$$\mathbb{E}[\Pi] \equiv \int_{-\infty}^{\infty} \delta(U - \tilde{u}) f_u(\tilde{u}; t) d\tilde{u} = f_u(U; t). \quad (22.5)$$

Multiplying (22.3) by $\partial_U \Pi$, using the fundamental properties of the Dirac delta function, and taking the expected value to a Cauchy problem:

$$\frac{\partial f_u}{\partial t} + \frac{\partial[G(U, t) f_u(U; t)]}{\partial U} = 0, \quad f_u(U; 0) = f_0(U), \quad (22.6)$$

whose solution yields the entire statistical profile of $u(t, \omega)$.

Challenges posed by the presence of multiplicative noise (parametric uncertainty) are often illustrated by the classic test problem [32]

$$\frac{du}{dt} = -ku, \quad u(0) = u_0, \quad (22.7)$$

in which both the coefficient $k(\omega)$ and initial condition $u_0(\omega)$ are random variables. While (22.7) looks simple, the determination of the statistical properties of its solution is a nonlinear problem. The need to deal with the mixed moment $\mathbb{E}[ku]$ suggests defining the raw joint PDF of $k(\omega)$ and $u(t, \omega)$,

$$\Pi(U, K; t, \omega) = \delta(U - u(t, \omega))\delta(K - k(\omega)). \quad (22.8)$$

Its ensemble mean is the joint PDF, $\mathbb{E}[\Pi] = f_{uk}(U, K; t)$. Manipulations similar to those used in the previous example lead to the PDF equation

$$\frac{\partial f_{uk}}{\partial t} = K \frac{\partial(U f_{uk})}{\partial U}. \quad (22.9)$$

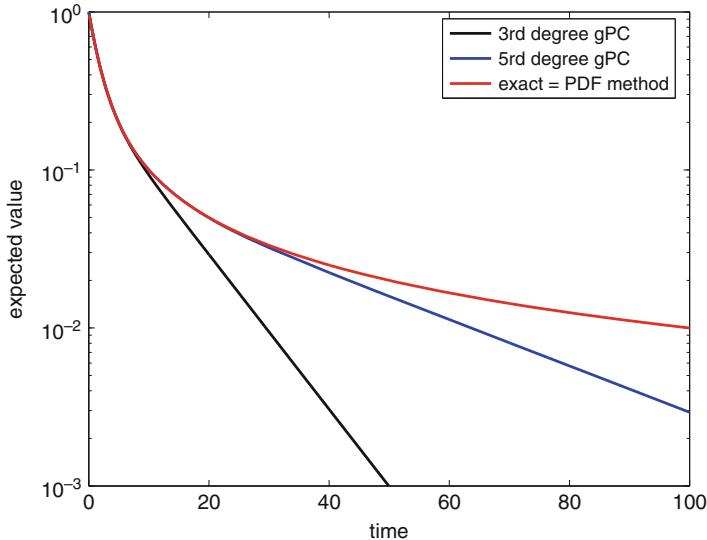

Fig. 22.1 Expected value of the solution to (22.7) with $k \sim \mathcal{U}(0, 1)$ and $u_0 \sim \mathcal{U}(-1, 1)$. The gPC approximations only capture the solution for small times. The PDF method is exact and yields $\mathbb{E}[u(t, \omega)] = (1 - e^{-t})/t$

This equation can be solved by the method of characteristics and the marginal $f_u(U; t)$ obtained by integration, see Fig. 22.1.

Numerical techniques such as gPC evolve approximations based on the statistical properties of the data (here k and u_0). These approximations become increasingly inappropriate under the stochastic drift generated by the nonlinear dynamics (see Fig. 22.1); in stark contrast to gPC, the PDF method is *exact*. Methods such as time-dependent and/or gPC (see the relevant chapters of this handbook) have been proposed to locally adapt the gPC polynomial bases; these improvements only partially solve the above problem at the price, however, of significant numerical costs and complexity.

The derivation of equations (22.6) and (22.9) for the PDFs of the solutions to (22.3) and (22.7), respectively, involves several delicate points that deserve further scrutiny. While PDF equations have been derived through the use of characteristic functions [14], we prefer a more explicit justification based on regularization arguments. We use the study of systems of nonlinear ODEs to provide a mathematical justification of the approach. Consider a set of state variables $\mathbf{u}(t) = (u_1, \dots, u_N)^\top$ whose dynamics are governed by a system of coupled ODEs subject to a random initial condition

$$\frac{du_i}{dt} = G_i(\mathbf{u}, t), \quad i = 1, \dots, N; \quad \mathbf{u}(0, \omega) = \mathbf{u}_0(\omega), \quad (22.10)$$

where \mathbf{u}_0 is an \mathbb{R}^N -valued random variable and $\mathbf{G} = (G_1, \dots, G_N)^\top : \mathbb{R}^N \rightarrow \mathbb{R}^N$ is a continuous function. For each $\omega \in \Omega$, (22.10) is an initial value problem which can be analyzed through deterministic calculus. An ω -wise modification of deterministic proofs [2] leads to the existence and uniqueness of solutions. It should be noticed however that the vector field $\mathbf{G}(\mathbf{u}, t)$ is generally only continuous in t but not differentiable even if \mathbf{G} is smooth.

We define a regularized PDF $f_{\mathbf{u}, \epsilon}$ of $\mathbf{u} = (u_1, \dots, u_N)^\top$, the solution to (22.10), as

$$f_{\mathbf{u}, \epsilon}(\mathbf{U}; t) = (\eta_\epsilon \star f_{\mathbf{u}})(\mathbf{U}, t) = \int_{-\infty}^{\infty} \eta_\epsilon(\mathbf{U} - \tilde{\mathbf{u}}) f_{\mathbf{u}}(\tilde{\mathbf{u}}; t) d\tilde{\mathbf{u}} = \mathbb{E}[\eta_\epsilon(\mathbf{U} - \mathbf{u})], \quad (22.11)$$

where $\mathbf{U} \in \mathbb{R}^N$, $f_{\mathbf{u}}$ is the PDF of \mathbf{u} , and $\eta_\epsilon \in \mathcal{C}_0^\infty(\mathbb{R}^N)$ is a standard mollifier, for instance,

$$\eta_\epsilon(\mathbf{x}) = \frac{\epsilon^{-N}}{\int \eta d\mathbf{x}} \eta\left(\frac{\mathbf{x}}{\epsilon}\right) \quad \text{where } \eta(\mathbf{x}) = \begin{cases} \exp\left(\frac{1}{|\mathbf{x}|^2 - 1}\right) & \text{if } |\mathbf{x}| < 1 \\ 0 & \text{if } |\mathbf{x}| \geq 1. \end{cases}$$

One can show (e.g., [8], Appendix C) that $f_{\mathbf{u}, \epsilon}$ is a smooth approximation of $f_{\mathbf{u}}$. Using this fact, we show in the Appendix that for any $\phi \in \mathcal{C}_c^1(\mathbb{R}^N \times [0, \infty))$, the PDF $f_{\mathbf{u}}$ satisfies

$$\int_0^\infty \int_{-\infty}^\infty f_{\mathbf{u}} \partial_t \phi d\mathbf{U} dt + \int_0^\infty \int_{-\infty}^\infty \mathbf{G} f_{\mathbf{u}} \partial_{\mathbf{U}} \phi d\mathbf{U} dt + \int_{-\infty}^\infty f_{\mathbf{u}}(\mathbf{U}; 0) \phi(\mathbf{U}, 0) d\mathbf{U} = 0. \quad (22.12)$$

In other words, $f_{\mathbf{u}}$ is a distributional solution to

$$\frac{\partial f_{\mathbf{u}}}{\partial t} + \nabla_{\mathbf{U}} \cdot [\mathbf{G}(\mathbf{U}, t) f_{\mathbf{u}}] = 0, \quad f_{\mathbf{u}}(\mathbf{U}, 0) = f_0(\mathbf{U}), \quad (22.13)$$

where $f_0(\mathbf{U})$ is the distribution corresponding to \mathbf{u}_0 . It is worthwhile emphasizing that the PDF equation (22.13) is *exact*. Figure 22.2 illustrates this approach in the case of the van der Pol equation

$$\frac{d}{dt} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} u_2 \\ \mu(1 - u_1^2)u_2 - u_1 \end{bmatrix} \quad (22.14a)$$

with $\mu \geq 0$ subject to Gaussian initial conditions

$$\begin{bmatrix} u_{1,0} \\ u_{2,0} \end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix} 1 \\ 0 \end{bmatrix}, \sigma^2 \mathbb{I}\right). \quad (22.14b)$$

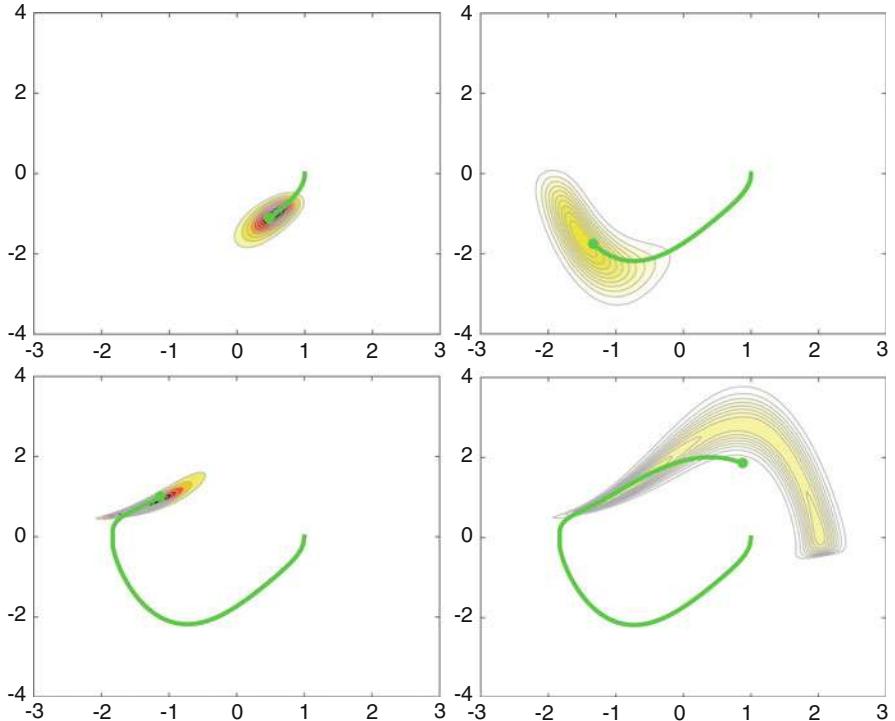

Fig. 22.2 Phase space trajectory of the PDF of the solution to the van der Pol equation (22.14a) with $\mu = 1.25$ subject to the Gaussian initial condition (22.14b) with $\sigma^2 = 0.01$ at times $t = 1.0, 2.0, 4.0$ and 5.2 ; the solid green line is the trajectory of the mean solution while the green “dot” corresponds to the expected value at the considered time. The PDF undergoes many “expansions” and “contractions”; this complex dynamics cannot be accurately described by a few moments of the solution

2.2 CDF Methods

CDF methods aim to derive deterministic PDEs governing the dynamics of a cumulative distribution function (CDF) of a state variable. For the ODE (22.3), instead of defining a raw PDF function (22.4), we introduce “raw CDF function”

$$\Pi(U; t, \omega) = \mathcal{H}[U - u(t, \omega)]. \quad (22.15)$$

where $\mathcal{H}(\cdot)$ is the Heaviside function. At time t , the ensemble mean $\mathbb{E}[\Pi]$ gives the CDF $F_u(U; t)$ of $u(t, \omega)$:

$$\mathbb{E}[\Pi] \equiv \int \mathcal{H}(U - \tilde{u}) f_u(\tilde{u}; t) d\tilde{u} = \int f_u(\tilde{u}; t) d\tilde{u} = F_u(U; t). \quad (22.16)$$

Multiplying (22.3) by $\partial_U \Pi$, using the fundamental properties of the Dirac delta function, and taking the expected value lead to a Cauchy problem for the CDF of the solution to (22.3):

$$\frac{\partial F_u}{\partial t} + G(U, t) \frac{\partial F_u}{\partial U} = 0, \quad F_u(U; 0) = F_0(U), \quad (22.17)$$

where $F_0(U)$ is the CDF of the random initial condition $u_0(\omega)$.

The PDF and CDF formulations of a specific system of ODEs, for instance, (22.6) and (22.17), are obviously related (through integration/derivation); they also display different properties which have implications for their numerical resolutions. First, PDF equations have a conservative form, while CDF equations do not. Second, solutions of CDF equations are monotonic in “space” (the U coordinate), while those of PDF equations are not. The situation is more involved in the case of PDEs and corresponding boundary conditions, as discussed in the next section.

3 Distribution Methods for PDEs

Consider a scalar balance law

$$\frac{\partial u}{\partial t} + \frac{\partial G(u)}{\partial x} = H(u, x, t), \quad u(x, 0, \omega) = u_0(x, \omega), \quad (22.18)$$

where $G : \mathbb{R} \rightarrow \mathbb{R}$ and $H : \mathbb{R} \times \mathbb{R} \times \mathbb{R}^+ \rightarrow \mathbb{R}$ are known smooth functions of their arguments. Following the procedure outlined above, we define a raw PDF as $\Pi(U; x, t) = \delta(U - u(x, t; \omega))$ and elementary properties of δ to formally derive an equation governing its dynamics

$$\frac{\partial \Pi}{\partial t} - \frac{\partial}{\partial U} \left(\frac{dG}{dU} \Pi \frac{\partial u}{\partial x} \right) = -\frac{\partial}{\partial U} (H(U, x, t) \Pi). \quad (22.19)$$

The expected value of this equation takes the form

$$\frac{\partial f_u}{\partial t} - \frac{dG}{dU} \mathbb{E} \left[\frac{\partial \Pi}{\partial U} \frac{\partial u}{\partial x} \right] - \frac{d^2 G}{dU^2} \mathbb{E} \left[\Pi \frac{\partial u}{\partial x} \right] = -\frac{\partial H(U, x, t) f_u}{\partial U}, \quad (22.20)$$

which yields a closed exact integro-differential equation for the PDF $f_u(U; x, t)$

$$\frac{\partial f_u}{\partial t} + \frac{dG}{dU} \frac{\partial f_u}{\partial x} + \frac{d^2G}{dU^2} \frac{\partial}{\partial x} \int_{-\infty}^U f_u(\tilde{U}; x, t) d\tilde{U} + \frac{\partial H(U, x, t) f_u}{\partial U} = 0. \quad (22.21)$$

A CDF formulation can also be derived (through integration); it takes the simple form

$$\frac{\partial F_u}{\partial t} + \frac{dG}{dU} \frac{\partial F_u}{\partial x} + H(U, x, t) \frac{\partial F_u}{\partial U} = 0. \quad (22.22)$$

A few computational examples are presented below.

3.1 Weakly Nonlinear PDEs Subject to Random Initial Conditions

Consider a reaction-advection equation

$$\frac{\partial u}{\partial t} + \frac{\partial u}{\partial x} = H(u, x, t), \quad u(x, 0) = u_0(x, \omega) \quad (22.23)$$

Defining the raw PDF and CDF, $\Pi = \delta[U - u(x, t, \omega)]$ and $\Pi = \mathcal{H}[U - u(x, t, \omega)]$, and following the procedure described above yields Cauchy problems for the single-point PDF and CDF of u ,

$$\frac{\partial f_u}{\partial t} + \frac{\partial f_u}{\partial x} = -\frac{\partial[H(U) f_u]}{\partial U}, \quad f_u(U; x, 0) = f_{u_0}(U; x) \quad (22.24)$$

and

$$\frac{\partial F_u}{\partial t} + \frac{\partial F_u}{\partial x} = -H(U) \frac{\partial F_u}{\partial U}, \quad F_u(U; x, 0) = F_{u_0}(U; x). \quad (22.25)$$

The above equations can be numerically solved to high accuracy with standard methods. In fact, due to their linear structure, they can often be solved exactly through a characteristic analysis; the PDF solution for $H(u, x, t) \equiv u - u^3$ and a standard Gaussian initial condition $u_0(\omega)$ is shown in Fig. 22.3.

Additional probabilistic information can be gained by similar means. For instance, for an initial condition u_0 corresponding to a random field, the equation for the two-point CDF of u is given by

$$\frac{\partial F_{u,u'}}{\partial t} + \frac{\partial F_{u,u'}}{\partial x} + \frac{\partial F_{u,u'}}{\partial x'} = -H(U) \frac{\partial F_{u,u'}}{\partial U} - H(U') \frac{\partial F_{u,u'}}{\partial U'}, \quad (22.26)$$

where $F_{u,u'}(U, U'; x, x', t) = \mathbb{P}[u(x, t) \leq U, u(x', t) \leq U']$ and $F_{u,u'}(U, U'; x, x', 0)$ is a known initial condition.

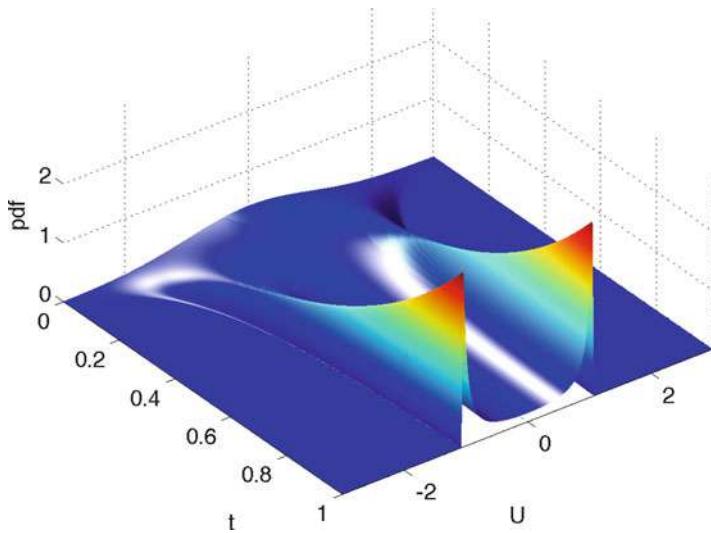

Fig. 22.3 PDF of the solution to (22.23) for a spatially constant initial condition $u_0 \sim \mathcal{N}(0, 1)$ and for $H(u, x, t) \equiv u - u^3$ (the solution u does not depend on x)

3.2 Weakly Nonlinear PDEs with Random Coefficients

Consider the advection-reaction equation (22.2) with random coefficients $a(x, \omega)$ and $b(x, \omega)$, which can be either correlated or uncorrelated in space. This equation is subject to an initial condition $u(x, 0) = u_0$. As in previous examples, the raw CDF $\Pi(U; x, t, \omega) = \mathcal{H}[U - u(x, t, \omega)]$ satisfies exactly an equation

$$\frac{\partial \Pi}{\partial t} + a \frac{\partial \Pi}{\partial x} = -bH(U, x, t) \frac{\partial \Pi}{\partial U}, \quad \Pi(U; x, 0, \omega) = \mathcal{H}(U - u_0). \quad (22.27)$$

It describes two-dimensional, $\mathbf{x} = (x, U)^\top \in \mathbb{R} \times \mathbb{R}$, advection of Π in the random velocity field $\mathbf{v} = (a, bH)^\top$. Stochastic averaging of this equation is a classical problem that requires a closure approximation (see, e.g., [5] and the references therein). Such closures can be constructed by representing the random coefficients $a(x, \omega)$ and $b(x, \omega)$ with their finite-term approximations obtained, e.g., via Karhunen-Loëve or Fourier transformations [25, 27, 28]. The number of terms in the resulting expansions of $a(x, \omega)$ and $b(x, \omega)$, which is necessary to achieve a required representational accuracy, increases as correlation lengths of $a(x, \omega)$ and $b(x, \omega)$ decrease. Beyond a certain range, solving (22.27) with Monte Carlo simulations becomes the most efficient option (curse of dimensionality).

Perturbation-based closures [5, 6, 24] provide a computational alternative which does not require approximations of random parameter fields such as $a(x, \omega)$ and $b(x, \omega)$. For example, the ensemble average of (22.27) yields a nonlocal equation [5]

$$\frac{\partial F}{\partial t} + \mathbb{E}[\mathbf{v}] \cdot \nabla F = \Phi(F), \quad \Phi(F; \mathbf{x}, t) \equiv \mathbb{E}[\mathbf{v}' \cdot \nabla \Pi'] \quad (22.28a)$$

where $\mathbf{v}' = \mathbf{v} - \mathbb{E}[\mathbf{v}]$ and $\Pi' = \Pi - F$; the nonlocal term $\Phi(F)$ is approximated by

$$\Phi(F; \mathbf{x}, t) \approx \int_0^t \int_D \mathbb{E}[v'_i(\mathbf{y}) v'_j(\mathbf{x})] \frac{\partial G}{\partial x_j}(\mathbf{x}, \mathbf{y}, t - \tau) \frac{\partial F}{\partial y_i}(\mathbf{y}, \tau) d\mathbf{y} d\tau, \quad (22.28b)$$

where $D \subset \mathbb{R}^2$. Here the Einstein notation is used to indicate summation over repeated indices, and $G(\mathbf{x}, \mathbf{y}, t - \tau)$ is the “mean-field” Green’s function for (22.27) defined as a solution of

$$\frac{\partial G}{\partial \tau} + \nabla_{\mathbf{y}} \cdot (\mathbb{E}[\mathbf{v}] G) = -\delta(\mathbf{x} - \mathbf{y}) \delta(t - \tau), \quad (22.29)$$

subject to the homogeneous initial and boundary conditions. Note that the CDF equation (22.28) accounts for arbitrary auto- and cross-correlations of the input parameter fields $a(x, \omega)$ and $b(x, \omega)$. Correlated random coefficients necessitate either space-time localization of (22.28b), as was done in [5, 6], or solving an integro-differential CDF equation (22.28). The accuracy of the localization approximation increases as the correlation lengths of $a(x, \omega)$ and $b(x, \omega)$, λ_a and λ_b become smaller ($\lambda_a, \lambda_b \rightarrow 0$). Thus, the methods of distribution work best in the regime in which the methods based on finite-term representations of parameter fields (e.g., gPC and stochastic collocation methods) fail.

3.3 Nonlinear PDEs with Shocks

The solutions to generic nonlinear hyperbolic balance laws such as (22.18) are in general non-smooth and can present shocks even for smooth initial conditions. The various types of probabilistic distributions describing such solutions are also expected to not be smooth. As a result, the resolution of the evolution equations describing such distributions (see, for instance, (22.21) and (22.22)) becomes problematic. A way to incorporate shock dynamics in the method of distributions (CDF equation) can be found in [31] and consists essentially in adapting the concept of front tracking to the present framework (see [30] for a different approach in the context of kinematic-wave equations).

Following [31], we illustrate the approach on a model of multiphase flow in porous media given by the Buckley-Leverett equation,

$$\frac{\partial u}{\partial t} + q \frac{\partial G(u)}{\partial x} = 0, \quad G = \frac{(u - s_{wi})^2}{(u - s_{wi})^2 + (1 - s_{oi} - u)^2 \epsilon_\mu}. \quad (22.30)$$

The above model describes the dynamics of water saturation $u(x, t) : \mathbb{R}^+ \times \mathbb{R}^+ \rightarrow [s_{wi}, 1 - s_{oi}]$ due to displacement of oil by water with macroscopic velocity $q(t)$. The ratio of the water and oil viscosities is denoted by ϵ_μ . The porous medium is initially mostly saturated with oil and has a uniform (irreducible) water saturation s_{wi} , such that $u(x, t = 0) = s_{wi}$. Equation (22.30) is subject to the boundary condition $u(x = 0, t) = 1 - s_{oi}$, where s_{oi} is the irreducible oil saturation. Both s_{oi} and s_{wi} are treated as deterministic constants. The macroscopic flow velocity is uncertain and treated as a random function $q(t, \omega)$ with known PDF $f_q(Q; t)$.

