to derive new effective mathematical models [4] and to quantify parametric uncertainty in existing ones (see this Handbook). Regardless of their *raison d'être*, such probabilistic approaches introduce randomness in quantitative predictions of system behavior. Randomness also stems from stochastic representations of subscale processes in mesoscopic models through either internally generated or externally imposed random excitations (Langevin forces) [22]. Despite their superficial similarity, these two sources of randomness pose different challenges. First, Langevin forces are time-dependent random processes, while uncertain parameters are spatially distributed but time-invariant random fields. Second, Langevin forces are (space-time uncorrelated) "white" noise or exhibit short-range correlations. Random (uncertain) coefficients, on the other hand, typically exhibit pronounced spatial correlations, reflecting the underlying structure of heterogeneous but fundamentally deterministic environments.

1.1 Randomness in Mathematical Models

The distinct challenges posed by the two types of randomness (Langevin forces and uncertain parameters) are illustrated by the following two examples. The first is provided by a Langevin (stochastic ordinary-differential) equation (sODE)

$$\frac{du}{dt} = h(u, t) + g(u, t)\xi(t, \omega). \quad (22.1a)$$

It describes the dynamics of the state variable $u(t, \omega)$, which consists of a slowly varying (deterministic) part h and a fast varying random part $g\xi$; the random fluctuations $\xi(t, \omega)$ have zero mean and a two-point covariance function

$$C(t, s) \equiv \langle \xi(t, \omega)\xi(s, \omega) \rangle = \sigma^2 \rho(t, s). \quad (22.1b)$$

Here ω is an element of a probability space $(\Omega, \mathcal{F}, \mathcal{P})$, $\langle \cdot \rangle \equiv \mathbb{E}(\cdot)$ denotes the ensemble mean over this space, and σ^2 and ρ are the variance and correlation function of ξ , respectively. At time t , the system's state is characterized by the probability $\mathbb{P}[u(t) \leq U]$ or, equivalently, by its probability density function (PDF) $f_u(U; t)$.

The second example is an advection-reaction partial-differential equation (PDE)

$$\frac{\partial u}{\partial t} + a \frac{\partial u}{\partial x} = b H(u) \quad (22.2)$$

where the spatially varying and uncertain coefficients a and b are correlated random fields $a(x, \omega)$ and $b(x, \omega)$. This equation is subject to deterministic or random initial and boundary conditions. Rather than having a unique solution, this problem admits an infinite set of solutions that is characterized by a PDF $f_u(U; x, t)$.

1.2 Uncertainty Quantification in Langevin sODEs

Derivation of deterministic equations governing the dynamics of $f_u(U; t)$ for Langevin equation (22.1) with white noise $\xi(t, \omega)$, i.e., with $\rho(t, s) = \tau \delta(t - s)$ where τ is a characteristic time, is relatively straightforward. For $\xi(t, \omega)$ with an arbitrary distribution, these equations are called the Kramers-Moyal expansion; the latter reduces to the Fokker-Planck equation (FPE) if $\xi(t, \omega)$ is Gaussian [22].

Non-Markovian Langevin equations, e.g., (22.1) with temporally correlated (colored) noise, pose an open challenge. Existing methods for their analysis fall into two categories. The *first approach* introduces an additional Markovian process describing the evolution of $\xi(t, \omega)$. The resulting enlarged system is Markovian and hence can be described by a FPE for the joint PDF of u and ξ [22, Sec. 3.5]. Then f_u is obtained by marginalizing a solution of this FPE with respect to ξ . Alternatively, under certain conditions, the enlarged (Markovian) system of Langevin equations can be solved with the unified colored noise approximation [13]. The *second approach* (see [20] for a review) is to derive a differential equation for f_u , which involves random variables and requires a closure. Such closures place restrictions on the noise properties: the decoupling theory [13] requires the nondimensionalized ξ to be second-order stationary and Gaussian, with variance $\sigma^2 \ll 1$; the small correlation-time expansion [9] is applicable to correlation times $\lambda \rightarrow 0$ and $\lambda/\sigma^2 \ll 1$; the functional integral [13] and path-integral [10] require ξ to be statistically homogeneous; and the large-eddy-diffusivity closure [23] requires ξ to have small variance σ^2 and short correlation length λ .