Let $x_f(t)$ denote the position of a water-oil shock front. Ahead of the front, a rarefaction wave follows well-defined characteristic curves. Behind the front, the saturation remains at the initial value, $u^+ = s_{wi}$. The Rankine-Hugoniot condition defines the front location,

$$\frac{dx_f}{dt} = q \frac{G(u^-) - G(u^+)}{u^- - u^+}. \quad (22.31)$$

The saturation value ahead of the front, u^- , is constant along the characteristic curve defined by

$$\frac{dx}{dt} = v(u^-) = q \frac{dG}{du}(u^-),$$

which must match the shock speed:

$$\frac{G(u^-) - G(u^+)}{u^- - u^+} = \frac{dG}{du}(u^-). \quad (22.32)$$

Solving (22.32) gives u^- and hence the location of the shock front $x_f(t)$. The continuous rarefaction solution $u_r(x, t)$ ahead of the front is found by using the method of characteristics in the range $u^- \leq u_r \leq 1 - u_{oi}$. The complete solution is given by [31]:

$$u(x, t) = \begin{cases} u_r(x, t), & 0 \leq x < x_f(t) \\ s_{wi}, & x > x_f(t) \end{cases} \quad (22.33)$$

The raw CDF Π is subdivided into two parts, Π_a and Π_b , according to the saturation solution (22.33):

$$\Pi(U, x, t) = \begin{cases} \Pi_a = \mathcal{H}(U - s_{wi}), & U < u^-, \quad x > x_f(t) \\ \Pi_b = \mathcal{H}(U - s_i), & s^- < U, \quad x < x_f(t) \end{cases} \quad (22.34a)$$

where

$$\Pi_b = \mathcal{H}(U - 1 + s_{oi})\mathcal{H}(C - x) + \mathcal{H}(U - s_{wi})\mathcal{H}(x - C) \quad (22.34b)$$

with

$$C(U, t) = \frac{dG}{dU} \int_0^t q(\tau) d\tau. \quad (22.34c)$$

The ensemble average of (22.34) yields a formal expression for the CDF $F_u(U; x, t)$ [31],

$$F_u = \begin{cases} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \Pi_a \mathcal{H}(x - X_f) f_{u, x_f}^+(U, X_f; x, t) dU dX_f, & U < u^- \\ \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} [\Pi_a \mathcal{H}(x - X_f) f_{u, x_f}^+ + \Pi_b \mathcal{H}(X_f - x) f_{u, x_f}^-] dU dX_f, & U \geq u^-. \end{cases} \quad (22.35)$$

Here $f_{u, x_f}(U, X_f; x, t)$ is the (unknown) joint PDF of u and x_f , with the superscripts $-$ and $+$ indicating the parts of this PDF restricted to values of u before and after the front, respectively. Since $f_{u, x_f} dU dX_f = f_q dQ$, this yields a computable solution (see [31] for details)

$$F_u(U; x, t) = \begin{cases} \int_{-\infty}^{\infty} \Pi_a \mathcal{H}[x - X_f(Q)] p_q dQ, & U < u^- \\ \int_{-\infty}^{\infty} [\Pi_a \mathcal{H}(x - X_f(Q)) + \Pi_b \mathcal{H}[X_f(Q) - x]] p_q dQ, & U \geq u^-. \end{cases} \quad (22.36)$$

Evaluation of this expression requires one to compute the stochastic integral in (22.34c). The performance of three alternative approximations, whose performance depends on the ratio of the correlation length of the random input $q(t, \omega)$ and the integration time t , is shown in Fig. 22.4. Note that no approximation would be needed if $q(t, \omega)$ is white noise.

3.4 Systems of PDEs

The local nature in x and t of (22.21) and (22.22) is a direct result of the simple dependency structure associated to (22.18): solutions can be constructed using one family of characteristics. The situation is more involved for random hyperbolic systems of balance laws such as

$$\frac{\partial u_i}{\partial t} + \frac{\partial G_i(\mathbf{u})}{\partial x} = H_i(\mathbf{u}, x, t), \quad i = 1, \dots, N, \quad (22.37)$$

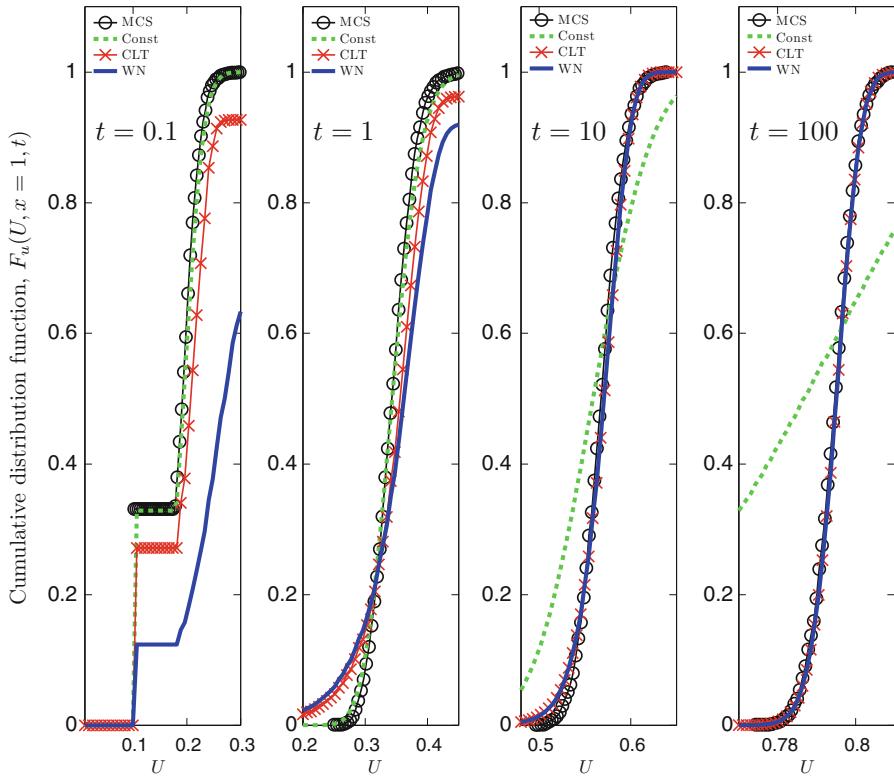

Fig. 22.4 CDF $F_u(U; x = 1, t)$ at $t = 0.1$, $t = 1$, $t = 10$, and $t = 100$ obtained with Monte Carlo simulations (MCS) and the CDF solution (22.36) under the three alternatively approximations: the random constant approximation (Const), an approximation based on the central limit theorem (CLT), and the white-noise approximation (WN). Only the portion of the domain in which the CDF varies is shown (This figure is reproduced from [31])

where $\mathbf{u} = (u_1, \dots, u_N)^\top$. Similar to the above, $G_i : \mathbb{R}^N \rightarrow \mathbb{R}$ and $H_i : \mathbb{R}^N \times \mathbb{R} \times \mathbb{R}^+ \rightarrow \mathbb{R}$ ($i = 1, \dots, N$) are known smooth functions with respect to all their arguments, and the initial condition is given by $\mathbf{u}(x, 0, \omega) = \mathbf{u}_0(x, \omega)$. The evolution equation for the raw PDF $\Pi(\mathbf{U}; x, t) \equiv \prod_{i=1}^N \delta(U_i - u_i(x, t; \omega))$ with $\mathbf{U} = (U_1, \dots, U_N)^\top$ is here

$$\frac{\partial \Pi}{\partial t} - \frac{\partial \Pi}{\partial U_i} \frac{\partial G_i(\mathbf{u})}{\partial x} = - \frac{\partial (H_i(\mathbf{U})\Pi)}{\partial U_i}, \quad (22.38)$$

where the Einstein notation is used to indicate the summation over the repeated indices. Relying again on properties of δ , we obtain the integro-differential equation

$$\frac{\partial \Pi}{\partial t} - \frac{\partial \Pi}{\partial U_i} \frac{\partial}{\partial x} \int G_i(\mathbf{U}^*) \Pi(\mathbf{U}^*; x, t) d\mathbf{U}^* = - \frac{\partial (H_i(\mathbf{U})\Pi)}{\partial U_i}. \quad (22.39)$$

An equation for the joint PDF $f_{\mathbf{u}}(\mathbf{U}; x, t)$ can in principle be obtained as the ensemble mean (over realizations of random u_i , $i = 1, \dots, N$ at point x and time t), i.e., $\langle \Pi \rangle = f_{\mathbf{u}}(\mathbf{U}; x, t)$; a closed exact equation – such as (22.21) or (22.22) in the scalar case – is however not available in general.

We illustrate this point on a simple example: the wave equation with constant speed of propagation $c > 0$

$$\frac{\partial}{\partial t} \begin{bmatrix} v \\ w \end{bmatrix} + \begin{bmatrix} 0 & -c^2 \\ -1 & 0 \end{bmatrix} \frac{\partial}{\partial x} \begin{bmatrix} v \\ w \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}. \quad (22.40)$$

Equation (22.38) takes here the form

$$\frac{\partial \Pi}{\partial t} + \frac{\partial \Pi}{\partial W} \frac{\partial v}{\partial x} + c^2 \frac{\partial \Pi}{\partial V} \frac{\partial w}{\partial x} = 0, \quad (22.41)$$

the expectation of which yields

$$\frac{\partial f_{vw}}{\partial t} + \mathbb{E} \left[\frac{\partial \Pi}{\partial W} \frac{\partial v}{\partial x} \right] + c^2 \mathbb{E} \left[\frac{\partial \Pi}{\partial V} \frac{\partial w}{\partial x} \right] = 0. \quad (22.42)$$

Unlike the scalar case, there is here no simple way of expressing the arguments of the expectation(s) as exact differentials in order to close the equation.

A more direct approach illustrates this phenomenon in another way. Consider the wave equation (22.40) in the form

$$\frac{\partial^2 u}{\partial t^2} - c^2 \frac{\partial^2 u}{\partial x^2} = 0, \quad (22.43)$$

with

$$v = \frac{\partial u}{\partial x} \quad \text{and} \quad w = \frac{\partial u}{\partial t}.$$

Defining the raw PDF as $\Pi(U; x, t) = \delta(U - u(x, t; \omega))$ and differentiating twice with respect to x and t , we get

$$\frac{\partial^2 f_u}{\partial t^2} - c^2 \frac{\partial^2 f_u}{\partial x^2} = \frac{\partial}{\partial U^2} \mathbb{E} \left\{ \Pi \left[\left(\frac{\partial u}{\partial t} \right)^2 - c^2 \left(\frac{\partial u}{\partial x} \right)^2 \right] \right\}, \quad (22.44)$$

which, again, is an equation that does admit an elementary closure. This difficulty is not specific to the wave equation: the nonlocal nature and self-interacting character of most partial differential equations unfortunately precludes the existence of pointwise equations for the PDF of their solutions. The determination of PDF equations for the solutions of random PDEs is an active area of research; three approaches can be considered.

First, PDF equations can be obtained from the principles outlined above through the use of closure approximations. Such approximations are typically application dependent and attention must be to the resulting accuracy. For instance, we show

below that the simple approximation, when applied to the wave equation, leads to exact means but that the higher moments are not evolved exactly.

Second, using functional integral methods, sets of differential constraints satisfied by PDFs of random PDEs have been proposed [26]. We note however that this approach may still require closure approximations and that, in general, the existence of a set of differential constraints allowing the unique determination of a PDF is an open question.

Third, the need to invoke a closure approximation can, in principle, be avoided through discretization. Let's consider again the hyperbolic system of balance laws (22.37). Spatial semi-discretization of (22.37) by appropriate methods such as central schemes [15–18] leads to ODE systems akin to (22.10). A PDF approach can then be applied to the semi-discrete problems following the lines of Sect. 2. We note however that dimension reduction methods have to be considered for the numerical resolution of the resulting PDF equations. Analyzing the accuracy of the approach, i.e., the closeness of the PDF of solutions to a discretized problem to the PDF of solutions to the original problem, is an open question.

For most applications corresponding to systems of balance laws such as (22.37), the spatial domain is *finite*. This seemingly innocuous remark has profound consequences. The imposition of boundary conditions requires a characteristic analysis. Let $\mathbb{B} = (\partial G_i / \partial u_j)$ be the Jacobian of the system and let $\mathbb{B} = V \Lambda V^{-1}$ be its eigenvalue decomposition (which exists by hyperbolicity assumption). Assuming for now a linear system, i.e., a constant Jacobian and a problem defined on the half line $x > 0$, the number of boundary conditions to be imposed at $x = 0$ is q , the number of positive eigenvalues of \mathbb{B} . The boundary condition is then imposed on the characteristic variables with positive wave speed. If the problem is defined on an interval, the process is simply repeated at the other end by considering again the characteristics entering the computational domain there.

For nonlinear systems with smooth solutions, one can linearize the equations about an appropriate local state (frozen coefficient method). (The situation is much more involved for nonlinear problems admitting shock formation [3, 7, 11, 12].) The back and forth transformations between characteristic variables ($\mathbf{z} = V^{-1}\mathbf{u}$) and “conserved” variables (\mathbf{u}) are trivial in a deterministic setting. In the present framework, the unknowns are joint PDF functions or marginals of random variables that are *not* independent. Therefore, even linear transformations require additional, detailed analysis.

We now illustrate the effect of a closure approximation in the case of the wave equation (22.40). The application of the simple approximation to (22.42) yields

$$\mathbb{E} \left[\frac{\partial \Pi}{\partial W} \frac{\partial v}{\partial x} \right] \approx \mathbb{E} \left[\frac{\partial \Pi}{\partial W} \right] \mathbb{E} \left[\frac{\partial v}{\partial x} \right] = \frac{\partial \mathbb{E}[v]}{\partial x} \frac{\partial f_{vw}}{\partial W}, \quad (22.45)$$

where

$$\mathbb{E}[v] = \iint_{-\infty}^{\infty} V^* f_{vw}(V^*, W^*; x, t) dV^* dW^*,$$

and similarly for the other term in (22.42). This leads to the Fokker-Planck equation

$$\frac{\partial \tilde{f}_{vw}}{\partial t} + c^2 \frac{\partial \mathbb{E}[w]}{\partial x} \frac{\partial \tilde{f}_{vw}}{\partial V} + \frac{\partial \mathbb{E}[v]}{\partial x} \frac{\partial \tilde{f}_{vw}}{\partial W} = 0, \quad (22.46)$$

where \tilde{f}_{vw} is the approximation of f_{vw} under the above closure.

How accurate is this approximation? By multiplying (22.46) alternatively by V and W , and integrating, we obtain

$$\frac{\partial \tilde{\mathbb{E}}[v]}{\partial t} - c^2 \frac{\partial \mathbb{E}[w]}{\partial x} = 0 \quad \text{and} \quad \frac{\partial \tilde{\mathbb{E}}[w]}{\partial t} - \frac{\partial \mathbb{E}[v]}{\partial x} = 0, \quad (22.47)$$

where $\tilde{\mathbb{E}}$ denotes the expected value taken with respect to \tilde{f}_{vw} . On the other hand, by taking directly the expectation of (22.40), we get

$$\frac{\partial \mathbb{E}[v]}{\partial t} - c^2 \frac{\partial \mathbb{E}[w]}{\partial x} = 0 \quad \text{and} \quad \frac{\partial \mathbb{E}[w]}{\partial t} - \frac{\partial \mathbb{E}[v]}{\partial x} = 0. \quad (22.48)$$

Subtracting the two above systems equation by equation yields that the difference between $\tilde{\mathbb{E}}[v]$ and $\mathbb{E}[v]$ is constant in time and can be made zero through consistent initial conditions; a similar result holds for $\mathbb{E}[w]$. Therefore (22.46) evolves the means exactly. Similar arguments show that

$$\frac{\partial}{\partial t} \left(\mathbb{E}[v^2] - \tilde{\mathbb{E}}[v^2] \right) = 2 \operatorname{Cov} \left(v, c^2 \frac{\partial w}{\partial x} \right), \quad (22.49)$$

$$\frac{\partial}{\partial t} \left(\mathbb{E}[w^2] - \tilde{\mathbb{E}}[w^2] \right) = 2 \operatorname{Cov} \left(w, \frac{\partial v}{\partial x} \right), \quad (22.50)$$

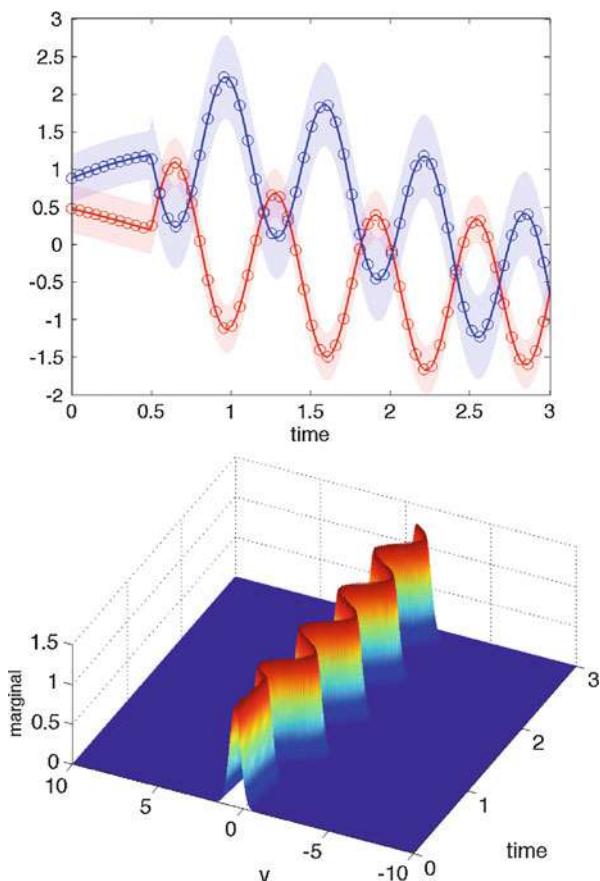

and thus, in general, (22.46) does not evolve the higher-order moments exactly.

Figure 22.5 illustrates the case of the wave equation on the half space $x > 0$ with random initial and boundary conditions. The retained closure is the simple mean field approximation.

4 Conclusions

The method of distributions, which comprises PDF and CDF methods, quantifies uncertainty in model parameters and driving forces (source terms and initial and boundary conditions) by deriving deterministic equations for either probability density function (PDF) or cumulative distribution function (CDF) of model outputs. Since it does not rely on finite-term approximations (e.g., a truncated Karhunen-Loëve transformation) of random parameter fields, the method of distributions does not suffer from the “curse of dimensionality.” On the contrary, it is exact for

Fig. 22.5 Solutions to the wave equation (22.40) in a half-space with random boundary condition. *Top:* the expected values of v and w (solid curves) computed from the PDF equation plus or minus one standard deviation are plotted at a fixed point in space. The boundary condition “hits” at about $t = 0.5$. The “circles” are the Monte Carlo results. *Bottom:* marginal for the v -component at the same spatial point

a class of nonlinear hyperbolic equations whose coefficients lack spatiotemporal correlation, i.e., exhibit an infinite number of random dimensions.

Appendix

It follows from (22.11) and the fact that \mathbf{u} solves (22.10) that

$$\begin{aligned} I &\equiv \int_0^\infty \int_{-\infty}^\infty f_{\mathbf{u},\epsilon}(\mathbf{U}; t) \frac{\partial \phi}{\partial t}(\mathbf{U}, t) d\mathbf{U} dt = \mathbb{E} \left[\int_0^\infty \int_{-\infty}^\infty \eta_\epsilon(\mathbf{U} - \mathbf{u}) \frac{\partial \phi}{\partial t}(\mathbf{U}, t) d\mathbf{U} dt \right] \\ &= \mathbb{E} \left[\int_0^\infty \int_{-\infty}^\infty \eta'_\epsilon(\mathbf{U} - \mathbf{u}) \mathbf{G}(\mathbf{u}) \phi(\mathbf{U}, t) d\mathbf{U} dt \right] - \int_{-\infty}^\infty \mathbb{E}[\eta_\epsilon(\mathbf{U} - \mathbf{u}_0)] \phi(\mathbf{U}, 0) d\mathbf{U}, \end{aligned}$$

for any $\phi \in \mathcal{C}_c^1(\mathbb{R}^N \times [0, \infty))$. Therefore

$$I = \int_0^\infty \int_{-\infty}^\infty \int_{-\infty}^\infty \eta'_\epsilon(\mathbf{U} - \tilde{\mathbf{u}}) \mathbf{G}(\tilde{\mathbf{u}}) \phi(\mathbf{U}, t) f_{\mathbf{u}}(\tilde{\mathbf{u}}; t) d\mathbf{U} d\tilde{\mathbf{u}} dt - \int_{-\infty}^\infty f_{\mathbf{u}, \epsilon}(\mathbf{U}; 0) \phi(\mathbf{U}, 0) d\mathbf{U}.$$

Integration by parts in \mathbf{U} yields

$$I = - \int_0^\infty \int_{-\infty}^\infty (\eta_\epsilon \star \mathbf{G} f_{\mathbf{u}})(\mathbf{U}, t) \nabla_{\mathbf{U}} \phi(\mathbf{U}, t) d\mathbf{U} dt - \int_{-\infty}^\infty f_{\mathbf{u}, \epsilon}(\mathbf{U}; 0) \phi(\mathbf{U}, 0) d\mathbf{U}.$$

By the above definition of I , we have established that, for any $\phi \in \mathcal{C}_c^1(\mathbb{R}^N \times [0, \infty))$,

$$\int_0^\infty \int_{-\infty}^\infty f_{\mathbf{u}, \epsilon} \frac{\partial \phi}{\partial t} d\mathbf{U} dt + \int_0^\infty \int_{-\infty}^\infty (\eta_\epsilon \star \mathbf{G} f_{\mathbf{u}}) \nabla_{\mathbf{U}} \phi d\mathbf{U} dt + \int_{-\infty}^\infty f_{\mathbf{u}, \epsilon}(\mathbf{U}; 0) \phi(\mathbf{U}, 0) d\mathbf{U} = 0.$$

Using standard arguments [1], taking the limit $\epsilon \rightarrow 0$ leads to (22.12).

Sampling via Measure Transport: An Introduction

23

Youssef Marzouk, Tarek Moselhy, Matthew Parno, and Alessio Spantini

Abstract

We present the fundamentals of a measure transport approach to sampling. The idea is to construct a deterministic coupling – i.e., a transport map – between a complex “target” probability measure of interest and a simpler reference measure. Given a transport map, one can generate arbitrarily many independent and unweighted samples from the target simply by pushing forward reference samples through the map. If the map is endowed with a triangular structure, one can also easily generate samples from conditionals of the target measure. We consider two different and complementary scenarios: first, when only evaluations of the unnormalized target density are available and, second, when the target distribution is known only through a finite collection of samples. We show that in both settings, the desired transports can be characterized as the solutions of variational problems. We then address practical issues associated with the optimization-based construction of transports: choosing finite-dimensional parameterizations of the map, enforcing monotonicity, quantifying the error of approximate transports, and refining approximate transports by enriching

the corresponding approximation spaces. Approximate transports can also be used to “Gaussianize” complex distributions and thus precondition conventional asymptotically exact sampling schemes. We place the measure transport approach in broader context, describing connections with other optimization-based samplers, with inference and density estimation schemes using optimal transport, and with alternative transformation-based approaches to simulation. We also sketch current work aimed at the construction of transport maps in high dimensions, exploiting essential features of the target distribution (e.g., conditional independence, low-rank structure). The approaches and algorithms presented here have direct applications to Bayesian computation and to broader problems of stochastic simulation.

1 Introduction

Characterizing complex probability distributions is a fundamental and ubiquitous task in uncertainty quantification. In this context, the notion of “complexity” encompasses many possible challenges: non-Gaussian features, strong correlations

and nonlinear dependencies, high dimensionality, the high computational cost of evaluating the (unnormalized) probability density associated with the distribution, or even intractability of the probability density altogether. Typically one wishes to characterize a distribution by evaluating its moments, or by computing the probability of an event of interest. These goals can be cast as the computation of *expectations* under the distribution, e.g., the computation of $\mathbb{E}[g(\mathbf{Z})]$ where g is some measurable function and \mathbf{Z} is the random variable whose distribution we wish to characterize.

The workhorse algorithms in this setting are sampling or “simulation” methods, of which the most broadly useful are Markov chain Monte Carlo (MCMC) [16, 33, 69] or sequential Monte Carlo (SMC) [26, 49, 73] approaches. Direct sampling from the distribution of interest – i.e., generating independent and unweighted samples – is typically impossible. However, MCMC and SMC methods generate samples that can nonetheless be used to compute the desired expectations. In the case of MCMC, these samples are correlated, while in the case of importance sampling or SMC, the samples are endowed with weights. Nonzero correlations or nonuniform weights are in a sense the price to be paid for flexibility – for these approaches’ ability to characterize arbitrary probability distributions. But if the correlations between successive MCMC samples decay too slowly, or if importance sampling weights become too nonuniform and the sample population thus degenerates, all these approaches become extremely inefficient. Accordingly, enormous efforts have been devoted to the design of improved MCMC and SMC samplers – schemes that generate more nearly independent or unweighted samples. While these efforts are too diverse to summarize easily, they often rest on the design of improved (and structure-exploiting) proposal mechanisms within the algorithms [3, 22, 24, 26, 34, 37, 53, 62].

As an alternative to the sampling approaches described above, we will consider *transformations* of random variables, or perhaps more abstractly, *transport maps* between probability measures. Let $\mu_{\text{tar}} : \mathcal{B}(\mathbb{R}^n) \rightarrow \mathbb{R}_+$ be a probability measure that we wish to characterize, defined over the Borel σ -algebra on \mathbb{R}^n , and let $\mu_{\text{ref}} : \mathcal{B}(\mathbb{R}^n) \rightarrow \mathbb{R}_+$ be another probability measure from which we can easily generate independent and unweighted samples, e.g., a standard Gaussian. Then a transport map $T : \mathbb{R}^n \rightarrow \mathbb{R}^n$ pushes forward μ_{ref} to μ_{tar} if and only if $\mu_{\text{tar}}(A) = \mu_{\text{ref}}(T^{-1}(A))$ for any set $A \in \mathcal{B}(\mathbb{R}^n)$. We can write this compactly as

$$T_\sharp \mu_{\text{ref}} = \mu_{\text{tar}}. \quad (23.1)$$

In simpler terms, imagine generating samples $\mathbf{x}_i \in \mathbb{R}^n$ that are distributed according to μ_{ref} and then applying T to each of these samples. Then the transformed samples $T(\mathbf{x}_i)$ are distributed according to μ_{tar} .

Setting aside for a moment questions of how to find such a transformation T and what its properties might be, consider the significance of having T in hand. First of all, given T and the ability to sample directly from μ_{ref} , one can generate independent and unweighted samples from μ_{tar} and from any of its marginal distributions. Moreover one can generate these samples cheaply, regardless of the cost of evaluating the probability density associated with μ_{tar} ; with a map T in hand,

no further appeals to μ_{tar} are needed. A transport map can also be used to devise deterministic sampling approaches, i.e., quadratures for nonstandard measures μ_{tar} , based on quadratures for the reference measure μ_{ref} . Going further, if the transport map is endowed with an appropriate structure, it can enable direct simulation from particular conditionals of μ_{tar} . (We will describe this last point in more detail later.)

The potential to accomplish all of these tasks using measure transport is the launching point for this chapter. We will present a variational approach to the construction of transport maps, i.e., characterizing the desired maps as the solutions of particular optimization problems. We will also discuss the parameterization of transport maps – a challenging task since maps are, in general, high-dimensional multivariate functions, which ultimately must be approximated in finite-dimensional spaces. Because maps are sought via optimization, standard tools for assessing convergence can be used. In particular, it will be useful to quantify the error incurred when the map is not exact, i.e., when we have only $T_{\#}\mu_{\text{ref}} \approx \mu_{\text{tar}}$, and to develop strategies for refining the map parameterization in order to reduce this error. More broadly, it will be useful to understand how the structure of the transport map (e.g., sparsity and other low-dimensional features) depends on the properties of the target distribution and how this structure can be exploited to construct and represent maps more efficiently.

In discussing these issues, we will focus on two classes of map construction problems: (P1) constructing transport maps given the ability to evaluate only the unnormalized probability density of the target distribution and (P2) constructing transport maps given only *samples* from a distribution of interest, but no explicit density. These problems are frequently motivated by Bayesian inference, though their applicability is more general. In the Bayesian context, the first problem corresponds to the typical setup where one can evaluate the unnormalized density of the Bayesian posterior. The second problem can arise when one has samples from the joint distribution of parameters and observations and wishes to condition the former on a particular realization of the latter. This situation is related to approximate Bayesian computation (ABC) [9, 52], and here our ultimate goal is conditional simulation.

This chapter will present the basic formulations employed in the transport map framework and illustrate them with simple numerical examples. First, in Sect. 2, we will recall foundational notions in measure transport and *optimal transportation*. Then we will present variational formulations corresponding to Problems P1 and P2 above. In particular, Sect. 3 will explore the details of Problem P1: constructing transport maps from density evaluations. Section 4 will explore Problem P2: sample-based map construction. Section 5 then discusses useful finite-dimensional parameterizations of transport maps. After presenting these formulations, we will describe connections between the transport map framework and other work in Sect. 6. In Sect. 7 we describe how to simulate from certain conditionals of the target measure using a map, and in Sect. 8 we illustrate the framework on a Bayesian inference problem, including some comparisons with MCMC. Because this area is rapidly developing, this chapter will not attempt to capture all of the latest efforts and extensions. Instead, we will provide the reader with pointers to current work in Sect. 9, along with a summary of important open issues.

2 Transport Maps and Optimal Transport

A transport map T satisfying (23.1) can be understood as a deterministic coupling of two probability measures, and it is natural to ask under what conditions on μ_{ref} and μ_{tar} such a map exists. Consider, for instance, the case where μ_{ref} has as an atom but μ_{tar} does not; then there is no deterministic map that can push forward μ_{ref} to μ_{tar} , since the probability contained in the atom cannot be split. Fortunately, the conditions for the existence of a map are quite weak – for instance, that μ_{ref} be atomless [85]. Henceforth we will assume that both the reference measure μ_{ref} and the target measure μ_{tar} are absolutely continuous with respect to the Lebesgue measure on \mathbb{R}^n , thus assuring the existence of transport maps satisfying (23.1).

There may be infinitely many such transformations, however. One way of choosing a particular map is to introduce a transport cost $c : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}$ such that $c(\mathbf{x}, \mathbf{z})$ represents the “work” needed to move a unit of mass from \mathbf{x} to \mathbf{z} . The resulting cost of a particular map is then

$$C(T) = \int_{\mathbb{R}^n} c(\mathbf{x}, T(\mathbf{x})) \, d\mu_{\text{ref}}(\mathbf{x}). \quad (23.2)$$

Minimizing (23.2) while simultaneously satisfying (23.1) corresponds to a problem first posed by Monge [57] in 1781. The solution of this constrained minimization problem is the *optimal* transport map. Numerous properties of optimal transport have been studied in the centuries since. Of particular interest is the result of [15], later extended by [55], which shows that when $c(\mathbf{x}, T(\mathbf{x}))$ is quadratic and μ_{ref} is atomless, the optimal transport map exists and is unique; moreover this map is the gradient of a convex function and thus is monotone. Generalizations of this result accounting for different cost functions and spaces can be found in [2, 11, 19, 27]. For a thorough contemporary development of optimal transport, we refer to [84, 85]. The structure of the optimal transport map follows not only from the target and reference measures but also from the cost function in (23.2). For example, the quadratic cost of [15] and [55] leads to maps that are in general dense, i.e., with each output of the map depending on every input to the map. However, if the cost is taken to be

$$c(\mathbf{x}, \mathbf{z}) = \sum_{i=1}^n t^{i-1} |x_i - z_i|^2, \quad t > 0, \quad (23.3)$$

then [18] and [13] show that the optimal map becomes lower triangular as $t \rightarrow 0$. Lower triangular maps take the form

$$T(\mathbf{x}) = \begin{bmatrix} T^1(x_1) \\ T^2(x_1, x_2) \\ \vdots \\ T^n(x_1, x_2, \dots, x_n) \end{bmatrix} \quad \forall \mathbf{x} = (x_1, \dots, x_n) \in \mathbb{R}^n, \quad (23.4)$$

where T^i represents output i of the map. Importantly, when μ_{tar} and μ_{ref} are absolutely continuous, a unique lower triangular map satisfying (23.1) exists; this map is exactly the Knothe–Rosenblatt rearrangement [13, 18, 70].

The numerical computation of the optimal transport map, for generic measures on \mathbb{R}^n , is a challenging task that is often restricted to very low dimensions [4, 10, 38, 50]. Fortunately, in the context of stochastic simulation and Bayesian inference, we are not particularly concerned with the optimality aspect of the transport; we just need to push forward the reference measure to the target measure. Thus we will focus on transports that are easy to compute, but that do not necessarily satisfy an optimality criterion based on transport cost. Triangular transports will thus be of particular interest to us. The triangular structure will make constructing transport maps feasible (see Sects. 3 and 4), conditional sampling straightforward (see Sect. 7), and map inversion efficient (see Sect. 4.3). Accordingly, we will require the transport map to be (lower) triangular and search for a transformation that satisfies (23.1). The optimization problems arising from this formulation are described in the next two sections.

3 Direct Transport: Constructing Maps from Unnormalized Densities

In this section we show how to construct a transport map that pushes forward a reference measure to the target measure when only evaluations of the *unnormalized target density* are available. This is a central task in Bayesian inference, where the target is the posterior measure.

3.1 Preliminaries

We assume that both target and reference measures are absolutely continuous with respect to the Lebesgue measure on \mathbb{R}^n . Let π and η be, respectively, the normalized target and reference densities with respect to the Lebesgue measure. In what follows and for the sake of simplicity, we assume that both π and η are smooth strictly positive functions on their support. We seek a diffeomorphism T (a smooth function with smooth inverse) that pushes forward the reference to the target measure,

$$\mu_{\text{tar}} = \mu_{\text{ref}} \circ T^{-1}, \quad (23.5)$$

where \circ denotes the composition of functions. In terms of densities, we will rewrite (23.5) as $T_{\sharp}\eta = \pi$ over the support of the reference density. $T_{\sharp}\eta$ is the pushforward of the reference density under the map T , and it is defined as:

$$T_{\sharp}\eta := \eta \circ T^{-1} |\det \nabla T^{-1}|, \quad (23.6)$$

where ∇T^{-1} denotes the Jacobian of the inverse of the map. (Recall that the Jacobian determinant $\det \nabla T^{-1}$ is equal to $1/(\det \nabla T \circ T^{-1})$.) As noted in the introduction, if $(\mathbf{x}_i)_i$ are independent samples from η , then $(T(\mathbf{x}_i))_i$ are independent samples from $T_{\sharp}\eta$. (Here and throughout the chapter, we use the notation $(\mathbf{x}_i)_i$ as a shorthand for $(\mathbf{x}_i)_{i=1}^M$ to denote a collection $(\mathbf{x}_1, \dots, \mathbf{x}_M)$ whenever the definition of the cardinality M is either unimportant or possibly infinite.) Hence, if we find a transport map T that satisfies $T_{\sharp}\eta = \pi$, then $(T(\mathbf{x}_i))_i$ will be independent samples from the target distribution. In particular, the change of variables formula:

$$\int g(\mathbf{x}) \pi(\mathbf{x}) d\mathbf{x} = \int [g \circ T](\mathbf{x}) \eta(\mathbf{x}) d\mathbf{x} \quad (23.7)$$

holds for any integrable real-valued function g on \mathbb{R}^n [1]. The map therefore allows for direct computation of posterior expectations.

3.2 Optimization Problems

Now we describe a series of optimization problems whose solution yields the desired transport map. Let $\mathcal{D}_{\text{KL}}(\pi_1 \parallel \pi_2)$ denote the Kullback–Leibler (K–L) divergence from a probability measure with density π_1 to a probability measure with density π_2 , i.e.,

$$\mathcal{D}_{\text{KL}}(\pi_1 \parallel \pi_2) = \mathbb{E}_{\pi_1} \left(\log \frac{\pi_1}{\pi_2} \right),$$

and let \mathcal{T} be an appropriate set of diffeomorphisms. Then, any global minimizer of the optimization problem:

$$\begin{aligned} & \min \mathcal{D}_{\text{KL}}(T_{\sharp}\eta \parallel \pi) \\ & \text{s.t. } \det \nabla T > 0, \quad (\eta - \text{a.e.}) \\ & \qquad T \in \mathcal{T} \end{aligned} \quad (23.8)$$

is a valid transport map that pushes forward the reference to the target measure¹. In fact, any global minimizer of (23.8) achieves the minimum cost $\mathcal{D}_{\text{KL}}(T_{\sharp}\eta \parallel \pi) = 0$ and implies that $T_{\sharp}\eta = \pi$. The constraint $\det \nabla T > 0$ ensures that the pushforward density $T_{\sharp}\eta$ is strictly positive on the support of the target. In particular, the constraint $\det \nabla T > 0$ ensures that the K–L divergence evaluates to finite values over \mathcal{T} and does not rule out any useful transport map since we assume that both target and reference densities are positive. The existence of global minimizers of (23.8) is a standard result in the theory of deterministic couplings between random variables [85].

¹See [61] for a discussion on the asymptotic equivalence of the K–L divergence and Hellinger distance in the context of transport maps.

Among these minimizers, a particularly useful map is given by the Knothe–Rosenblatt rearrangement [18]. In our hypothesis, the Knothe–Rosenblatt rearrangement is a *triangular* (in the sense that the k th component of the map depends only on the first k input variables) diffeomorphism T such that $\nabla T \succ 0$. That is, each eigenvalue of ∇T is real and positive. Thus it holds that $\det \nabla T > 0$. Notice that for a triangular map, the eigenvalues of ∇T are just the diagonal entries of this matrix. The Knothe–Rosenblatt rearrangement is also monotone increasing according to the lexicographic order on \mathbb{R}^{n^2} .

It turns out that we can further constrain (23.8) so that the Knothe–Rosenblatt rearrangement is the *unique* global minimizer of:

$$\begin{aligned} \min \mathcal{D}_{\text{KL}}(T_{\sharp}\eta \parallel \pi) \\ \text{s.t. } \nabla T \succ 0, \quad (\eta - \text{a.e.}) \\ T \in \mathcal{T}_{\Delta} \end{aligned} \tag{23.9}$$

where \mathcal{T}_{Δ} is now the vector space of smooth triangular maps. The constraint $\nabla T \succ 0$ suffices to enforce invertibility of a feasible triangular map. Equation (23.9) is a far better behaved optimization problem than the original formulation (23.8). Hence, for the rest of this section, we will focus on the computation of a Knothe–Rosenblatt rearrangement by solving (23.9). Recall that our goal is just to compute a transport map from μ_{ref} to μ_{tar} . If there are multiple transports, we can opt for the easiest one to compute. A possible drawback of a triangular transport is that the complexity of a parameterization of the map depends on the ordering of the input variables. This dependence motivates questions of what is the “best” ordering, or how to find at least a “good” ordering. We refer the reader to [75] for an in-depth discussion of this topic. For the computation of general non-triangular transports, see [61]; for a generalization of the framework to compositions of maps, see [61, 63]; and for the computation of optimal transports, see, for instance, [4, 10, 50, 85].

Now let $\bar{\pi}$ denote any *unnormalized* version of the target density. For any map T in the feasible set of (23.9), the objective function can be written as:

$$\begin{aligned} \mathcal{D}_{\text{KL}}(T_{\sharp}\eta \parallel \pi) &= \mathcal{D}_{\text{KL}}(\eta \parallel T_{\sharp}^{-1}\pi) \\ &= \mathbb{E}_{\eta}[-\log \bar{\pi} \circ T - \log \det \nabla T] + \mathfrak{C}, \end{aligned} \tag{23.10}$$

²The lexicographic order on \mathbb{R}^n is defined as follows. For $x, y \in \mathbb{R}^n$, we define $x \preceq y$ if and only if either $x = y$ or the first nonzero coordinate in $y - x$ is positive [32]. \preceq is a total order on \mathbb{R}^n . Thus, we define T to be a monotone increasing function if and only if $x \preceq y$ implies $T(x) \preceq T(y)$. Notice that monotonicity can be defined with respect to any order on \mathbb{R}^n (e.g., \preceq need not be the lexicographic order). There is no natural order on \mathbb{R}^n except when $n = 1$. It is easy to verify that for a triangular function T , monotonicity with respect to the lexicographic order is equivalent to the following: the k th component of T is a monotone function of the k th input variable.

where $\mathbb{E}_\eta[\cdot]$ denotes integration with respect to the reference measure, and \mathfrak{C} is a term independent of the transport map and thus a constant for the purposes of optimization. (In this case, $\mathfrak{C} = \log \beta + \log \eta$, where $\beta := \bar{\pi}/\pi$ is the normalizing constant of the target density.) The resulting optimization problem reads as:

$$\begin{aligned} & \min \mathbb{E}_\eta[-\log \bar{\pi} \circ T - \log \det \nabla T] \\ & \text{s.t. } \nabla T \succ 0, \quad (\eta \text{-a.e.}) \\ & \quad T \in \mathcal{T}_\Delta \end{aligned} \tag{23.11}$$

Notice that we can evaluate the objective of (23.11) given only the unnormalized density $\bar{\pi}$ and a way to compute the integral $\mathbb{E}_\eta[\cdot]$. There exist a host of techniques to approximate the integral with respect to the reference measure, including quadrature and cubature formulas, sparse quadratures, Monte Carlo methods, and quasi-Monte Carlo (QMC) methods. The choice between these methods is typically dictated by the dimension of the reference space. In any case, the reference measure is usually chosen so that the integral with respect to η can be approximated easily and accurately. For instance, if μ_{ref} is a standard Gaussian measure, then we can generate arbitrarily many independent samples to yield an approximation of $\mathbb{E}_\eta[\cdot]$ to any desired accuracy. This will be a crucial difference relative to the sample-based construction of the map described in Sect. 4, where samples from the target distribution are required to accurately solve the corresponding optimization problem.

Equation (23.11) is a linearly constrained nonlinear differentiable optimization problem. It is also non-convex unless, for instance, the target density is log concave [41]. That said, many statistical models have log-concave posterior distributions and hence yield convex map optimization problems; consider, for example, a log-Gaussian Cox process [34]. All n components of the map have to be computed simultaneously, and each evaluation of the objective function of (23.11) requires an evaluation of the unnormalized target density. The latter is also the minimum requirement for alternative sampling techniques such as MCMC. Of course, the use of derivatives in the context of the optimization problem is crucial for computational efficiency, especially for high-dimensional parameterizations of the map. The same can be said of the state-of-the-art MCMC algorithms that use gradient or Hessian information from the log-target density to yield better proposal distributions, such as Langevin or Hamiltonian MCMC [34]. In the present context, we advocate the use of quasi-Newton (e.g., BFGS) or Newton methods [90] to solve (23.11). These methods must be paired with a finite-dimensional parameterization of the map; in other words, we must solve (23.11) over a finite-dimensional space $\mathcal{T}_\Delta^h \subset \mathcal{T}_\Delta$ of triangular diffeomorphisms. In Sect. 5 we will discuss various choices for \mathcal{T}_Δ^h along with ways of enforcing the monotonicity constraint $\nabla T \succ 0$.

3.3 Convergence, Bias, and Approximate Maps

A transport map provides a deterministic solution to the problem of sampling from a given unnormalized density, avoiding classical stochastic tools such as MCMC. Once the transport map is computed, we can quickly generate independent and unweighted samples from the target distribution without further evaluating the target density [61]. This is a major difference with respect to MCMC. Of course, the density-based transport map framework essentially exchanges a challenging sampling task for a challenging optimization problem involving function approximation. Yet there are several advantages to dealing with an optimization problem rather than a sampling problem. Not only can we rely on a rich literature of robust algorithms for the solution of high-dimensional nonlinear optimization problems, but we also inherit the notion of convergence criteria. The latter point is crucial.

A major concern in MCMC sampling methods is the lack of clear and generally applicable convergence criteria. It is a nontrivial task to assess the stationarity of an ergodic Markov chain, let alone to measure the distance between the empirical measure given by the MCMC samples and the target distribution [36]. In the transport map framework, on the other hand, the convergence criterion is borrowed directly from standard optimization theory [51]. As shown in [61], the K–L divergence $\mathcal{D}_{\text{KL}}(T_{\sharp}\eta \parallel \pi)$ can be estimated as:

$$\mathcal{D}_{\text{KL}}(T_{\sharp}\eta \parallel \pi) \approx \frac{1}{2} \text{Var}_{\eta}[\log \eta - \log T_{\sharp}^{-1}\bar{\pi}] \quad (23.12)$$

up to second-order terms in the limit of $\text{Var}_{\eta}[\log \eta - \log T_{\sharp}^{-1}\bar{\pi}] \rightarrow 0$, even if the normalizing constant of the target density is unknown. (Notice that (23.12) contains only the unnormalized target density $\bar{\pi}$.) Thus one can monitor (23.12) to estimate the divergence between the pushforward of a given map and the desired target distribution. Moreover, the transport map algorithm also provides an estimate of the normalizing constant $\beta := \bar{\pi}/\pi$ of the target density as [61]:

$$\beta = \exp \mathbb{E}_{\eta}[\log \eta - \log T_{\sharp}^{-1}\bar{\pi}] . \quad (23.13)$$

The normalizing constant is a particularly useful quantity in the context of Bayesian model selection [30]. Reliably retrieving this normalizing constant from MCMC samples requires additional effort (e.g., [20, 31]). The numerical solution of (23.11) entails at least two different approximations. First, the infinite-dimensional function space \mathcal{T}_{Δ} must be replaced with a finite-dimensional subspace $\mathcal{T}_{\Delta}^h \subset \mathcal{T}_{\Delta}$. For example, each component of the map can be approximated in a total-degree polynomial space, as discussed in Sect. 5. Let h parameterize a sequence of possibly nested finite-dimensional approximation spaces $(\mathcal{T}_{\Delta}^h)_h$. Then, as the dimension of \mathcal{T}_{Δ}^h grows, we can represent increasingly complex maps. Second, the expectation with respect to the reference measure in the objective of (23.11) must also be approximated. As discussed earlier, one may take any of several approaches. As a concrete example, consider approximating $\mathbb{E}_{\eta}[\cdot]$ by a Monte Carlo sum with M

independent samples $(\mathbf{x}_i)_i$ from the reference measure. Clearly, as the cardinality of the sample set grows, the approximation of $\mathbb{E}_\eta[\cdot]$ becomes increasingly accurate. An instance of an approximation of (23.11) is then:

$$\begin{aligned} \min \frac{1}{M} \sum_{i=1}^M & \left(-\log \tilde{\pi}(T(\mathbf{x}_i)) - \sum_{k=1}^n \log \partial_k T^k(\mathbf{x}_i) \right) \\ \text{s.t. } & \partial_k T^k > 0, \quad k = 1, \dots, n, \quad (\eta - \text{a.e.}) \\ & T \in \mathcal{T}_\Delta^h \subset \mathcal{T}_\Delta \end{aligned} \quad (23.14)$$

where we have simplified the monotonicity constraint $\nabla T > 0$ by using the fact that ∇T is lower triangular for maps in \mathcal{T}_Δ . Above we require that the monotonicity constraint be satisfied over the whole support of the reference density. We will discuss ways of strictly guaranteeing such a property in Sect. 5. Depending on the parameterization of the map, however, the monotonicity constraint is sometimes relaxed (e.g., in the tails of η); doing so comprises a third source of approximation.