1.3 Uncertainty Quantification in PDEs with Random Coefficients

Monte Carlo simulations (MCS) provide the most robust and straightforward way to solve PDEs with random coefficients. In the case of (22.2), for instance, they consist of (i) generating multiple realizations of the input parameters a and b , (ii) solving deterministic PDEs for each realization, and (iii) evaluating ensemble statistics or PDFs of these solutions. MCS do not impose limitations on statistical properties of input parameters, entail no modifications of existing deterministic solvers, and are ideal for parallel computing. Yet MCS have a slow convergence rate which renders them computationally expensive (often, prohibitively so). Research in the field of

uncertainty quantification is driven by the goal of designing numerical techniques that are computationally more efficient than MCS.

Various types of stochastic finite element methods (FEMs) provide an alternative to MCS. They start by constructing (e.g., by means of truncated Karhunen-Loëve (K-L) expansions) a finite-dimensional probability space on which an SPDE solution is defined. The Galerkin FEM, often equipped with h -type and p -type adaptivity, approximates such solutions in the resulting composite probability-physical space. Stochastic Galerkin and collocation methods (both discussed elsewhere in this Handbook) employ orthogonal basis expansions of an SPDE solution in the chosen finite-dimensional probability space. These types of methods – sometimes referred to as generalized polynomial chaos (gPC) – outperform MCS when random parameter fields exhibit long correlations and, therefore, can be accurately represented by, e.g., a few terms of their K-L expansions. As the correlation length of an input parameter decreases, its K-L expansion requires more terms to maintain the same accuracy, thus increasing the dimensionality of the probability space on which solution is defined. Once the number of random variables exceeds a certain threshold, the stochastic FEMs become computationally less efficient than MCS, a phenomenon known as the curse of dimensionality.

This discussion illustrates the difficulty in developing efficient UQ tools capable of handling both short correlations (or lack thereof) typical of Langevin systems (22.1), and long correlations often present in PDEs with random coefficients such as (22.2). It also highlights the complementary nature of the method of distributions (of which Fokker-Planck equations are a classical example) and stochastic FEMs. While the former work best for random inputs with short correlation lengths (and are often exact in the absence of correlations), the latter outperform MCS when random inputs exhibit long correlations.

This chapter discusses the method of distributions, which aims to derive deterministic equations satisfied by a probabilistic distribution (e.g., PDF) of a system state, as a computationally efficient framework for dealing with both types of uncertainty (randomness). PDF methods originated in the statistical theory of turbulence [21] and have since been used to derive PDF (or Fokker-Planck) equations for systems of coupled Langevin (stochastic ordinary-differential) equations with colored noise [29], to homogenize ordinary-differential equations (ODEs) with random coefficients [19], and to quantify parametric uncertainty in advection-diffusion [23, 24, 28], shallow water [30], and multiphase flow [31] equations.

2 Method of Distributions

We use the term “the method of distributions” to designate a class of approaches based on the derivation of deterministic PDEs for either a probability density function (PDF) or a cumulative distribution function (CDF) of a state variable. The type of the distribution function used gives rise to PDF or CDF methods, respectively.

2.1 PDF Methods

We illustrate the nature of the PDF method by considering a deterministic version of (22.1) subject to an uncertain (random) initial condition,

$$\frac{du}{dt} = G(u, t), \quad u(0, \omega) = u_0(\omega). \quad (22.3)$$

Here $u_0 \in \mathbb{R}$ has a known PDF $f_0(U)$, and $G : \mathbb{R} \times \mathbb{R}^+ \rightarrow \mathbb{R}$ is a known smooth function. In order to derive an equation for the PDF $f_u(U; t)$ of $u(t; \omega)$, we define a random “raw PDF function” Π in terms of the Dirac delta function $\delta(\cdot)$ such that

$$\Pi(U; t, \omega) = \delta[U - u(t, \omega)]. \quad (22.4)$$

Its ensemble mean $\mathbb{E}[\Pi]$ at any time t equals the PDF $f_u(U; t)$. Indeed,