Given a fixed sample set, (23.14) is a sample-average approximation (SAA) [42] of (23.11), to which we can apply standard numerical optimization techniques [90]. Alternatively, one can regard (23.11) as a stochastic program and solve it using stochastic approximation techniques [43, 74]. In either case, the transport map framework allows efficient *global* exploration of the parameter space via optimization. The exploration is global since with a transport map T we are essentially trying to push forward the entire collection of reference samples $(\mathbf{x}_i)_i$ to samples $(T(\mathbf{x}_i))_i$ that fit the entire target distribution. Additionally, we can interpret the finite-dimensional parameterization of a candidate transport as a constraint on the relative motion of the pushforward particles $(T(\mathbf{x}_i))_i$.

The discretization of the integral $\mathbb{E}_\eta[\cdot]$ in (23.14) reveals another important distinction of the transport map framework from MCMC methods. At every optimization iteration, we need to evaluate the target density M times. If we want an accurate approximation of $\mathbb{E}_\eta[\cdot]$, then M can be large. But these M evaluations of the target density can be performed in an embarrassingly *parallel* manner. This is a fundamental difference from standard MCMC, where the evaluations of the target density are inherently sequential. (For exceptions to this paradigm, see, e.g., [17]).

A minimizer of (23.14) is an approximate transport map \tilde{T} ; this map can be written as $\tilde{T}(\cdot; M, h)$ to reflect dependence on the approximation parameters (M, h) defined above. Ideally, we would like the approximate map \tilde{T} to be as close as possible to the true minimizer $T \in \mathcal{T}_\Delta$ of (23.11). Yet it is also important to understand the potential of an approximate map alone. If \tilde{T} is not the exact transport map, then $\tilde{T}_\# \eta$ will not be the target density. The pushforward density $\tilde{T}_\# \eta$ instead defines an approximate target: $\tilde{\pi} := \tilde{T}_\# \eta$. We can easily sample from $\tilde{\pi}$ by pushing forward reference samples through \tilde{T} . If we are interested in estimating integrals of the form $\mathbb{E}_\pi[g]$ for some integrable function g , then we can try to use Monte Carlo estimators of $\mathbb{E}_{\tilde{\pi}}[g]$ to approximate $\mathbb{E}_\pi[g]$. This procedure will result in a biased

estimator for $\mathbb{E}_\pi[g]$ since $\tilde{\pi}$ is not the target density. It turns out that this bias can be bounded as:

$$\|\mathbb{E}_\pi[g] - \mathbb{E}_{\tilde{\pi}}[g]\| \leq \mathcal{C}(g, \pi, \tilde{\pi}) \sqrt{\mathcal{D}_{\text{KL}}(T_\sharp \eta || \pi)} \quad (23.15)$$

where $\mathcal{C}(g, \pi, \tilde{\pi}) := \sqrt{2} (\mathbb{E}_\pi[\|g\|^2] + \mathbb{E}_{\tilde{\pi}}[\|g\|^2])^{\frac{1}{2}}$. The proof of this result is in [79, Lemma 6.37] together with a similar result for the approximation of the second moments. Note that the K–L divergence on the right-hand side of (23.15) is exactly the quantity we minimize in (23.11) during the computation of a transport map, and it can easily be estimated using (23.12). Thus the transport map framework allows a systematic control of the bias resulting from estimation of $\mathbb{E}_\pi[g]$ by means of an approximate map \tilde{T} .

In practice, the mean-square error in approximating $\mathbb{E}_\pi[g]$ using $\mathbb{E}_{\tilde{\pi}}[g]$ will be entirely due to the bias described in (23.15). The reason is that a Monte Carlo estimator of $\mathbb{E}_{\tilde{\pi}}[g]$ can be constructed to have virtually no variance: one can cheaply generate an arbitrary number of independent and unweighted samples from $\tilde{\pi}$ using the approximate map. Hence the approximate transport map yields an essentially zero-variance biased estimator of the quantity of interest $\mathbb{E}_\pi[g]$. This property should be contrasted with MCMC methods which, while asymptotically unbiased, yield estimators of $\mathbb{E}_\pi[g]$ that have nonzero variance and bias for finite sample size.

If one is not content with the bias associated with an approximate map, then there are at least two ways to proceed. First, one can simply refine the approximation parameters (M, h) to improve the current approximation of the transport map. On the other hand, it is straightforward to apply any classical sampling technique (e.g., MCMC, importance sampling) to the *pullback* density $\tilde{T}^\# \pi = \tilde{T}_\sharp^{-1} \pi$. This density is defined as

$$\tilde{T}^\# \pi := \pi \circ \tilde{T} |\det \nabla \tilde{T}|, \quad (23.16)$$

and can be evaluated (up to a normalizing constant) at no significant additional cost compared to the original target density π . If $(\mathbf{x}_i)_i$ are samples from the pullback $\tilde{T}^\# \pi$, then $(\tilde{T}(\mathbf{x}_i))_i$ will be samples from the *exact* target distribution. But there are clear advantages to sampling $\tilde{T}^\# \pi$ instead of the original target distribution. Consider the following: if \tilde{T} were the exact transport map, then $\tilde{T}^\# \pi$ would simply be the reference density. With an approximate map, we still expect $\tilde{T}^\# \pi$ to be close to the reference density – more precisely, closer to the reference (in the sense of K–L divergence) than was the original target distribution. In particular, when the reference is a standard Gaussian, the pullback will be closer to a standard Gaussian than the original target. Pulling back through an approximate map thus “Gaussianizes” the target and can remove the correlations and nonlinear dependencies that make sampling a challenging task. In this sense, we can interpret an approximate map as a general *preconditioner* for any known sampling scheme. See [64] for a full development of this idea in the context of MCMC.

There is clearly a trade-off between the computational cost associated with constructing a more accurate transport map and the costs of “correcting” an approximate map by applying an exact sampling scheme to the pullback. Focusing on the former, it is natural to ask how to refine the finite-dimensional approximation space \mathcal{T}_Δ^h so that it can better capture the true map T . Depending on the problem at hand, a naïve finite-dimensional parameterization of the map might require a very large number of degrees of freedom before reaching a satisfactory approximation. This is particularly true when the parameter dimension n is large and is a challenge shared by any function approximation algorithm (e.g., high-dimensional regression). We will revisit this issue in Sect. 9, but the essential way forward is to realize that the structure of the target distribution is reflected in the structure of the transport map. For instance, conditional independence in the target distribution yields certain kinds of *sparsity* in the transport, which can be exploited when solving the optimization problems above. Many Bayesian inference problems also contain low-rank structure that causes the map to depart from the identity only on low-dimensional subspace of \mathbb{R}^n . From the optimization perspective, adaptivity can also be driven via a systematic analysis of the first variation of the K–L divergence $\mathcal{D}_{\text{KL}}(T_\sharp \eta \parallel \pi)$ as a function of $T \in \mathcal{T}$.

4 Inverse Transport: Constructing Maps from Samples

In the previous section, we focused on the computation of a transport map that pushes forward a reference measure to a target measure, in settings where the target density can be evaluated up to a normalizing constant and where it is simple to approximate integrals with respect to the reference measure (e.g., using quadrature, Monte Carlo, or QMC). In many problems of interest, including density estimation [81] and approximate Bayesian computation, however, it is not possible to evaluate the unnormalized target density $\bar{\pi}$.

In this section we assume that the target density is unknown and that we are only given a finite number of samples distributed according to the target measure. We show that under these hypotheses, it is possible to efficiently compute an *inverse transport* – a transport map that pushes forward the target to the reference measure – via convex optimization. The direct transport – a transport map that pushes forward the reference to the target measure – can then be easily recovered by inverting the inverse transport map pointwise, taking advantage of the map’s triangular structure.

4.1 Optimization Problem

We denote the inverse transport by $S : \mathbb{R}^n \rightarrow \mathbb{R}^n$ and again assume that the reference and target measures are absolutely continuous with respect to the Lebesgue measure on \mathbb{R}^n , with smooth and positive densities. The inverse transport pushes forward the target to the reference measure:

$$\mu_{\text{ref}} = \mu_{\text{tar}} \circ S^{-1}. \quad (23.17)$$

We focus on the inverse triangular transport because it can be computed via convex optimization given samples from the target distribution. It is easy to see that the monotone increasing Knothe–Rosenblatt rearrangement that pushes forward μ_{tar} to μ_{ref} is the unique minimizer of

$$\begin{aligned} & \min \mathcal{D}_{\text{KL}}(S_{\sharp}\pi \parallel \eta) \\ \text{s.t. } & \nabla S \succ 0, \quad (\pi - \text{a.e.}) \\ & S \in \mathcal{T}_{\Delta} \end{aligned} \tag{23.18}$$

where \mathcal{T}_{Δ} is the space of smooth triangular maps. If S is a minimizer of (23.18), then $\mathcal{D}_{\text{KL}}(S_{\sharp}\pi \parallel \eta) = 0$ and thus $S_{\sharp}\pi = \eta$. For any map S in the feasible set of (23.18), the objective function can be written as:

$$\begin{aligned} \mathcal{D}_{\text{KL}}(S_{\sharp}\pi \parallel \eta) &= \mathcal{D}_{\text{KL}}(\pi \parallel S_{\sharp}^{-1}\eta) \\ &= \mathbb{E}_{\pi}[-\log \eta \circ S - \log \det \nabla S] + \mathfrak{C} \end{aligned} \tag{23.19}$$

where $\mathbb{E}_{\pi}[\cdot]$ denotes integration with respect to the target measure, and where \mathfrak{C} is once again a term independent of the transport map and thus a constant for the purposes of optimization. The resulting optimization problem is a stochastic program given by:

$$\begin{aligned} & \min \mathbb{E}_{\pi}[-\log \eta \circ S - \log \det \nabla S] \\ \text{s.t. } & \nabla S \succ 0, \quad (\pi - \text{a.e.}) \\ & S \in \mathcal{T}_{\Delta} \end{aligned} \tag{23.20}$$

Notice that (23.20) is equivalent to (23.11) if we interchange the roles of target and reference densities. Indeed, the K–L divergence is not a symmetric function. The direction of the K–L divergence, i.e., $\mathcal{D}_{\text{KL}}(S_{\sharp}\pi \parallel \eta)$ versus $\mathcal{D}_{\text{KL}}(T_{\sharp}\eta \parallel \pi)$, is one of the key distinctions between the sample-based map construction presented in this section and the density-based construction of Sect. 3. The choice of direction in (23.19) involves integration over the target distribution, as in the objective function of (23.20), which we approximate using the given samples. Let $(z_i)_{i=1}^M$ be M samples from the target distribution. Then, a sample-average approximation (SAA) [42] of (23.20) is given by:

$$\begin{aligned} & \min \frac{1}{M} \sum_{i=1}^M -\log \eta(S(z_i)) - \log \det \nabla S(z_i) \\ \text{s.t. } & \partial_k S^k > 0 \quad k = 1, \dots, n, \quad (\pi - \text{a.e.}) \\ & S \in \mathcal{T}_{\Delta} \end{aligned} \tag{23.21}$$

where we use the lower triangular structure of ∇S to rewrite the monotonicity constraint, $\nabla S \succ 0$, as a sequence of essentially one-dimensional monotonicity constraints: $\partial_k S^k > 0$ for $k = 1, \dots, n$. We note, in passing, that the monotonicity constraint can be satisfied automatically by using monotone parameterizations of the triangular transport (see Sect. 5.3). One can certainly use stochastic programming techniques to solve (23.20) depending on the availability of target samples (e.g., stochastic approximation [43, 74]). SAA, on the other hand, turns (23.20) into a deterministic optimization problem and does not require generating new samples from the target distribution, which could involve running additional expensive simulations or performing new experiments. Thus, SAA is generally the method of choice to solve (23.20). However, stochastic approximation may be better suited for applications involving streaming data or massive sample sets requiring single pass algorithms.

4.2 Convexity and Separability of the Optimization Problem

Note that (23.21) is a convex optimization problem as long as the reference density is log concave [41]. Since the reference density is a degree of freedom of the problem, it can always be chosen to be log concave. Thus, (23.21) can be a convex optimization problem *regardless* of the particular structure of the target. This is a major difference from the density-based construction of the map in Sect. 3, where the corresponding optimization problem (23.11) is convex only under certain conditions on the target (e.g., that the target density be log concave).

For smooth reference densities, the objective function of (23.21) is also smooth. Moreover, its gradients do not involve derivatives of the log-target density – which might require expensive adjoint calculations when the target density contains a PDE model. Indeed, the objective function of (23.21) does not contain the target density at all! This feature should be contrasted with the density-based construction of the map, where the objective function of (23.11) depends explicitly on the log-target density. Moreover, if the reference density can be written as the product of its marginals, then (23.21) is a separable optimization problem, i.e., each component of the inverse transport can be computed independently and in parallel.

As a concrete example, let the reference measure be standard Gaussian. In this case, (23.21) can be written as

$$\begin{aligned} \min \frac{1}{M} \sum_{i=1}^M \sum_{k=1}^n \left[\frac{1}{2} (S^k)^2(z_i) - \log \partial_k S^k(z_i) \right] \\ \text{s.t. } \partial_k S^k > 0 \quad k = 1, \dots, n, \quad (\pi - \text{a.e.}) \\ S \in \mathcal{T}_\Delta \end{aligned} \tag{23.22}$$

where we use the identity $\log \det \nabla S \equiv \sum_{k=1}^n \log \partial_k S^k$, which holds for triangular maps. Almost magically, the objective function and the constraining set of (23.22)

are *separable*: the k th component of the inverse transport can be computed as the solution of a single convex optimization problem,

$$\begin{aligned} \min \frac{1}{M} \sum_{i=1}^M \frac{1}{2} (S^k)^2(z_i) - \log \partial_k S^k(z_i) \\ \text{s.t. } \partial_k S^k > 0, \quad (\pi - \text{a.e.}) \\ S^k \in \mathcal{T}_k \end{aligned} \quad (23.23)$$

where \mathcal{T}_k denotes the space of smooth real-valued functions of k variables. Most importantly, (23.23) depends only on the k th component of the map. Thus, all the components of the inverse transport can be computed independently and in parallel by solving optimization problems of the form (23.23). This is another major difference from the density-based construction of the map, where all the components of the transport must be computed simultaneously as a solution of (23.11) (unless, for instance, the target density can be written as the product of its marginals).

As in the previous section, the numerical solution of (23.23) requires replacing the infinite-dimensional function space \mathcal{T}_k with a finite-dimensional subspace $\mathcal{T}_k^h \subset \mathcal{T}_k$. The monotonicity constraint $\partial_k S^k > 0$ can be discretized and enforced at only finitely many points in the parameter space, for instance at the samples $(z_i)_{i=1}^M$ (see Sect. 5). However, a better approach is to use monotone parameterizations of the triangular transport in order to turn (23.23) into an unconstrained optimization problem (see Sect. 5). In either case, the solution of (23.23) over a finite-dimensional approximation space \mathcal{T}_k^h yields a component of the approximate inverse transport. The quality of this approximation is a function of at least two parameters of the problem: the structure of the space \mathcal{T}_k^h and the number of target samples M . While enriching the space \mathcal{T}_k^h is often a straightforward task, increasing the number of target samples can be nontrivial, especially when exact sampling from the target density is impossible. This is an important difference from density-based construction of the map, wherein the objective function of (23.11) only requires integration with respect to the reference measure and thus can be approximated to any desired degree of accuracy during each stage of the computation. Of course, in many cases of interest, exact sampling from the target distribution is possible. Consider, for instance, the joint density of data and parameters in a typical Bayesian inference problem [63] or the forecast distribution in a filtering problem where the forward model is a stochastic difference equation.

Quantifying the quality of an approximate inverse transport is an important issue. If the target density can be evaluated up to a normalizing constant, then the K–L divergence between the pushforward of the target through the map and the reference density can be estimated as

$$\mathcal{D}_{\text{KL}}(S_\# \pi || \eta) \approx \frac{1}{2} \text{Var}_\pi [\log \bar{\pi} - \log S^\# \eta] \quad (23.24)$$

up to second-order terms in the limit of $\mathbb{V}\text{ar}_\pi[\log \bar{\pi} - \log S^\# \eta] \rightarrow 0$. This expression is analogous to (23.12) (see Sect. 3 for further details on this topic). When the target density cannot be evaluated, however, one can rely on statistical tests to monitor convergence to the exact inverse transport. For instance, if the reference density is a standard Gaussian, then we know that pushing forward the target samples $(z_i)_i$ through the inverse transport should yield jointly Gaussian samples, with independent and standard normal components. If the inverse transport is only approximate, then the pushforward samples will not have independent and standard normal components, and one can quantify their deviation from such normality using standard statistical tests [83].

4.3 Computing the Inverse Map

Up to now, we have shown how to compute the triangular inverse transport S via convex optimization given samples from the target density. In many problems of interest, however, the goal is to evaluate the direct transport T , i.e., a map that pushes forward the reference to the target measure. Clearly, the following relationship between the direct and inverse transports holds:

$$T(\mathbf{x}) = S^{-1}(\mathbf{x}), \quad \forall \mathbf{x} \in \mathbb{R}^n. \quad (23.25)$$

Thus, if we want to evaluate the direct transport at a particular $\mathbf{x}^* \in \mathbb{R}^n$, i.e., $\mathbf{z}^* := T(\mathbf{x}^*)$, then by (23.25) we can simply invert S at \mathbf{x}^* to obtain \mathbf{z}^* . In particular, if $\mathbf{x}^* = (x_1^*, \dots, x_n^*)$ and $\mathbf{z}^* = (z_1^*, \dots, z_n^*)$, then \mathbf{z}^* is a solution of the following lower triangular system of equations:

$$S(\mathbf{z}^*) = \begin{bmatrix} S^1(z_1^*) \\ S^2(z_1^*, z_2^*) \\ \vdots \\ S^n(z_1^*, z_2^*, \dots, z_n^*) \end{bmatrix} = \begin{bmatrix} x_1^* \\ x_2^* \\ \vdots \\ x_n^* \end{bmatrix} = \mathbf{x}^* \quad (23.26)$$

where the k th component of S is just a function of the first k input variables. This system is in general nonlinear, but we can devise a simple recursion in k to compute each component of \mathbf{z}^* as

$$z_k^* := (S_{z_1^*, \dots, z_{k-1}^*}^k)^{-1}(x_k^*), \quad k = 1, \dots, n, \quad (23.27)$$

where $S_{z_1^*, \dots, z_{k-1}^*}^k : \mathbb{R} \rightarrow \mathbb{R}$ is a one-dimensional function defined as $w \mapsto S^k(z_1^*, \dots, z_{k-1}^*, w)$. That is, $S_{z_1^*, \dots, z_{k-1}^*}^k$ is the restriction of the k th component of the inverse transport obtained by fixing the first $k-1$ input variables z_1^*, \dots, z_{k-1}^* . Thus, \mathbf{z}^* can be computed recursively via a sequence of n one-dimensional root-finding problems. Monotonicity of the triangular maps guarantees that (23.27) has a

unique real solution for each k and any given \mathbf{x}^* . Here, one can use any off-the-shelf root-finding algorithm³. Whenever the transport is high-dimensional (e.g., hundreds or thousands of components), this recursive approach might become inaccurate, as it is sequential in nature. In this case, we recommend running a few Newton iterations of the form

$$\mathbf{z}_{j+1} = \mathbf{z}_j - \nabla S(\mathbf{z}_j)^{-1}(S(\mathbf{z}_j) - \mathbf{x}^*) \quad (23.28)$$

to clean up the approximation of the root \mathbf{z}^* obtained from the recursive algorithm (23.27).

An alternative way to evaluate the direct transport is to build a parametric representation of T itself via standard regression techniques. In particular, if $\{\mathbf{z}_1, \dots, \mathbf{z}_M\}$ are samples from the target distribution, then $\{\mathbf{x}_1, \dots, \mathbf{x}_M\}$, with $\mathbf{x}_k := S(\mathbf{z}_k)$ for $k = 1, \dots, M$, are samples from the reference distribution. Note that there is a one-to-one correspondence between target and reference samples. Thus, we can use these pairs of samples to define a simple constrained least-squares problem to approximate the direct transport as:

$$\begin{aligned} & \min \sum_{k=1}^M \sum_{i=1}^n (T^i(\mathbf{x}_k) - z_k)^2 \\ & \text{s.t. } \partial_i T^i > 0 \quad i = 1, \dots, n, \quad (\eta - \text{a.e.}) \\ & \quad T \in \mathcal{T}_\Delta. \end{aligned} \quad (23.29)$$

In particular, each component of the direct transport can be approximated independently (and in parallel) as the minimizer of

$$\begin{aligned} & \min \sum_{k=1}^M (T^i(\mathbf{x}_k) - z_k)^2 \\ & \text{s.t. } \partial_i T^i > 0, \quad (\eta - \text{a.e.}) \\ & \quad T^i \in \mathcal{T}_i, \end{aligned} \quad (23.30)$$

where \mathcal{T}_i denotes the space of smooth real-valued functions of i variables. Of course, the numerical solution of (23.31) requires the suitable choice of a finite-dimensional approximation space $\mathcal{T}_i^h \subset \mathcal{T}_i$.

³Roots can be found using, for instance, Newton's method. When a component of the inverse transport is parameterized using polynomials, however, then a more robust root-finding approach is to use a bisection method based on Sturm sequences (e.g., [63]).

5 Parameterization of Transport Maps

As noted in the previous sections, the optimization problems that one solves to obtain either the direct or inverse transport must, at some point, introduce discretization. In particular, we must define finite-dimensional approximation spaces (e.g., \mathcal{T}_Δ^h) within which we search for a best map. In this section we describe several useful choices for \mathcal{T}_Δ^h and the associated map parameterizations. Closely related to the map parameterization is the question of how to enforce the monotonicity constraints $\partial_k T^k > 0$ or $\partial_k S^k > 0$ over the support of the reference and target densities, respectively. For some parameterizations, we will explicitly introduce discretizations of these monotonicity constraints. A different map parameterization, discussed in Sect. 5.3, will satisfy these monotonicity conditions automatically.

For simplicity, we will present the parameterizations below mostly in the context of the direct transport T . But these parameterizations can be used interchangeably for both the direct and inverse transports.

5.1 Polynomial Representations

A natural way to parameterize each component of the map T is by expanding it in a basis of multivariate polynomials. We define each multivariate polynomial ψ_j as a product of n univariate polynomials, specified via a multi-index $\mathbf{j} = (j_1, j_2, \dots, j_n) \in \mathbb{N}_0^n$, as:

$$\psi_{\mathbf{j}}(\mathbf{x}) = \prod_{i=1}^n \varphi_{j_i}(x_i), \quad (23.31)$$

where φ_{j_i} is a univariate polynomial of degree j_i . The univariate polynomials can be chosen from any standard orthogonal polynomial family (e.g., Hermite, Legendre, Laguerre) or they can even be monomials. That said, it is common practice in uncertainty quantification to choose univariate polynomials that are orthogonal with respect to the input measure, which in the case of the direct transport is μ_{ref} . If μ_{ref} is a standard Gaussian, the $(\varphi_i)_i$ above would be (suitably scaled and normalized) Hermite polynomials. The resulting map can then be viewed as a *polynomial chaos* expansion [46, 91] of a random variable distributed according to the target measure. From the coefficients of this polynomial expansion, moments of the target measure can be directly – that is, *analytically* – evaluated. In the case of inverse transports, however, μ_{tar} is typically not among the canonical distributions found in the Askey scheme for which standard orthogonal polynomials can be easily evaluated. While it is possible to construct orthogonal polynomials for more general measures [29], the relative benefits of doing so are limited, and hence with inverse transports we do not employ a basis orthogonal with respect to μ_{tar} .

Using multivariate polynomials given in (23.31), we can express each component of the transport map $T \in \mathcal{T}_\Delta^h$ as

$$T^k(\mathbf{x}) = \sum_{\mathbf{j} \in \mathcal{J}_k} \gamma_{k,\mathbf{j}} \psi_{\mathbf{j}}(\mathbf{x}), \quad k = 1, \dots, n, \quad (23.32)$$

where \mathcal{J}_k is a set of multi-indices defining the polynomial terms in the expansion for dimension k and $\gamma_{k,\mathbf{j}} \in \mathbb{R}$ is a scalar coefficient. Importantly, the proper choice of each multi-index set \mathcal{J}_k will force T to be lower triangular. For instance, a standard choice of \mathcal{J}_k involves restricting each map component to a total-degree polynomial space:

$$\mathcal{J}_k^{TO} = \{\mathbf{j} : \|\mathbf{j}\|_1 \leq p \wedge j_i = 0, \forall i > k\}, \quad k = 1, \dots, n \quad (23.33)$$

The first constraint in this set, $\|\mathbf{j}\|_1 \leq p$, limits the total degree of each polynomial to p , while the second constraint, $j_i = 0, \forall i > k$, forces T to be lower triangular. Expansions built using \mathcal{J}_d^{TO} are quite “expressive” in the sense of being able to capture complex nonlinear dependencies in the target measure. However, the number of terms in \mathcal{J}_k^{TO} grows rapidly with k and p . A smaller multi-index set can be obtained by removing all the mixed terms in the basis:

$$\mathcal{J}_k^{NM} = \{\mathbf{j} : \|\mathbf{j}\|_1 \leq p \wedge j_i j_\ell = 0, \forall i \neq \ell \wedge j_i = 0, \forall i > k\}.$$

An even more parsimonious option is to use diagonal maps, via the multi-index sets

$$\mathcal{J}_k^D = \{\mathbf{j} : \|\mathbf{j}\|_1 \leq p \wedge j_i = 0, \forall i \neq k\}.$$

Figure 23.1 illustrates the difference between these three sets for $p = 3$ and $k = 2$.

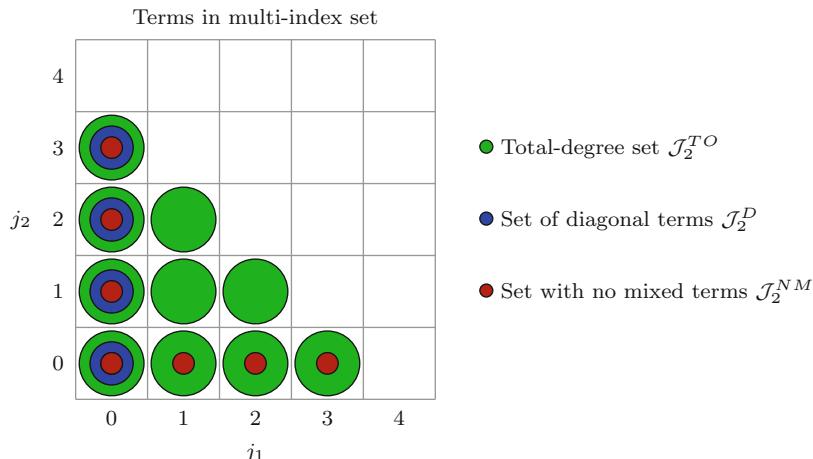

Fig. 23.1 Visualization of multi-index sets for the second component of a two-dimensional map, $T^2(x_1, x_2)$. In this case, j_1 is the degree of a basis polynomial in x_1 and j_2 is the degree in x_2 . A filled circle indicates that a term is present in the set of multi-indices

An alternative to using these standard and isotropic bases is to adapt the polynomial approximation space to the problem at hand. This becomes particularly important in high dimensions. For instance, beginning with linear maps (e.g., \mathcal{T}_k^{TO} with $p = 1$) [61] introduces an iterative scheme for enriching the polynomial basis, incrementing the degree of \mathcal{T}_{Δ}^h in a few input variables at a time. Doing so enables the construction of a transport map in $O(100)$ dimensions. In a different context, [65] uses the conditional independence structure of the posterior distribution in a multiscale inference problem to enable map construction in $O(1000)$ dimensions. Further comments on adapting \mathcal{T}_{Δ}^h are given in Sect. 9.

5.2 Radial Basis Functions

An alternative to a polynomial parameterization of the map is to employ a combination of linear terms and radial basis functions. This representation can be more efficient than a polynomial representation in certain cases – for example, when the target density is multimodal. The general form of the expansion in (23.32) remains the same, but we replace polynomials of degree greater than one with radial basis functions as follows:

$$T^k(\mathbf{x}) = a_{k,0} + \sum_{j=1}^k a_{k,j} x_j + \sum_{j=1}^{P_k} b_{k,j} \phi_j(x_1, x_2, \dots, x_k; \bar{\mathbf{x}}^{k,j}), \quad k = 1, \dots, n, \quad (23.34)$$

where P_k is the total number of radial basis functions used for the k th component of the map and $\phi_j(x_1, x_2, \dots, x_k; \bar{\mathbf{x}}^{k,j})$ is a radial basis function centered at $\bar{\mathbf{x}}^{k,j} \in \mathbb{R}^k$. Note that this representation ensures that the overall map T is lower triangular. The a and b coefficients can then be exposed to the optimization algorithm used to search for the map.

Choosing the centers and scales of the radial basis functions can be challenging in high dimensions, though some heuristics for doing so are given in [63]. To circumvent this difficulty, [63] also proposes using only univariate radial basis functions and embedding them within a composition of maps.

5.3 Monotonicity Constraints and Monotone Parameterizations

Neither the polynomial representation (23.32) nor the radial basis function representation (23.34) yields monotone maps for all values of the coefficients. With either of these choices for the approximation space \mathcal{T}_{Δ}^h , we need to enforce the monotonicity constraints explicitly. Recall that, for the triangular maps considered here, the monotonicity constraint reduces to requiring that $\partial_k T^k > 0$ over the entire support of the reference density, for $k = 1, \dots, n$. It is difficult to enforce this condition everywhere, so instead we choose a finite sequence of points $(\mathbf{x}_i)_i$ – a

stream of samples from the reference distribution, and very often the same samples used for the sample-average approximation of the objective (23.14) – and enforce local monotonicity at each point: $\partial_k T^k(\mathbf{x}_i) > 0$, for $k = 1, \dots, n$. The result is a finite set of linear constraints. Collectively these constraints are weaker than requiring monotonicity everywhere, but as the cardinality of the sequence $(\mathbf{x}_i)_i$ grows, we have stronger guarantees on the monotonicity of the transport map over the entire support of the reference density. When monotonicity is lost, it is typically only in the tails of μ_{ref} where samples are fewer. We should also point out that the $(-\log \det \nabla T)$ term in the objective of (23.11) acts as a barrier function for the constraint $\nabla T > 0$ [68].

A more elegant alternative to discretizing and explicitly enforcing the monotonicity constraints is to employ parameterizations of the map that are in fact *guaranteed* to be monotone [12]. Here we take advantage of the fact that monotonicity of a triangular function can be expressed in terms of one-dimensional monotonicity of its components. A smooth monotone increasing function of one variable, e.g., the first component of the lower triangular map, can be written as [66]:

$$T^1(x_1) = a_1 + \int_0^{x_1} \exp(b_1(w)) dw, \quad (23.35)$$

where $a_1 \in \mathbb{R}$ is a constant and $b_1 : \mathbb{R} \rightarrow \mathbb{R}$ is an arbitrary function. This can be generalized to the k th component of the map as:

$$T^k(x_1, \dots, x_k) = a_k(x_1, \dots, x_{k-1}) + \int_0^{x_k} \exp(b_k(x_1, \dots, x_{k-1}, w)) dw \quad (23.36)$$

for some functions $a_k : \mathbb{R}^{k-1} \rightarrow \mathbb{R}$ and $b_k : \mathbb{R}^k \rightarrow \mathbb{R}$. Note that a_k is not a function of the k th input variable. Of course, we now have to pick a finite-dimensional parameterization of the functions a_k, b_k , but the monotonicity constraint is automatically enforced since

$$\partial_k T^k(\mathbf{x}) = \exp(b_k(x_1, \dots, x_k)) > 0, \quad \forall \mathbf{x} \in \mathbb{R}^n, \quad (23.37)$$

and for all choices of a_k and b_k . Enforcing monotonicity through the map parameterization in this way, i.e., choosing \mathcal{T}_{Δ}^h so that it only contains monotone lower triangular functions, allows the resulting finite-dimensional optimization problem to be unconstrained.

6 Related Work

The idea of using nonlinear transformations to accelerate or simplify sampling has appeared in many different settings. Here we review several relevant instantiations.

Perhaps the closest analogue of the density-based map construction of Sect. 3 is the implicit sampling approach of [21, 22]. While implicit sampling was first

proposed in the context of Bayesian filtering [5, 21, 22, 58], it is in fact a more general scheme for importance simulation [60]. Consider the K–L divergence objective of the optimization problem (23.9). At optimality, the K–L divergence is zero. Rearranging this condition and explicitly writing out the arguments yields:

$$\mathbb{E}_\eta [\log \bar{\pi}(T(\mathbf{x})) + \log \det \nabla T(\mathbf{x}) - \log \beta - \log \eta(\mathbf{x})] = 0, \quad (23.38)$$

where β is the normalizing constant of the unnormalized target density $\bar{\pi}$ (23.13). Now let $\mathbf{z} = T(\mathbf{x})$. The central equation in implicit sampling methods is [22]:

$$\log \bar{\pi}(\mathbf{z}) - \mathcal{C} = \log \eta(\mathbf{x}), \quad (23.39)$$

where \mathcal{C} is an easily computed constant. Implicit sampling first draws a sample \mathbf{x}_i from the reference density η and then seeks a corresponding \mathbf{z}_i that satisfies (23.39). This problem is generally underdetermined, as terms in (23.39) are scalar valued while the samples $\mathbf{x}_i, \mathbf{z}_i$ are in \mathbb{R}^n . Accordingly, the random map implementation of implicit sampling [59] restricts the search for \mathbf{z}_i to a one-dimensional optimization problem along randomly oriented rays emanating from a point in \mathbb{R}^n , e.g., the mode of the target distribution. This scheme is efficient to implement, though it is restricted to target densities whose contours are star convex with respect to the chosen point [35]. Satisfying (23.39) in this way defines the *action* of a map from η to another distribution, and the intent of implicit sampling is that this pushforward distribution should be close to the target. There are several interesting contrasts between (23.38) and (23.39), however. First is the absence of the Jacobian determinant in (23.39). The samples \mathbf{z}_i produced by implicit sampling must then (outside of the Gaussian case) be endowed with weights, which result from the Jacobian determinant of the implicit map. The closeness of the implicit samples to the desired target is reflected in the variation of these weights. A second contrast is that (23.38) is a global statement about the action of a map T over the entire support of η , wherein the map T appears explicitly. On the other hand, (23.39) is a relationship between points in \mathbb{R}^n . The map does not appear explicitly in this relationship; rather, the way in which (23.39) is satisfied *implicitly* defines the map.

Another optimization-based sampling algorithm, similar in spirit to implicit sampling though different in construction, is the randomize-then-optimize (RTO) approach of [8]. This scheme is well defined for target distributions whose log densities can be written in a particular quadratic form following a transformation of the parameters, with some restrictions on the target’s degree of non-Gaussianity. The algorithm proceeds in three steps. First, one draws a sample \mathbf{x}_i from a Gaussian (reference) measure and uses this sample to fix the objective of an unconstrained optimization problem in n variables. Next, one solves this optimization problem to obtain a sample \mathbf{z}_i . And finally, this sample is “corrected” either via an importance weight or a Metropolis step. The goal, once again, is that the distribution of the samples \mathbf{z}_i should be close to the true target π – though as in implicit sampling, outside of the Gaussian case these two distributions will not be identical and the correction step is required.

Hence, another way of understanding the contrast between these optimization-based samplers and the transport map framework is that the latter defines an optimization problem *over maps*, where minimizing the left-hand side of (23.38) is the objective. Implicit sampling and RTO instead solve simpler optimization problems *over samples*, where each minimization yields the action of a particular transport. A crucial feature of these transports is that the pushforward densities they induce can be evaluated in closed form, thus allowing implicit samples and RTO samples to be reweighted or Metropolized in order to obtain asymptotically unbiased estimates of target expectations. Nonetheless, implicit sampling and RTO each implement a particular transport, and they are *bound* to these choices. In other words, these transports cannot be refined, and it is difficult to predict their quality for arbitrarily non-Gaussian targets. The transport map framework instead implements a search over a space of maps and therefore contains a tunable knob between computational effort and accuracy: by enriching the search space \mathcal{T}_Δ^h , one can get arbitrarily close to any target measure. Of course, the major disadvantage of the transport map framework is that one must then parameterize maps $T \in \mathcal{T}_\Delta^h$ rather than just computing the action of a particular map. But parameterization subsequently allows direct evaluation and sampling of the pushforward $T_\sharp \eta$ without appealing again to the target density.

Focusing for a moment on the specific problem of Bayesian inference, another class of approaches related to the transport map framework are the sampling-free Bayesian updates introduced in [47, 48, 54, 71, 72]. These methods treat Bayesian inference as a projection. In particular, they approximate the conditional expectation of any prescribed function of the parameters, where conditioning is with respect to the σ -field generated by the data. The approximation of the conditional expectation may be refined by enlarging the space of functions (typically polynomials) on which one projects; hence one can generalize linear Bayesian updates [71] to nonlinear Bayesian updates [48]. The precise goal of these approximations is different from that of the transport map framework, however. Both methods approximate random variables, but different ones: [48] focuses on the conditional expectation of a function of the parameters (e.g., mean, second moment) as a function of the data random variable, whereas the transport approach to inference [61] aims to fully characterize the posterior random variable for a particular realization of the data.

Ideas from *optimal* transportation have also proven useful in the context of Bayesian inference. In particular, [67] solves a *discrete* Kantorovich optimal transport problem to find an optimal transport plan from a set of unweighted samples representing the prior distribution to a weighted set of samples at the same locations, where the weights reflect the update from prior to posterior. This transport plan is then used to construct a linear transformation of the prior ensemble that yields consistent posterior estimates. The linear transformation can be understood as a resampling strategy, replacing the weighted samples with new samples that are convex combinations of the prior samples. The ability to “move” the samples within the convex hull of the prior ensemble leads to improved performance over other resampling strategies, though the prior samples should then have good coverage of the support of the posterior.

Turning to the sample-based map construction of Sect. 4, it is interesting to note that attempts to Gaussianize collections of samples using nonlinear transformations date back at least to 1964 [14]. In the geostatistics literature, the notion of Gaussian anamorphosis [86] uses the empirical cumulative distribution function (CDF), or Hermite polynomial approximations of the CDF, to Gaussianize the *marginals* of multivariate data. These transformations do not create joint Gaussianity, however.

To construct joint transformations of dependent multivariate data, [77] proposes a scheme employing discrete optimal transport. This approach generates an equivalent number of samples from a reference measure; solves a discrete assignment problem between the two sample sets, given a quadratic transport cost; and uses the resulting pairs to estimate a polynomial map using linear regression. This is a two-stage approach, in contrast with the single convex optimization problem proposed in Sect. 4. For reference and target distributions with compact support, it yields an approximation of the Monge optimal transport rather than the Knothe–Rosenblatt rearrangement.

Moving from polynomial approximations to nonparametric approaches, [45, 81, 82] introduce schemes for multivariate density estimation based on progressively transforming a given set of samples to a (joint) standard Gaussian by *composing* a sequence of monotone maps. The maps are typically chosen to be rather simple in form (e.g., sigmoid-type functions of one variable). In this context, we note that the empirical K–L divergence objective in (23.21) is the pullback density $S_{\sharp}^{-1}\eta$ evaluated at the samples $(z_i)_{i=1}^M$ and hence can be viewed as the log likelihood of the map S given the target samples. In [81], each new element of the composition of maps is guaranteed not to decrease this log-likelihood function. A related scheme is presented in [44]; here the sequence of maps alternates between rotations and diagonal maps that transform the marginals. Rotations are chosen via principle component analysis (PCA) or independent component analysis (ICA). The resulting composition of maps can Gaussianize remarkably complex distributions in hundreds of dimensions (e.g., samples from a face database). Both of these methods, however, reveal an interesting tension between the number of maps in the composition and the complexity of a single map. When each map in the composition is very simple (e.g., diagonal, or even constant in all but one variable), the maps are easy to construct, but their composition can converge very slowly to a Gaussianizing transformation. On the other hand, we know that there exist maps (e.g., the Knothe–Rosenblatt rearrangement or the Monge optimal transport map) that can Gaussianize the samples immediately, but approximating them directly requires much more effort. Some of these trade-offs are explored in [63].

Yet another use of transformations in stochastic simulation is the warp bridge sampling approach of [56]. The goal of bridge sampling is to estimate the ratio of normalizing constants of two probability densities (e.g., the ratio of Bayesian model evidences). Meng and Schilling [56] introduces several deterministic and/or stochastic transformations to increase the overlap of the two densities – by translating, scaling, and even symmetrizing them. These transformations can reduce the asymptotic variance of the bridge sampling estimator. More recent generalizations

use Gaussian mixture approximations of the densities to design transformations suitable for multimodal problems [88].

Finally, setting aside the notion of nonlinear transformations, it is useful to think of the minimization problem (23.9) in the broader context of variational Bayesian methods [6, 28, 40, 87]. As in typical variational Bayesian approaches, we seek to approximate some complex or intractable distribution (represented by π) with a simpler one. But the approximating distribution in the transport map framework is any pushforward of a reference density. In contrast with variational Bayesian approaches, this distribution can be found without imposing strong assumptions on its factorization (e.g., the mean field approximation) or on the family of distributions from which it is drawn (e.g., an exponential family). The transport map framework is also distinguished from variational Bayesian approaches due to the availability of the pullback density (23.16) – in an intuitive sense, the “leftover” after approximation with any given map. Using evaluations of the pullback density, one can compose sequences of maps, enrich the approximation space of any given map, or use the current transport to precondition an exact sampling scheme.

7 Conditional Sampling

In this section we will show how the triangular structure of the transport map allows efficient sampling from particular conditionals of the target density. This capability is important because, in general, the ability to sample from a distribution does not necessarily provide efficient techniques for also sampling its conditionals. As in the previous sections, assume that the reference and target measures are absolutely continuous with respect to the Lebesgue measure on \mathbb{R}^n with smooth and positive densities. Let $T : \mathbb{R}^n \rightarrow \mathbb{R}^n$ be a triangular and monotone increasing transport that pushes forward the reference to the target density, i.e., $T_{\sharp}\eta = \pi$, where T is the Knothe–Rosenblatt rearrangement.

We first need to introduce some additional notation. There is no loss of generality in thinking of the target as the joint distribution of some random vector \mathbf{Z} in \mathbb{R}^n . Consider a partition of this random vector as $\mathbf{Z} = (\mathbf{D}, \boldsymbol{\Theta})$ where $\mathbf{D} \in \mathbb{R}^{n_d}$, $\boldsymbol{\Theta} \in \mathbb{R}^{n_\theta}$, and $n = n_d + n_\theta$. In other words, \mathbf{D} simply comprises the first n_d components of \mathbf{Z} . We equivalently denote the joint density of $\mathbf{Z} = (\mathbf{D}, \boldsymbol{\Theta})$ by either π or $\pi_{\mathbf{D}, \boldsymbol{\Theta}}$. That is, $\pi \equiv \pi_{\mathbf{D}, \boldsymbol{\Theta}}$. We define the conditional density of $\boldsymbol{\Theta}$ given \mathbf{D} as

$$\pi_{\boldsymbol{\Theta}|\mathbf{D}} := \frac{\pi_{\mathbf{D}, \boldsymbol{\Theta}}}{\pi_{\mathbf{D}}}, \quad (23.40)$$

where $\pi_{\mathbf{D}} := \int \pi_{\mathbf{D}, \boldsymbol{\Theta}}(\cdot, \boldsymbol{\theta}) d\boldsymbol{\theta}$ is the marginal density of \mathbf{D} . In particular, $\pi_{\boldsymbol{\Theta}|\mathbf{D}}(\boldsymbol{\theta}|\mathbf{d})$ is the conditional density of $\boldsymbol{\Theta}$ at $\boldsymbol{\theta} \in \mathbb{R}^{n_\theta}$ given the event $\{\mathbf{D} = \mathbf{d}\}$. Finally, we define $\pi_{\boldsymbol{\Theta}|\mathbf{D}=\mathbf{d}}$ as a map from \mathbb{R}^{n_θ} to \mathbb{R} such that

$$\boldsymbol{\theta} \mapsto \pi_{\boldsymbol{\Theta}|\mathbf{D}}(\boldsymbol{\theta}|\mathbf{d}). \quad (23.41)$$

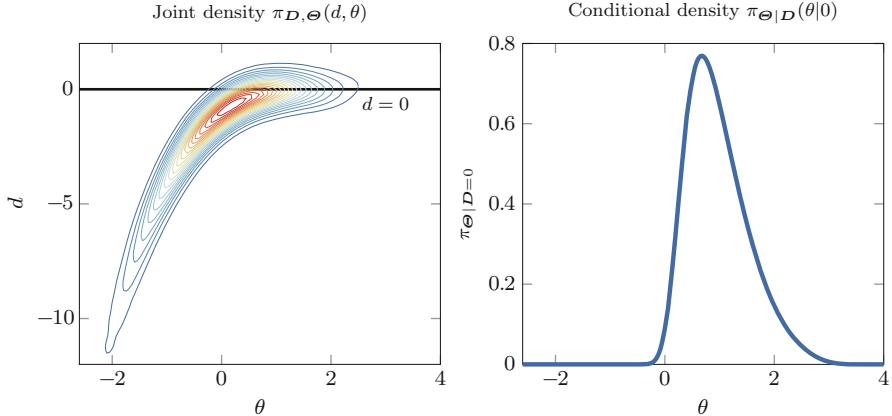

Fig. 23.2 (left) Illustration of a two-dimensional joint density $\pi_{D,\Theta}$ together with a particular slice at $d = 0$. (right) Conditional density $\pi_{\Theta|D}(\theta|0)$ obtained from a normalized slice of the joint density at $d = 0$

We can think of $\pi_{\Theta|D=d}$ as a particular normalized slice of the joint density $\pi_{D,\Theta}$ for $D = \mathbf{d}$, as shown in Fig. 23.2. Our goal is to show how the triangular transport map T can be used to efficiently sample the conditional density $\pi_{\Theta|D=d}$.

If T is a monotone increasing lower triangular transport on \mathbb{R}^n , we can denote its components by

$$T(\mathbf{x}) := T(\mathbf{x}_D, \mathbf{x}_\Theta) = \begin{bmatrix} T^D(\mathbf{x}_D) \\ T^\Theta(\mathbf{x}_D, \mathbf{x}_\Theta) \end{bmatrix}, \quad \forall \mathbf{x} \in \mathbb{R}^n, \quad (23.42)$$

where $T^D : \mathbb{R}^{n_d} \rightarrow \mathbb{R}^{n_d}$, $T^\Theta : \mathbb{R}^{n_d} \times \mathbb{R}^{n_\theta} \rightarrow \mathbb{R}^{n_\theta}$, and where $\mathbf{x} := (\mathbf{x}_D, \mathbf{x}_\Theta)$ is a partition of the dummy variable $\mathbf{x} \in \mathbb{R}^n$ as $\mathbf{x}_D \in \mathbb{R}^{n_d}$ and $\mathbf{x}_\Theta \in \mathbb{R}^{n_\theta}$, i.e., \mathbf{x}_D consists of the first n_d components of \mathbf{x} .

In the context of Bayesian inference, Θ could represent the inversion parameters or latent variables and D the observational data. In this interpretation, $\pi_{\Theta|D=d}$ is just the posterior distribution of the parameters for a particular realization of the data. Sampling this posterior distribution yields an explicit characterization of the Bayesian solution and is thus of crucial importance. This scenario is particularly relevant in the context of online Bayesian inference where one is concerned with fast posterior computations for multiple realizations of the data (e.g., [39, 63]). Of course, if one is only interested in $\pi_{\Theta|D=d}$ for a single realization of the data, then there is no need to first approximate the joint density $\pi_{D,\Theta}$ and subsequently perform conditioning to sample $\pi_{\Theta|D=d}$. Instead, one should simply pick $\pi_{\Theta|D=d}$ as the target density and compute the corresponding transport [61]. In the latter case, the dimension of the transport map would be independent of the size of the data.

The following lemma shows how to efficiently sample the conditional density $\pi_{\Theta|D=d}$ given a monotone increasing triangular transport T . In what follows we

assume that the reference density can be written as the product of its marginals; that is, $\eta(\mathbf{x}) = \eta_D(\mathbf{x}_D)\eta_\Theta(\mathbf{x}_\Theta)$ for all $\mathbf{x} = (\mathbf{x}_D, \mathbf{x}_\Theta)$ in \mathbb{R}^n and with marginal densities η_D and η_Θ . This hypothesis is not restrictive as the reference density is a degree of freedom of the problem (e.g., η is often a standard normal density).

Lemma 1. *For a fixed $\mathbf{d} \in \mathbb{R}^{n_d}$, define \mathbf{x}_d^* as the unique element of \mathbb{R}^{n_d} such that $T^D(\mathbf{x}_d^*) = \mathbf{d}$. Then, the map $T_d : \mathbb{R}^{n_\theta} \rightarrow \mathbb{R}^{n_\theta}$, defined as*

$$\mathbf{w} \mapsto T^\Theta(\mathbf{x}_d^*, \mathbf{w}), \quad (23.43)$$

pushes forward η_Θ to the desired conditional density $\pi_{\Theta|D=d}$.

Proof. First of all, notice that $\mathbf{x}_d^* := (T^D)^{-1}(\mathbf{d})$ is well defined since $T^D : \mathbb{R}^{n_d} \rightarrow \mathbb{R}^{n_d}$ is a monotone increasing and invertible function by definition of the Knothe–Rosenblatt rearrangement T . Then:

$$\begin{aligned} T_d^\# \pi_{\Theta|D=d}(\mathbf{w}) &= \pi_{\Theta|D}(T_d(\mathbf{w})|\mathbf{d}) |\det \nabla T_d(\mathbf{w})| \\ &= \frac{\pi_{D,\Theta}(\mathbf{d}, T^\Theta(\mathbf{x}_d^*, \mathbf{w}))}{\pi_D(\mathbf{d})} \det \nabla_w T^\Theta(\mathbf{x}_d^*, \mathbf{w}) \end{aligned} \quad (23.44)$$

Since, by definition, $T^D(\mathbf{x}_d^*) = \mathbf{d}$, we have for all $\mathbf{w} \in \mathbb{R}^{n_\theta}$:

$$\begin{aligned} T_d^\# \pi_{\Theta|D=d}(\mathbf{w}) &= \frac{\pi_{D,\Theta}(T^D(\mathbf{x}_d^*), T^\Theta(\mathbf{x}_d^*, \mathbf{w}))}{\pi_D(T^D(\mathbf{x}_d^*))} \det \nabla_w T^\Theta(\mathbf{x}_d^*, \mathbf{w}) \\ &= \frac{\pi_{D,\Theta}(T^D(\mathbf{x}_d^*), T^\Theta(\mathbf{x}_d^*, \mathbf{w}))}{(T^D)^\# \pi_D(\mathbf{x}_d^*)} \det \nabla T^D(\mathbf{x}_d^*) \det \nabla_w T^\Theta(\mathbf{x}_d^*, \mathbf{w}) \\ &= \frac{T^\# \pi_{D,\Theta}(\mathbf{x}_d^*, \mathbf{w})}{\eta_D(\mathbf{x}_d^*)} = \frac{\eta(\mathbf{x}_d^*, \mathbf{w})}{\eta_D(\mathbf{x}_d^*)} = \eta_\Theta(\mathbf{w}) \end{aligned}$$

where we used the identity $T_d^\# \eta_D = \pi_D$ which follows from the definition of Knothe–Rosenblatt rearrangement (e.g., [85]). \square

We can interpret the content of Lemma 1 in the context of Bayesian inference. If we observe a particular realization of the data, i.e., $\mathbf{D} = \mathbf{d}$, then we can easily sample the posterior distribution $\pi_{\Theta|D=d}$ as follows. First, solve the nonlinear triangular system $T^D(\mathbf{x}_d^*) = \mathbf{d}$ to get \mathbf{x}_d^* . Since T^D is a lower triangular and invertible map, one can solve this system using the techniques described in Sect. 4.3. Then, define a new map $T_d : \mathbb{R}^{n_\theta} \rightarrow \mathbb{R}^{n_\theta}$ as $T_d(\mathbf{w}) := T^\Theta(\mathbf{x}_d^*, \mathbf{w})$ for all $\mathbf{w} \in \mathbb{R}^{n_\theta}$, and notice that the pushforward through the map of the marginal distribution of the reference over the parameters, i.e., $(T_d)_\# \eta_\Theta$, is precisely the desired posterior distribution.

Notice that T_d is a single transformation parameterized by $\mathbf{d} \in \mathbb{R}^{nd}$. Thus it is straightforward to condition on a different value of \mathbf{D} , say $\mathbf{D} = \tilde{\mathbf{d}}$. We only need to solve a new nonlinear triangular system of the form $T^{\mathbf{D}}(\mathbf{x}_{\tilde{\mathbf{d}}}^*) = \tilde{\mathbf{d}}$ to define a transport $T_{\tilde{\mathbf{d}}}$ according to (23.43). Moreover, note that the particular triangular structure of the transport map T is essential to achieving efficient sampling from the conditional $\pi_{\Theta|\mathbf{D}=d}$ in the manner described by Lemma 1.

8 Example: Biochemical Oxygen Demand Model

Here we demonstrate some of the measure transport approaches described in previous sections with a simple Bayesian inference problem, involving a model of biochemical oxygen demand (BOD) commonly used in water quality monitoring [80]. This problem is a popular and interesting test case for sampling methods (e.g., MCMC [64], RTO [8]). The time-dependent forward model is defined by

$$\mathfrak{B}(t) = A(1 - \exp(-Bt)) + \mathcal{E}, \quad (23.45)$$

where A and B are unknown scalar parameters modeled as random variables, t represents time, and $\mathcal{E} \sim \mathcal{N}(0, 10^{-3})$ is an additive Gaussian observational noise that is statistically independent of A and B . In this example, the data \mathbf{D} consist of five observations of $\mathfrak{B}(t)$ at $t = \{1, 2, 3, 4, 5\}$ and is thus a vector-valued random variable defined by

$$\mathbf{D} := [\mathfrak{B}(1), \mathfrak{B}(2), \mathfrak{B}(3), \mathfrak{B}(4), \mathfrak{B}(5)].$$

Our goal is to characterize the joint distribution of A and B conditioned on the observed data. We assume that A and B are independent under the prior measure, with uniformly distributed marginals:

$$A \sim \mathcal{U}(0.4, 1.2), \quad B \sim \mathcal{U}(0.01, 0.31). \quad (23.46)$$

Instead of inferring A and B directly, we choose to invert for some new target parameters, Θ_1 and Θ_2 , that are related to the original parameters through the CDF of a standard normal distribution:

$$A := \left[0.4 + 0.4 \left(1 + \text{erf} \left(\frac{\Theta_1}{\sqrt{2}} \right) \right) \right] \quad (23.47)$$

$$B := \left[0.01 + 0.15 \left(1 + \text{erf} \left(\frac{\Theta_2}{\sqrt{2}} \right) \right) \right]. \quad (23.48)$$

Notice that these transformations are invertible. Moreover, the resulting prior marginal distributions over the target parameters Θ_1 and Θ_2 are given by

$$\Theta_1 \sim \mathcal{N}(0, 1), \quad \Theta_2 \sim \mathcal{N}(0, 1). \quad (23.49)$$

We denote the target random vector by $\Theta := (\Theta_1, \Theta_2)$. The main advantage of inferring Θ as opposed to the original parameters A and B directly is that the support of Θ is unbounded. Thus, there is no need to impose any geometric constraints on the range of the transport map.

8.1 Inverse Transport: Map from Samples

We start with a problem of efficient online Bayesian inference – where one is concerned with fast posterior computations for multiple realizations of the data – using the inverse transport of Sect. 4. Our first goal is to characterize the joint distribution of data and parameters, $\pi_{D,\Theta}$, by means of a lower triangular transport. As explained in Sect. 7, this transport will then enable efficient *conditioning* on different realizations of the data D . Posterior computations associated with the conditional $\pi_{\Theta|D=d}$, for arbitrary instances of d , will thus become computationally trivial tasks.

Note that having defined the prior and likelihood via (23.47)–(23.49) and (23.45), respectively, we can generate arbitrarily many independent “exact” samples from the joint target $\pi_{D,\Theta}$. For the purpose of this demonstration, we will pretend that we cannot evaluate the unnormalized target density and that we can access the target only through these samples. This is a common scenario in Bayesian inference problems with intractable likelihoods [23, 52, 89]. This sample-based setting is well suited to the computation of a triangular inverse transport – a transport map that pushes forward the target to a standard normal reference density – as the solution of a convex and separable optimization problem (23.22). The direct transport can then be evaluated implicitly using the techniques described in Sect. 4.3.

We will solve (23.22) for a matrix of different numerical configurations. The expectation with respect to the target measure is discretized using different Monte Carlo sample sizes (5×10^3 versus 5×10^4). The reference and target are measures on \mathbb{R}^7 , and thus the finite-dimensional approximation space for the inverse transport, $\mathcal{T}_\Delta^h \subset \mathcal{T}_\Delta$, is taken to be a total-degree polynomial space in $n = 7$ variables, parameterized with a Hermite basis and using range of different degrees (23.33). In particular, we will consider maps ranging from linear ($p = 1$) to seventh degree ($p = 7$). The result of (23.22) is an approximate inverse transport $\tilde{\mathcal{S}}$. An approximation to the direct transport, $\tilde{\mathcal{T}}$, is then obtained via standard regression techniques as explained in Sect. 4.3. In particular, the direct transport is sought in the same approximation space \mathcal{T}_Δ^h as the inverse transport.

In order to assess the accuracy of the computed transports, we will characterize the conditional density $\pi_{\Theta|D=d}$ (see Lemma 1 in Sect. 7) for a value of the data given by

$$d = [0.18, 0.32, 0.42, 0.49, 0.54].$$

Table 23.1 compares moments of the approximate conditional $\pi_{\Theta|D=d}$ computed via the inverse transports to the “true” moments of this distribution as estimated via a

Table 23.1 BOD problem of Section 8.1 via inverse transport and conditioning. First four moments of the conditional density $\pi_{\Theta|D=d}$, for $d = [0.18, 0.32, 0.42, 0.49, 0.54]$, estimated by a “reference” run of an adaptive Metropolis sampler with 6×10^6 steps, and by transport maps up to degree $p = 7$ with 3×10^4 samples

Map type	# training samples	Mean		Variance		Skewness		Kurtosis	
		Θ_1	Θ_2	Θ_1	Θ_2	Θ_1	Θ_2	Θ_1	Θ_2

	50000	0.034	0.902	0.206	0.457	1.628	0.872	7.568	3.876

“reference” adaptive Metropolis MCMC scheme [37]. While more efficient MCMC algorithms exist, the adaptive Metropolis algorithm is well known and enables a qualitative comparison of the computational cost of the transport approach to that of a widely used and standard method. The MCMC sampler was tuned to have an acceptance rate of 26%. The chain was run for 6×10^6 steps, 2×10^4 of which were discarded as burn-in. The moments of the approximate conditional density $\pi_{\Theta|D=d}$ given by each computed transport are estimated using 3×10^4 independent samples generated from the conditional map. The accuracy comparison in Table 23.1 shows that the cubic map captures the mean and variance of $\pi_{\Theta|D=d}$ but does not accurately capture the higher moments. Increasing the map degree, together with the number of target samples, yields better estimates of these moments. For instance, degree-seven maps constructed with 5×10^4 target samples can reproduce the skewness and kurtosis of the conditional density reasonably well. Kernel density estimates of the two-dimensional conditional density $\pi_{\Theta|D=d}$ using 50,000 samples are also shown in Fig. 23.3 for different orders of the computed transport. The degree-seven map gives results that are nearly identical to the MCMC reference computation.

In a typical application of Bayesian inference, we can regard the time required to compute an approximate inverse transport \tilde{S} and a corresponding approximate direct transport \tilde{T} as “offline” time. This is the expensive step of the computations, but it is independent of the observed data. The “online” time is that required to generate samples from the conditional distribution $\pi_{\Theta|D=d}$ when a new realization of the data $\{D = d\}$ becomes available. The online step is computationally inexpensive since it requires, essentially, only the solution of a single nonlinear triangular system of the dimension of the data (see Lemma 1).

In Table 23.2 we compare the computational time of the map-based approach to that of the reference adaptive Metropolis MCMC scheme. The online time column shows how long each method takes to generate 30,000 independent samples

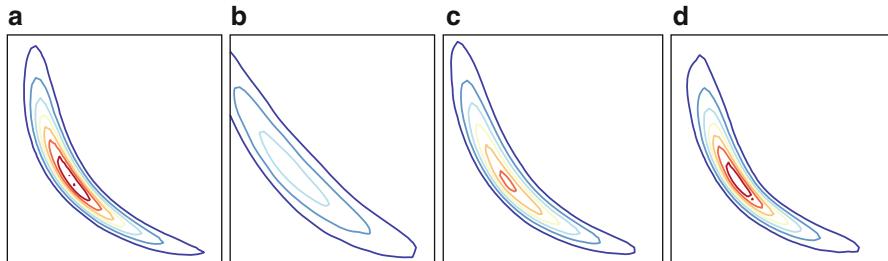

Fig. 23.3 BOD problem of Sect. 8.1 via inverse transport and conditioning. Kernel density estimates of the conditional density $\pi_{\theta|D=d}$, for $d = [0.18, 0.32, 0.42, 0.49, 0.54]$, using 50,000 samples from either a reference adaptive MCMC sampler (*left*) or conditioned transport maps of varying total degree. Contour levels and color scales are constant for all figures. **(a)** MCMC truth. **(b)** Degree $p = 3$. **(c)** Degree $p = 5$. **(d)** Degree $p = 7$

Table 23.2 BOD problem of Sect. 8.1 via inverse transport and conditioning. Efficiency of approximate Bayesian inference with inverse transport map from samples. The “offline” time is defined as the time it takes to compute an approximate inverse transport \tilde{S} and a corresponding approximate direct transport \tilde{T} via regression (see Sect. 4). The “online” time is the time required after observing $\{D = d\}$ to generate the equivalent of 30,000 independent samples from the conditional $\pi_{\theta|D=d}$. For MCMC, the “online” time is the average amount of time it takes to generate a chain with an effective sample size of 30,000

Map type	# training samples	Offline time (sec)		Online time (sec)
		\tilde{S} construction	\tilde{T} regression	
MCMC “truth”	NA			591.17
$p = 1$	5000	0.46	0.18	2.60
	50,000	4.55	1.65	2.32
$p = 3$	5000	4.13	1.36	3.54
	50,000	40.69	18.04	3.58
$p = 5$	5000	22.82	8.40	5.80
	50,000	334.25	103.47	6.15
$p = 7$	5000	145.00	40.46	8.60
	50,000	1070.67	432.95	8.83

from the conditional $\pi_{\theta|D=d}$. For MCMC, we use the average amount of time required to generate a chain with an effective sample size of 30,000. Measured in terms of online time, the polynomial transport maps are roughly two orders of magnitude more efficient than the adaptive MCMC sampler. More sophisticated MCMC samplers could be used, of course, but the conditional map approach will retain a significant advantage because, after solving for x_d^* in Lemma 1, it can generate *independent* samples at negligible cost. We must stress, however, that the samples produced in this way are from an *approximation* of the targeted conditional. In fact, the conditioning lemma holds true only if the computed joint transport is exact, and a solution of (23.22) is an approximate transport for the reasons discussed in Sect. 4.2. Put in another way, the conditioning lemma is exact for the pushforward

of the approximate map, $\tilde{\pi} = \widetilde{T}_\# \eta$. Nevertheless, if the conditional density $\pi_{\Theta|D=d}$ can be evaluated up to a normalizing constant, then one can quantify the error in the approximation of the conditional using (23.24). Under these conditions, if one is not satisfied with this error, then any of the approximate maps \widetilde{T}_d constructed here could be useful as a proposal mechanism for importance sampling or MCMC, to generate (asymptotically) exact samples from the conditional of interest. For example, the map constructed using the offline techniques discussed in this example could provide an excellent initial map for the MCMC scheme of [64]. Without this correction, however, the sample-based construction of lower triangular inverse maps, coupled with direct conditioning, can be seen as a flexible scheme for fast approximate Bayesian computation.

8.2 Direct Transport: Map from Densities

We now focus on the computation of a direct transport as described in Sect. 3, using evaluations of an unnormalized target density. Our goal here is to characterize a monotone increasing triangular transport map T that pushes forward a standard normal reference density η to the posterior distribution $\pi_{\Theta|D=d}$, i.e., the distribution of the BOD model parameters conditioned on a realization of the data d . We use the same realization of the data as in Sect. 8.1.

Figure 23.4 shows the reference and target densities. Notice that the target density exhibits a nonlinear dependence structure. This type of locally varying correlation can make sampling via standard MCMC methods (e.g., Metropolis–Hastings schemes with Gaussian proposals) quite challenging. In this example, the log-target density can be evaluated analytically up to a normalizing constant but direct sampling from the target distribution is impossible. Thus it is an ideal setting for the computation of the direct transport as the minimizer of the optimization problem (23.11). We just need to specify how to approximate integration with respect to the reference measure in the objective of (23.11) and to choose a

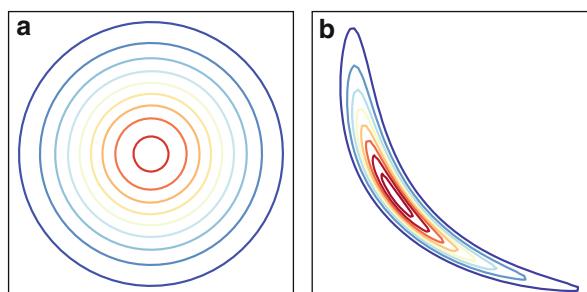

Fig. 23.4 BOD problem of Section 8.2 via direct transport. Observations are taken at times $t \in \{1, 2, 3, 4, 5\}$. The observed data vector is given by $d = [0.18; 0.32; 0.42; 0.49; 0.54]$. (a) Reference density. (b) Target density

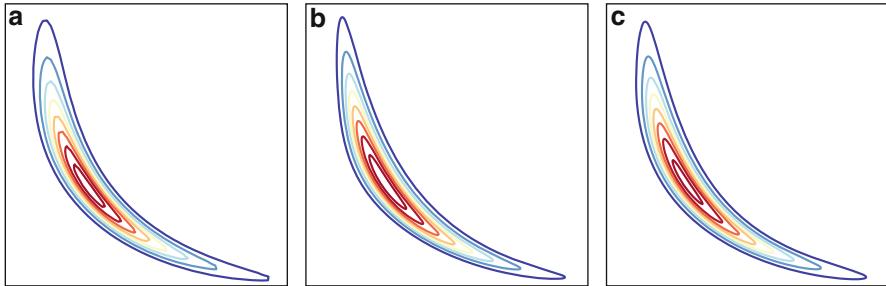

Fig. 23.5 BOD problem of Sect. 8.2 via direct transport: pushforwards of the reference density under a given total-degree triangular map. The basis of the map consists of multivariate Hermite polynomials. The expectation with respect to the reference measure is approximated with a full tensor product Gauss–Hermite quadrature rule. The approximation is already excellent with a map of degree $p = 3$. (a) Target density. (b) Pushforward $p = 3$. (c) Pushforward $p = 5$

finite-dimensional approximation space $\mathcal{T}_\Delta^h \subset \mathcal{T}_\Delta$ for the triangular map. Here we will approximate integration with respect to the reference measure using a tensor product of ten-point Gauss–Hermite quadrature rules. For this two-dimensional problem, this corresponds to 100 integration nodes (i.e., $M = 100$ in (23.14)). For \mathcal{T}_Δ^h we will employ a total-degree space of multivariate Hermite polynomials. In particular, we focus on third- and fifth-degree maps. The monotonicity constraint in (23.11) is discretized pointwise at the integration nodes as explained in Sect. 5.3.

Figure 23.5 shows the results of solving the discretized optimization problem (23.14) for the transport map. In particular, we show the pushforward of the reference density through the transport maps found by solving (23.14) for different truncations of \mathcal{T}_Δ^h . As we can see from Fig. 23.5, an excellent approximation of the target density is already achieved with a degree-three map (see Fig. 23.5b). This approximation improves and is almost indistinguishable from the true target density for a degree-five map (see Fig. 23.5c). Thus if we were to compute posterior expectations using the approximate map as explained in Sect. 3.3, we would expect virtually zero-variance estimators with extremely small bias. Moreover, we can estimate this bias using (23.15).

If one is not content with the bias of these estimators, then it is always possible to rely on asymptotically exact sampling of the pullback of the target distribution through the approximate map via, e.g., MCMC (see Sect. 3.3). Figure 23.6 illustrates such pullback densities for different total-degree truncations of the polynomial space \mathcal{T}_Δ^h . As we can see from Fig. 23.6b, c, the pullback density is progressively “Gaussianized” as the degree of the transport map increases. In particular, these pullbacks do not have the complex correlation structure of the original target density and are amenable to efficient sampling; for instance, even a Metropolis independence sampler [69] could be very effective. Thus, approximate transport maps can effectively precondition and improve the efficiency of existing sampling techniques.

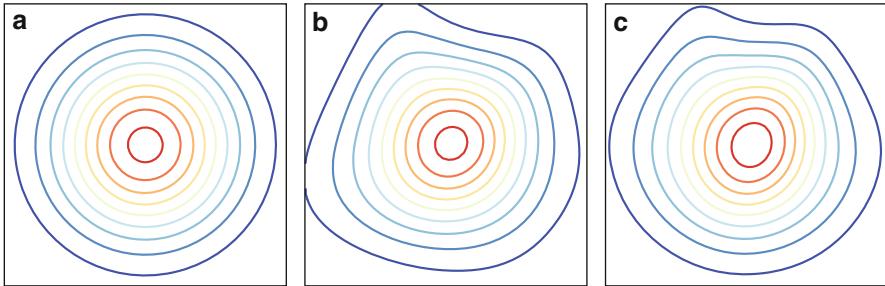

Fig. 23.6 BOD problem of Sect. 8.2 via direct transport: pullbacks under a given total order triangular map of the target density. Same setup of the optimization problem as in Fig. 23.5. The pullback density is progressively “Gaussianized” as the degree of the transport map increases. (a) Reference density. (b) Pullback $p = 3$. (c) Pullback $p = 5$

9 Conclusions and Outlook

In this chapter, we reviewed the fundamentals of the measure transport approach to sampling. The idea is simple but powerful. Assume that we wish to sample a given, possibly non-Gaussian, target measure. We solve this problem by constructing a deterministic transport map that pushes forward a reference measure to the target measure. The reference can be any measure from which we can easily draw samples or construct quadratures (e.g., a standard Gaussian). Under these assumptions, pushing forward independent samples from the reference through the transport map produces independent samples from the target. This construction turns sampling into a trivial task: we only need to evaluate a deterministic function. Of course, the challenge is now to determine a suitable transport. Though the existence of such transports is guaranteed under weak conditions [85], in this chapter we focused on target and reference measures that are absolutely continuous with respect to the Lebesgue measure, with smooth and positive densities. These hypotheses make the numerical computation of a continuous transport map particularly attractive. It turns out that a smooth triangular transport, the Knothe–Rosenblatt rearrangement [18, 70], can be computed via smooth and possibly unconstrained optimization.

To compute this transport, we considered two different scenarios. In Sect. 3 we addressed the computation of a monotone triangular *direct transport* – a transport map that pushes forward a reference measure to the target measure – given only the ability to evaluate the unnormalized target density [61]. This situation is very common in the context of Bayesian inference. The direct transport can be computed by solving a smooth optimization problem using standard gradient-based techniques. In Sect. 4, on the other hand, we focused on a setting where the target density is unavailable and we are instead given only finitely many samples from the target distribution. This scenario arises, for instance, in density estimation [81] or Bayesian inference with intractable likelihoods [23, 52, 89]. In this setting, we showed that a monotone triangular *inverse transport* – a transport

map that pushes forward the target measure to the reference measure – can be computed efficiently via separable convex optimization. The direct transport can then be evaluated by solving a nonlinear triangular system via a sequence of one-dimensional root findings (see Sect. 4.3). Moreover, we showed that characterizing the target distribution as the pushforward of a triangular transport enables efficient sampling from particular conditionals (and of course any marginal) of the target (see Sect. 7). This feature can be extremely useful in the context of online Bayesian inference, where one is concerned with fast posterior computations for multiple realizations of the data (see Sect. 8.1).

Ongoing efforts aim to expand the transport map framework by: (1) understanding the fundamental *structure* of transports and how this structure flows from certain properties of the target measure; (2) developing rigorous and automated methods for the adaptive refinement of maps; and (3) coupling these methods with more effective parameterizations and computational approaches.

An important preliminary issue, which we discussed briefly in Sect. 5.3, is how to enforce **monotonicity** and thus invertibility of the transport. In general, there is no easy way to parameterize a monotone map. However, as shown in Sect. 5.3 and detailed in [12], if we restrict our attention to triangular transports – that is, if we consider the computation of a Knothe–Rosenblatt rearrangement – then the monotonicity constraint can be enforced *strictly* in the parameterization of the map. This result is inspired by monotone regression techniques [66] and is useful in the transport map framework as it removes explicit monotonicity constraints altogether, enabling the use of unconstrained optimization techniques.

Another key challenge is the need to construct low-dimensional parameterizations of transport maps in high-dimensional settings. The critical observation in [75] is that Markov properties – i.e., the conditional independence structure – of the target distribution induce an intrinsic low dimensionality of the transport map in terms of **sparsity** and **decomposability**. A sparse transport is a multivariate map where each component is only a function of few input variables, whereas a decomposable transport is a map that can be written as the *exact* composition of a finite number of simple functions. The analysis in [75] reveals that these sparsity and decomposability properties can be predicted *before* computing the actual transport simply by examining the Markov structure of the target distribution. These properties can then be explicitly enforced in the parameterization of candidate transport maps, leading to optimization problems of considerably reduced dimension. Note that there is a constant effort in applications to formulate probabilistic models of phenomena of interest using sparse Markov structures; one prominent example is multiscale modeling [65]. A further source of low dimensionality in transports is **low-rank structure**, i.e., situations where a map departs from the identity only on a low-dimensional subspace of the input space [75]. This situation is fairly common in large-scale Bayesian inverse problems where the data are informative, relative to the prior, only about a handful of directions in the parameter space [25, 76].

Building on these varieties of low-dimensional structure, we still need to construct *explicit* representations of the transport. In this chapter, we have opted for a

parametric paradigm, seeking the transport map within a finite-dimensional approximation class. Parameterizing high-dimensional functions is broadly challenging (and can rapidly become intractable), but exploiting the sparsity, decomposability, and low-rank structure of transports can dramatically reduce the burden associated with explicit representations. Within any structure of this kind, however, we would still like to introduce the fewest degrees of freedom possible: for instance, we may know that a component of the map should depend only on a small subset of the input variables, but what are the best basis functions to capture this dependence? A possible approach is the **adaptive enrichment** of the approximation space of the map during the optimization routine. The main question is how to drive the enrichment. A standard approach is to compute the gradient of the objective of the optimization problem over a slightly richer approximation space and to detect the new degrees of freedom that should be incorporated in the parameterization of the transport. This is in the same spirit as adjoint-based techniques in adaptive finite element methods for differential equations [7]. In the context of transport maps, however, it turns out that one can *exactly* evaluate the first variation of the objective over an infinite-dimensional function space containing the transport. A rigorous and systematic analysis of this first variation can guide targeted enrichment of the approximation space for the map [12]. Alternatively, one could try to construct rather complex transports by **composing** simple maps and rotations of the space. This idea has proven successful in high-dimensional applications (see [63] for the details of an algorithm and [44, 81] for related approaches).

Even after finding efficient parameterizations that exploit available low-dimensional structure, we must still search for the best transport map within a finite-dimensional approximation space. As a result, our transports will in general be only approximate. This fact should not be surprising or alarming. It is the same issue that one faces, for instance, when solving a differential equation using the finite element method [78]. The important feature of the transport map framework, however, is that we can estimate the quality of an approximate transport and decide whether to enrich the approximation space to improve the accuracy of the map or to accept the bias resulting from use of an approximate map to sample the target distribution. In Sect. 3.3 we reviewed many properties and possible applications of approximate transports. Perhaps the most notable is the use of approximate maps to precondition existing sampling techniques such as MCMC. In particular, we refer to [64] for a use of approximate transport maps in the context of adaptive MCMC, where a low-order map is learned from MCMC samples and used to construct efficient non-Gaussian proposals that allow long-range global moves even for highly correlated targets.

So far, the transport map framework has been deployed successfully in a number of challenging applications: high-dimensional non-Gaussian Bayesian inference involving expensive forward models [61], multiscale methods for Bayesian inverse problems [65], non-Gaussian proposals for MCMC algorithms [64], and Bayesian optimal experimental design [39]. Ongoing and future applications of the framework include sequential data assimilation (Bayesian filtering and smoothing), statistical modeling via non-Gaussian Markov random fields, density estimation

and inference in likelihood-free settings (e.g., with radar and image data), and rare event simulation.

Abstract

A salient task in uncertainty quantification (UQ) is to study the dependence of a quantity of interest (QoI) on input variables representing system uncertainties. Relying on linear expansions of the QoI in orthogonal polynomial bases of inputs, polynomial chaos expansions (PCEs) are now among the widely used methods in UQ. When there exists a smoothness in the solution being approximated, the PCE exhibits sparsity in that a small fraction of expansion coefficients are significant. By exploiting this sparsity, *compressive sampling*, also known as *compressed sensing*, provides a natural framework for accurate PCE using relatively few evaluations of the QoI and in a manner that does not require intrusion into legacy solvers. The PCE possesses a rich structure between the QoI being approximated, the polynomials, and input variables used to perform the approximation and where the QoI is evaluated. In this chapter insights are provided into this structure, summarizing a portion of the current literature on PCE via compressive sampling within the context of UQ.

1 Introduction

One task of uncertainty quantification (UQ) is to understand how various quantities of interest (QoI) behave as functions of uncertain system inputs. An ineffective understanding may give unfounded confidence in the QoI or lead to unnecessary restrictions in the system inputs due to lack of knowledge of the QoI. In the probabilistic framework, input uncertainties are modeled by random variables. Polynomial chaos expansions (PCEs) have been significantly studied as a method to identify an approximation to the map between the inputs and the QoI that, for a variety of practical purposes, are both tractably computable and sufficiently accurate [36, 56, 84, 86]. The main idea behind PCEs is to expand a finite variance QoI in a basis of (multivariate) polynomials that are orthogonal with respect to the joint probability density function of the inputs. Estimating the expansion coefficients has classically relied on methods based on Galerkin projections [36, 86], Monte Carlo and quadrature integrations, [56, 85], as well as standard least-squares regression [8, 39, 41]. When the QoI depends *smoothly* on the inputs, the PCE coefficients associated with higher-order basis converge to zero rapidly. This results in a natural *sparsity* in the coefficient vector or, equivalently, a smaller set of unknown coefficients to be estimated. In such cases, compressive sampling techniques [12, 15, 16, 22, 25, 26, 33] have been recently employed and proven as a tool for generating PCEs with a reduced computational cost [1, 9, 10, 31, 32, 38, 40, 43, 46, 49, 50, 57, 59, 64, 65, 70, 72–74, 78, 83, 88–91].

This chapter will investigate how UQ problems may be formulated for use with PCE, how PCE may be computed via compressive sampling, theoretical measures that can gauge this recovery, and methods which attempt to accelerate the recovery.

1.1 Problem Formulation

Probability is a natural framework for modeling uncertain inputs by assuming that the input depends on a d -dimensional random vector $\boldsymbol{\xi} := (\xi_1, \dots, \xi_d)$ with some joint probability density function $f(\boldsymbol{\xi})$, where $\boldsymbol{\xi}$ represents a realization of

the random vector, $\boldsymbol{\Xi}$. In this manner a scalar QoI, denoted by $u(\boldsymbol{\Xi})$, is modeled as an unknown function of the random input, and the goal is to approximate this function. This approximation then forms a surrogate model for $u(\boldsymbol{\Xi})$, which can be accessed with negligible cost.

Often $u(\boldsymbol{\Xi})$ depends on a function $v(\mathbf{x}, t, \boldsymbol{\Xi})$, the solution to a set of partial or ordinary differential equations,

$$\mathcal{R}(\mathbf{x}, t, \boldsymbol{\Xi}; v) = \mathbf{0}, \quad (\mathbf{x}, t) \in \mathcal{D} \times [0, T], \quad (24.1)$$

with appropriate boundary and initial conditions. Here, \mathcal{R} denotes the set of governing equations, $\mathbf{x} \in \mathcal{D} \subseteq \mathbb{R}^D$, $D = 1, 2, 3$, the spatial variable, and $t \in [0, T]$ the time.

As the computation of realizations of $v(\mathbf{x}, t, \boldsymbol{\Xi})$, and hence of $u(\boldsymbol{\Xi})$, requires potentially the use of legacy codes, it is often preferred not to alter the solver for v to handle $\boldsymbol{\Xi}$ in a sophisticated manner, e.g., by considering the Galerkin projection of \mathcal{R} into a subspace spanned by a basis in $\boldsymbol{\Xi}$. Additionally, the evaluation of a realized $u(\boldsymbol{\Xi})$ can become a significant computational bottleneck, and in these cases it is prudent to identify an approximation using as few realizations of $u(\boldsymbol{\Xi})$ as is practical.

Approximating $u(\boldsymbol{\Xi})$, assumed to have finite variance, using a basis expansion in multivariate orthogonal polynomials, each of which is denoted by $\psi_k(\boldsymbol{\Xi})$, yields the PCE

$$u(\boldsymbol{\Xi}) = \sum_{k=1}^{\infty} c_k \psi_k(\boldsymbol{\Xi}). \quad (24.2)$$

The unknown coefficients $c_k, k = 1, 2, \dots$ can be computed via the projection equation

$$c_k = \int u(\boldsymbol{\xi}) \psi_k(\boldsymbol{\xi}) f(\boldsymbol{\xi}) d\boldsymbol{\xi} = \mathbb{E}[u(\boldsymbol{\Xi}) \psi_k(\boldsymbol{\Xi})], \quad (24.3)$$

leading to the mean-squares convergence of (24.2), when appropriately truncated. In (24.3), \mathbb{E} denotes the mathematical expectation operator and $\psi_k(\boldsymbol{\Xi})$ are assumed to be normalized such that $\mathbb{E}[\psi_k^2(\boldsymbol{\Xi})] = 1$. Although it is possible to construct polynomials that are orthogonal with respect to a larger class of $f(\boldsymbol{\xi})$, here it is assumed that the coordinates of $\boldsymbol{\Xi}$ are independent, which implies that $f(\boldsymbol{\xi})$ is a product of its d marginal distributions. Orthogonal polynomials are well understood for a variety of distributions, significantly easing the identification and evaluation of the orthogonal polynomials, as well as the analysis of approximation in those polynomials.

Within the PCE framework, it is possible to identify useful sets of basis polynomials, methods to truncate the series to be computationally tractable, and methods that cheaply and effectively approximate the coefficients c_k . These form the basis of the subsequent discussions.

Table 24.1 The orthogonal polynomials corresponding to several commonly used continuous distributions from the Askey scheme

Distribution of random variable, $f(\xi)$	Normal	Uniform	Gamma	Beta
Associated orthogonal polynomial, $\psi_k(\Xi)$	Hermite	Legendre	Laguerre	Jacobi

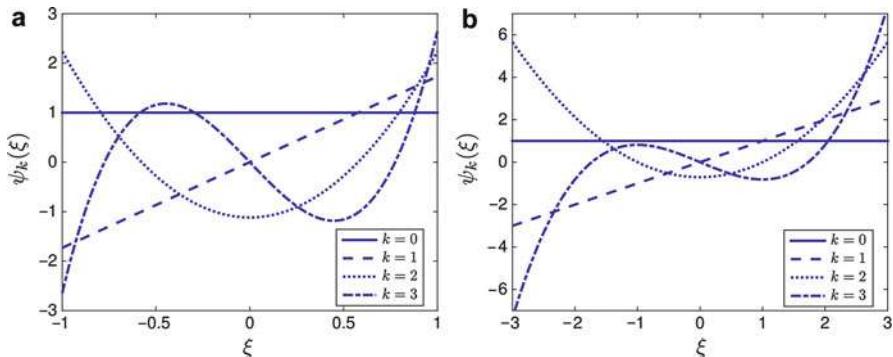

Fig. 24.1 Plots of orthonormal Legendre (a) and Hermite (b) polynomials of degree up to three

1.2 The Askey Scheme

In the one-dimensional case, where $\Xi = \Xi$ is distributed according to $f(\xi)$, $\psi_k(\Xi)$ are polynomials of order k that are orthogonal with respect to $f(\xi)$. For several commonly used distributions, such an association between $\psi_k(\Xi)$ and $f(\xi)$ is given by the Askey scheme of polynomials [4], as seen in Table 24.1.

The order k of the one-dimensional polynomial refers to the highest degree of that polynomial, allowing an indexing of these polynomials from zero to infinity. Figure 24.1 shows low-order orthonormal Legendre and Hermite examples, which are the focus in this chapter. Notice how the S-shape of the third-order Legendre polynomial is contained within $[-1, 1]$, while the third-order Hermite polynomial has an S-shape oscillation that is stretched over a larger domain. This behavior continues at higher orders, with high-order Hermite polynomials being oscillatory over ever-expanding domains, while Legendre polynomials are oscillatory within $[-1, 1]$, achieving their extreme values in that interval at the endpoints. Additionally, the Legendre polynomials tend to reach higher peaks in their oscillations than their Hermite counterparts. For results concerning properties of these and other orthogonal polynomial systems, the interested reader is referred to [3, 4, 75, 77].

In the d -dimensional case, the orthogonal polynomials are a tensor product of the d orthogonal polynomials in each respective dimension, thus allowing different orthogonal polynomials in the various coordinates of Ξ , when following different distributions. As an example, if Ξ_1 is normally distributed while Ξ_2 is uniformly distributed, then each basis polynomial is a product of a Hermite polynomial in Ξ_1 and a Legendre polynomial in Ξ_2 . For notational simplicity, considerations are needed to index the order of any polynomial with respect to each dimension. For this

purpose, a multi-index by the degree of polynomial along each dimension is utilized here. Specifically, if \mathbf{k} is a d -index, then k_i refers to the order of the polynomial in the i th dimension, and

$$\psi_{\mathbf{k}}(\boldsymbol{\Xi}) = \prod_{i=1}^d \psi_{k_i}(\Xi_i),$$

is the appropriate d -dimensional orthogonal polynomial, where the polynomial is of the appropriate type in each dimension. There are several potential notions of order for multidimensional polynomials, as described in the next section.

1.3 Polynomial Order

Definitions of multivariate order determine which multi-indices \mathbf{k} correspond to included basis functions, thus defining which basis functions are used in a given approximation. For a given approximation of a certain order, denote the set of basis functions in the set of order p by \mathcal{K}_p and the number of elements in that set by P or $|\mathcal{K}_p|$. The definition of order also determines which functions, u , may be accurately recovered for a given \mathcal{K}_p , in that the accuracy of the approximation relates to the basis functions available for the corresponding approximation,

$$u(\boldsymbol{\Xi}) \approx \hat{u}(\boldsymbol{\Xi}) := \sum_{\mathbf{k} \in \mathcal{K}_p} c_{\mathbf{k}} \psi_{\mathbf{k}}(\boldsymbol{\Xi}), \quad (24.4)$$

which by (24.3) is the approximation minimizing $\|u - \hat{u}\|_{\mathcal{L}_2(\boldsymbol{\Xi})}$. Perhaps, the simplest formulation of polynomial order is that of tensor order, defined to be

$$\mathcal{K}_p^{(\infty)} := \{\mathbf{k} : \|\mathbf{k}\|_{\infty} \leq p\},$$

where the superscript (∞) is chosen due to the norm on \mathbf{k} when viewed as a vector. This set has $|\mathcal{K}_p^{(\infty)}| = (p+1)^d$ polynomials in it, which is exponentially dependent on d , but has the benefit of being able to handle a high level of interaction among the different dimensions. However, it is rare that u has such a high dependence between dimensions so as to simultaneously require high-order polynomials in all dimensions to accurately reconstruct u . For this reason, a more popular definition of order for PCE, total order, is defined by

$$\mathcal{K}_p^{(1)} := \{\mathbf{k} : \|\mathbf{k}\|_1 \leq p\}. \quad (24.5)$$

A combinatorial consideration reveals that this definition yields $|\mathcal{K}_p^{(1)}| = \binom{p+d}{d} \leq \min\{(p+1)^d, (d+1)^p\}$ basis functions, which often gives a significant reduction in the number of basis functions though it grows rapidly if both p and d are large.

Most functions of interest have a weak enough interaction among dimensions to be effectively represented by this type of truncation for modest p .

A more general notion of order which has been used in building bases and generalizes the above definitions is given by

$$\mathcal{K}_p^{(\alpha)} := \left\{ \mathbf{k} : \left(\sum_{i=1}^d k_i^\alpha \right)^{1/\alpha} \leq p \right\}, \quad (24.6)$$

where $\alpha > 0$ is a parameter controlling the shape of this set of basis functions. Smaller α reduces the number of basis functions more dramatically, particularly by removing polynomials of higher orders in multiple dimensions. In contrast, larger α more rapidly increases the number of basis functions with the advantage of being more robust to recovering solutions possessing highly interactive dimensions.

In this chapter, the focus is on the total-order bases as defined in (24.5), corresponding to $\alpha = 1$ in (24.6), and the superscript is dropped. As seen in the next section, approximations to u using such a basis often require a relatively small proportion of these basis functions, leading to a sparsity in computed solutions.

1.4 Sparsity in PCE

The sparsity in the PCE is closely intertwined with recovery via compressive sampling. Intuitively, a PCE is sparse if a small but unknown subset of the basis set may still accurately approximate the function u . Refer to the set of indices of these basis functions as \mathcal{S}_p , noting that it depends on p , in the sense that with a higher-order approximation, previously unavailable basis functions may improve the approximation. Intuitively, smooth u are well approximated by a truncated Taylor series expansion, which can itself be constructed from a small number of basis polynomials. Specifically, a function u is s -sparse if for some $\mathcal{S}_p \subset \mathcal{K}_p$ with $|\mathcal{S}_p| = s$,

$$u(\boldsymbol{\xi}) = \sum_{\mathbf{k} \in \mathcal{S}_p} c_{\mathbf{k}} \psi_{\mathbf{k}}(\boldsymbol{\xi}).$$

Practically, this will not hold with equality, but rather only as an accurate approximation, often referred to as approximate sparsity. An example of such sparsity, adapted from [64], is a solution computed from a thermally driven cavity flow problem shown in Fig. 24.2 and discussed later, exhibiting a significant decay in coefficient magnitude as order increases and for polynomials which vary with respect to dimensions that are less useful for constructing an accurate approximation. This solution is for a problem summarized in Fig. 24.8. Though a priori information as to which basis functions are useful in approximating u is often unavailable, there is often reasonable certainty that the basis could be compressed to a smaller number

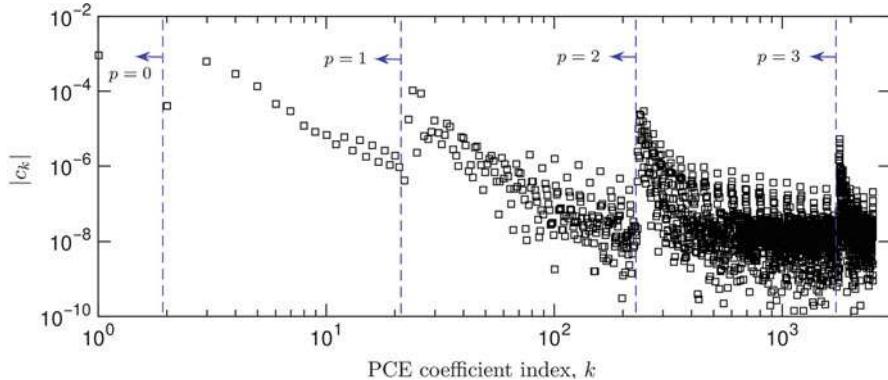

Fig. 24.2 Solution coefficient magnitude for basis functions of varied order, demonstrating coefficient decay motivating a sparse reconstruction. Coefficient indices to the left of the *vertical dashed lines* are included in the set of PC basis functions of order not larger than the specified p

of basis functions, in a set \mathcal{S}_p of size s . If it is known which basis functions were in \mathcal{S}_p , then one could accurately approximate the s corresponding coefficients using a relatively small, possibly linear in s , number of realizations. However, there is typically a large number of basis functions in the set \mathcal{K}_p , and no knowledge of what basis functions may or may not be in \mathcal{S}_p . Compressive sampling discerns which basis functions are appropriate at the time that the coefficients are accurately computed, revealing the sparsity in the solution while computing an approximation in this sparse basis.

2 Solution Computation

While there is motivation to identify a solution that has small support \mathcal{S}_p , finding the smallest such support is a difficult combinatorial problem [26], and instead a similar, tractable problem is solved. Starting from (24.4) a matrix equation can be constructed from realized data that may be solved to identify the coefficients c_k .

Specifically, utilizing N realizations of Ξ , each denoted by $\xi^{(i)}$, one can define N equations in a linear system, where methods to select these realizations are discussed in a later section. Here, let \mathbf{u} be a vector with $u_i = u(\xi^{(i)})$. For some indexing of polynomials that maps $\mathbf{k} \in \mathcal{K}_p$ to $j \in \{1, \dots, P\}$, let \mathbf{c} be a vector with entries c_j , and $\Psi_{i,j} = \psi_j(\xi^{(i)})$. This gives an $N \times 1$ vector \mathbf{u} , a $P \times 1$ vector \mathbf{c} , and an $N \times P$ matrix Ψ , referred to as the *measurement matrix*. Denote the approximation to \mathbf{c} by $\hat{\mathbf{c}}$. It is reasonable to approximate \mathbf{c} by $\hat{\mathbf{c}}$ computed using Ψ and \mathbf{u} . Moreover, compressive sampling allows this to be done while undersampling the $N \times P$ matrix Ψ , that is when $N < P$. One problem to investigate is

$$\hat{\mathbf{c}} = \arg \min_{\mathbf{c}} \|\mathbf{c}\|_0 \quad \text{subject to} \quad \Psi \mathbf{c} = \mathbf{u}, \quad (24.7)$$

where $\|\cdot\|_0$ is the number of nonzero elements of the argument. However, this is an NP-hard combinatorial problem [26], and so it is practical to instead consider approximate solutions. Two methods are considered here, though several other methods to approximately solve (24.7) exist; see, e.g., [6, 24, 51, 61, 62, 87].

2.1 Basis Pursuit Denoising (BPDN)

One useful method is the convex relaxation of the $\|\cdot\|_0$ objective function in (24.7) to the ℓ_1 norm $\|\cdot\|_1$,

$$\hat{\mathbf{c}} = \arg \min_{\mathbf{c}} \|\mathbf{c}\|_1 \quad \text{subject to} \quad \Psi \mathbf{c} = \mathbf{u}. \quad (24.8)$$

This problem, referred to as basis pursuit [23], is a convex optimization and may be solved efficiently via, for instance, primal-dual interior-point methods as implemented in [7, 30]. The ℓ_1 -minimization problem (24.8) is the main focus here, along with a greedy method to approximate the solution to (24.7). The relation between (24.7) and (24.8) is an important point of analysis, which is partially addressed by Theorems 2 and 4, whose presentation is deferred until later sections.

For many practical problems, the condition $\Psi \mathbf{c} = \mathbf{u}$ is often too restrictive, and so a nonzero residual is admitted, leading to a problem such as

$$\hat{\mathbf{c}} = \arg \min_{\mathbf{c}} \|\mathbf{c}\|_1 \quad \text{subject to} \quad \|\mathbf{u} - \Psi \mathbf{c}\|_2 < \epsilon, \quad (24.9)$$

which is known as basis pursuit denoising (BPDN). It is possible to select ϵ via the statistical technique of cross-validation [2, 11, 31, 82]. In many practical contexts, the truncation error defined via (24.4) as $u - \hat{u}$ implies a need for positive ϵ to account for the QoI not being fully explained by the chosen basis.

Closely connected with (24.9) is the regularized formulation (for some positive parameter τ),

$$\hat{\mathbf{c}} = \arg \min_{\mathbf{c}} \|\mathbf{u} - \Psi \mathbf{c}\|_2 \quad \text{subject to} \quad \|\mathbf{c}\|_1 \leq \tau, \quad (24.10)$$

which is known as LASSO [79]. Related to this is the Bayesian formulation [5, 45, 49, 63, 72], based on a model for the entries of the mismatch $\mathbf{u} - \Psi \mathbf{c}$, e.g., a centered Gaussian with prescribed or parametric standard deviation and a Laplace prior distribution on \mathbf{c} ,

$$\pi(\mathbf{c} | \lambda) := \prod_{k \in \mathcal{K}_p} \frac{\lambda}{2} e^{-\lambda|c_k|}, \quad (24.11)$$

for some parameter λ . For computational purposes, often an alternative, but similar in nature, prior distribution on \mathbf{c} is employed [5].

2.2 Orthogonal Matching Pursuit (OMP)

Orthogonal matching pursuit (OMP) is a popular greedy method which approximates a solution to (24.7) via a greedy search [80, 81]. Matching pursuits are greedy methods which update the approximation by using a matching criterion with the residual to iteratively include a new basis function to an active basis set, denoted here by \mathcal{A} , where coefficients are nonzero. Orthogonal matching pursuit, presented in Algorithm 1, recomputes the coefficients by a least-squares approximation after each iterative addition to the active set and updates the residual accordingly. Note that each iterative least-squares solve involves only $|\mathcal{A}|$ columns of Ψ , and these least squares can be computed efficiently and accurately [39, 60]. In practice this algorithm is faster than BPDN, while providing a good approximation to the solution of (24.9).

Algorithm 1 Orthogonal Matching Pursuit (OMP)

```

 $\mathcal{A} = \emptyset, \mathbf{r} = \mathbf{u}.$ 
while  $\|\mathbf{r}\|_2 > \delta$ 
     $k = \arg \max_{j \notin \mathcal{A}} \frac{\mathbf{r}^T \Psi(:, j)}{\|\Psi(:, j)\|_2^2}.$ 
     $\mathcal{A} = \mathcal{A} \cup k.$ 
     $\hat{\mathbf{c}} = \arg \min_{\mathbf{c}} \|\mathbf{u} - \Psi \mathbf{c}\|_2 \quad \text{subject to} \quad c_k = 0 \quad \forall k \notin \mathcal{A}.$ 
     $\mathbf{r} = \mathbf{u} - \Psi \hat{\mathbf{c}}.$ 
end while

```

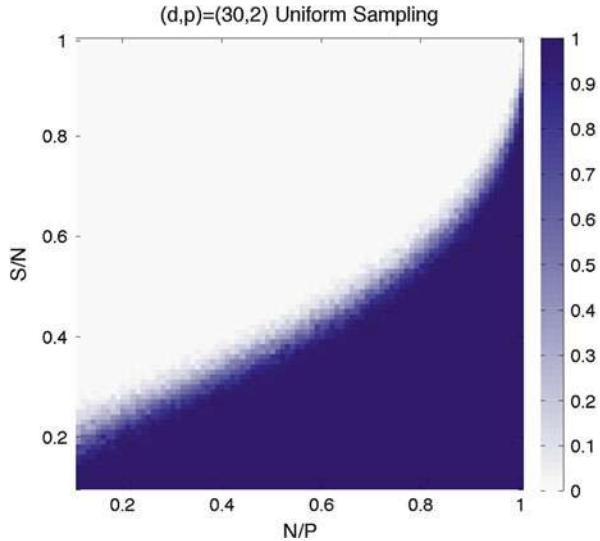

3 Measures for Recovery

Several measures for recovery are focused on identifying when the solution of the ℓ_1 -minimization problem (24.9) or OMP without noise is equivalent to the solution of (24.7). This recovery is also shown to be robust to noise, which includes the stability of the problem with respect to the truncation error as well as potential errors in identifying $u(\xi)$. Though a variety of measures are considered here, other properties relating to the spark and null space of a matrix are additionally useful [25, 47, 48].

3.1 Phase Transition Diagrams

A direct demonstration of recovery is how well randomly generated, sparse signals are recovered. An effective normalization to consider is the level of sparsity relative to the sampling s/N , as well as the degree of sampling relative to the number of basis functions N/P . There is a limiting transition with recovery in many cases, which describes the number of samples needed for a particular sparsity to recover a truly sparse solution [28]. For a large class of random matrices and solvers, there is a limiting behavior [28] as seen in Fig. 24.3. This phase transition is seen in many PCEs [39].

Fig. 24.3 Phase transition diagram associated with ℓ_1 -minimization's recovery of random sparse solutions with Legendre polynomials from a $d = 30, p = 2$ total-order basis with samples drawn uniformly from the d -dimensional hypercube, displaying archetypal transition behavior. The colors represent the probability of successful solution recovery (Figure adapted from [40])

3.2 Restricted Isometry Constant (RIC)

In this context, the Restricted isometry constant (RIC) [18, 34, 58], closely related to the uniform uncertainty principle [14], is defined to be the smallest constant δ_s satisfying

$$(1 - \delta_s) \|\mathbf{c}_s\|_2^2 \leq \frac{1}{N} \|\Psi \mathbf{c}_s\|_2^2 \leq (1 + \delta_s) \|\mathbf{c}_s\|_2^2, \quad (24.12)$$

for all \mathbf{c}_s having s or fewer nonzero elements. Note that smaller δ_s implies a near isometry of any s columns of Ψ , and it is for this reason that the RIC is analytically useful. Further, when δ_s is less than some threshold for an appropriate s , then the matrix Ψ is said to satisfy a restricted isometry property (RIP), guaranteeing several results. An example of such an RIP result is a theorem restated from [69].

Theorem 1 ([69]). Let $\mathbf{c} \in \mathbb{R}^P$ represent a solution to be approximated and $\hat{\mathbf{c}}$ be the solution to (24.9). Let

$$\boldsymbol{\eta} := \Psi \mathbf{c} - \mathbf{u}$$

denote the contribution from sources of error, and let the ϵ from (24.9) be chosen such that $\|\boldsymbol{\eta}\|_2 < \epsilon$. If

$$\delta_{2s} < \delta_\star := 3/(4 + \sqrt{6}) \approx 0.4652,$$

then the following error estimates hold, where c_1, c_2, c_3 , and c_4 depend only on δ_{2s} .

$$\|\mathbf{c} - \hat{\mathbf{c}}\|_2 \leq \frac{c_1}{\sqrt{s}} \inf_{\|\mathbf{c}_s\|_0 \leq s} \|\mathbf{c}_s - \mathbf{c}\|_1 + c_2 \epsilon;$$

$$\|\mathbf{c} - \hat{\mathbf{c}}\|_1 \leq c_3 \inf_{\|\mathbf{c}_s\|_0 \leq s} \|\mathbf{c}_s - \mathbf{c}\|_1 + c_4 \epsilon \sqrt{s},$$

and $\|\cdot\|_0$ again refers to the number of nonzero elements of the vector.

Unfortunately, for practically sized s , the RIC is difficult to compute for a given matrix, and as a result any RIP can be difficult to verify. Still, the RIC can be guaranteed in a probabilistic sense and lead to a minimum sampling size N for a successful solution recovery via (24.8). We defer the statement of any particular theorem until the coherence parameter of the next section is defined.

3.3 Coherence of Bounded Orthonormal Systems

Let $\Psi(i, :)$ denote the i th row of Ψ and $\Psi(:, j)$ denote the j th column of Ψ . The rows of Ψ are assumed to be independent and identically distributed. Recall that as basis polynomials are taken according to the Askey scheme, an appropriate normalization for the basis polynomials gives that

$$\frac{1}{N} \mathbb{E}(\Psi^T \Psi) = \mathbb{E}((\Psi(1, :))^T \Psi(1, :)) = I, \quad (24.13)$$

which is equivalent to using the orthonormalized basis polynomials. A useful measure is the parameter [19] given by

$$\mu := \sup_{k \in \mathcal{K}_p, \xi \in \Omega} |\psi_k(\xi)|^2, \quad (24.14)$$

where Ω is the support of Ξ . μ is often referred to as an incoherence or coherence parameter; here it is referred to as a coherence parameter. From (24.14), μ corresponds to the largest absolute value taken by any of the basis functions evaluated in the domain of the random input. This definition of coherence is related to the recovery of solutions by (24.7), (24.8), (24.9) and the RIC [13]. Often, such as when considering Hermite polynomials, (24.14) is unbounded over all of Ω , and it is necessary to restrict the domain of Ξ to a smaller set as in [19, 40], giving a boundedness with high probability. With μ defined in this way, one may bound the RIC as in Theorem 8.1 of [68], reproduced here.

Theorem 2 ([68]). Suppose $\eta \in (0, 1)$, and $\delta \in (0, 0.5]$. If $C \leq 243150$ and

$$\frac{N}{\log(10N)} \geq C \mu \delta^{-2} s \log^2(100s) \log(4P) \log(7\eta^{-1}), \quad (24.15)$$

then with probability at least $1 - \eta$, it follows that the RIC for Ψ satisfies $\delta_s \leq \delta$.

This result may be combined with Theorem 1 to bound recovery. Although not needed here, it is worthwhile noting that the result in Theorem 2 can be improved slightly to that of Theorem 8.4 in [68]. The RIC implies uniform recovery over all potential c , but this guarantee of uniform recovery is often unneeded in applications.

If one instead wishes to assure recovery for an arbitrary but fixed \mathbf{c} , then one may invoke Theorem 1.1 of [19], reproduced here.

Theorem 3 ([19]). *Let \mathbf{c} be a fixed but otherwise arbitrary vector satisfying $\|\mathbf{c}\|_0 = s$. Then with probability $1 - 5/P - \exp(-\beta)$, \mathbf{c} solves (24.8) provided that*

$$N \geq C_0(1 + \beta)\mu s \log(P). \quad (24.16)$$

We note that this result is stated for the solution to (24.8), though a similar result holds for the solution to (24.9) [19].

3.4 Mutual Coherence

Mutual coherence [27, 29], also referred to as coherence, is used to analyze recovery via BPDN, but is particularly useful for identifying when OMP reproduces the solution of (24.7). The mutual coherence is defined by

$$M := \sup_{1 \leq i \neq j \leq P} \frac{|\Psi^T(:, i)\Psi(:, j)|}{\|\Psi(:, i)\|_2 \|\Psi(:, j)\|_2}. \quad (24.17)$$

To eliminate potential confusion with the coherence parameter, μ , of the previous section, (24.17) is here referred to as mutual coherence. Note that this definition coincides with $M = \delta_2$ from (24.12), and Section 2.5 of [68] considers other relations in more depth. This definition relates closely to recovery via OMP, which relies heavily on inner products, as Theorem 5.1 of [29], restated here.

Theorem 4 ([29]). *Let ϵ be the error parameter in OMP, and let \mathbf{c} satisfy*

$$\|\mathbf{c}\|_0 \leq \frac{1+M}{2M} - \frac{\epsilon}{M} \cdot \frac{1}{\min_{c_k \neq 0} |c_k|}.$$

If $\hat{\mathbf{c}}$ is the recovered approximation to \mathbf{c} as calculated via OMP, then the supports are identical, that is

$$\text{supp}(\mathbf{c}) = \text{supp}(\hat{\mathbf{c}}).$$

Additionally, with regard to the ℓ_2 norm of error,

$$\|\hat{\mathbf{c}} - \mathbf{c}\|_2^2 \leq \frac{\epsilon^2}{1 - M(\|\mathbf{c}\|_0 - 1)}.$$

While this coherence involves the inner products between vectors, a different definition is useful for random matrices commonly utilized in PCE. This related

definition of mutual coherence is often given in terms of inner products of columns from two separate matrices [12, 53], although this two-matrix approach is not considered here. In this approach one matrix is the current matrix Ψ associated with realizations of $u(\Xi)$, and the second matrix is used in place of Ψ for computation of \hat{c} . This allows analysis of methods where the matrix used in the computation of c differs from the matrix used to recover u .

4 Improving Recovery

Knowing how the recovery of compressive sampling solutions relates to measurable quantities can provide insights into how to adjust the method to elicit change. Presented here are simple changes to standard approaches that may give considerable improvements. Other methods not discussed here which can significantly improve solution recovery include Bayesian adaptations [45, 49, 55] and iteratively adjusting the basis to generate quality approximations using fewer basis functions [43, 72].

4.1 Sampling Distribution

Several methods exist for identifying the $\xi^{(i)}$ used to form the linear system in (24.7). A straightforward approach is to draw $\xi^{(i)}$ independently from the distribution of Ξ , i.e., $f(\xi)$. This distribution is, in general, not an ideal sampling method for solution recovery [40], and it may be desired to sample from a different distribution, $g(\xi)$. Unfortunately, this would destroy the orthogonality of the basis functions in that (24.13) would no longer hold. This, however, can be corrected within the context of importance sampling by noting if $g(\xi) > 0$ for $\xi \in \Omega$, then

$$\delta_{i,j} = \int_{\Omega} \psi_i(\xi) \psi_j(\xi) f(\xi) d\xi = \int_{\Omega} \frac{f(\xi)}{g(\xi)} \psi_i(\xi) \psi_j(\xi) g(\xi) d\xi.$$

Thus, if Ξ is sampled according to $g(\xi)$, and each basis sample is weighted proportionally to $(f(\xi)/g(\xi))^{1/2}$, then orthogonality is restored. Motivated by this, define $w(\xi) := (f(\xi)/g(\xi))^{1/2}$ and W to be a diagonal matrix such that $W_{i,i} = w(\xi^{(i)})$. In practice, it is sufficient to know $w(\xi)$ up to a normalizing constant. Consider the solution to the preconditioned ℓ_1 -minimization problem

$$\hat{c} = \arg \min_c \|c\|_1 \quad \text{subject to} \quad \|Wu - W\Psi c\|_2 < \epsilon, \quad (24.18)$$

where the weight must also be applied to the corresponding realization of QoI, $u(\xi)$, as the matrix relation $W\Psi c = Wu$ insures that $\Psi c = u$. Here, the choice of $g(\xi)$ depends in particular on (24.14), as described in the next section. Note that the inclusion of $w(\xi)$ leads to a new definition for (24.14) given by

$$\mu_w := \sup_{k \in \mathcal{K}_p, \xi \in \Omega} |w(\xi) \psi_k(\xi)|^2, \quad (24.19)$$

for an appropriately normalized $w(\xi)$. This admits a modification to this parameter based solely on the sampling distribution and the corresponding weight.

4.1.1 Sampling for Minimizing (24.19)

To minimize (24.19), take $w(\xi)$ such that $\sup_{k \in \mathcal{K}_p} |w(\xi)\psi_k(\xi)|^2$ is constant in ξ [40].

This gives

$$w(\xi) := \left(\sup_{k \in \mathcal{K}_p} |\psi_k(\xi)| \right)^{-1}, \quad (24.20)$$

which implies the sampling distribution

$$g(\xi) := c \left(\sup_{k \in \mathcal{K}_p} |\psi_k(\xi)| \right)^2 f(\xi), \quad (24.21)$$

where c is the necessary normalizing constant to insure that $g(\xi)$ is a probability distribution and is typically unneeded in practice. Some of these coherence-minimizing distributions, $g(\xi)$, for one-dimensional Hermite and Legendre polynomials, are provided for reference in Fig. 24.4. Here, the limit for the Legendre sampling distribution when $p \rightarrow \infty$ is the Chebyshev distribution, defined to be

$$g(\xi) := \frac{1}{\pi \sqrt{1 - \xi^2}}. \quad (24.22)$$

In contrast, the limiting behavior for the Hermite sampling can be derived from theoretical results in [54] and is more nuanced, as depicted in Fig. 24.5. Here, the input on the horizontal axis scales as $\tilde{\xi} = \xi / (\sqrt{2} \sqrt{2p+1})$, and for $\tilde{\xi}$ defined this way the distribution has theoretical form $g(\tilde{\xi}) = \frac{6}{5} |\tilde{\xi}|^{-1/6}$ for $\tilde{\xi} \in [-1, 1]$.

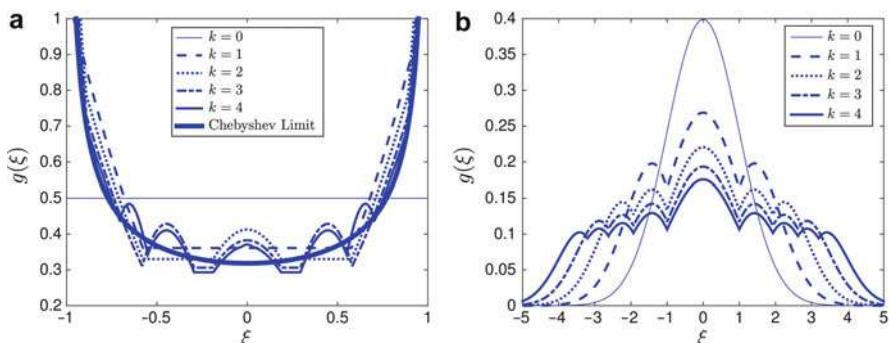

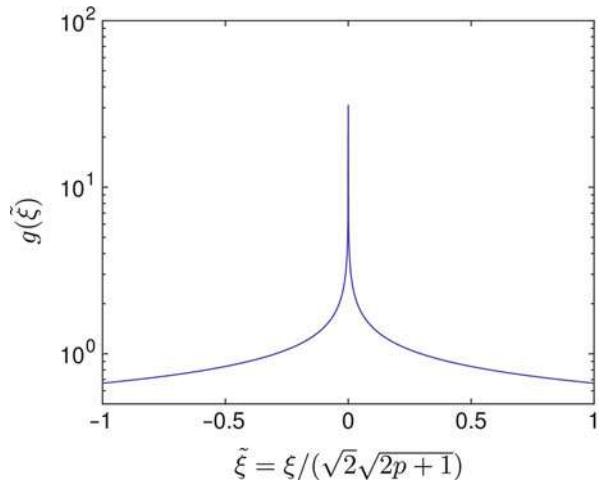

Fig. 24.4 Plots of a few coherence-minimizing sampling distributions for Legendre (a) and Hermite (b) polynomials

Fig. 24.5 Limiting behavior of $g(\xi)$ for Hermite polynomials in one dimension. Note that the scaled input maintains a dependence on the order p

As the support grows with p , a normalization dividing by $\sqrt{2}\sqrt{2p+1}$ is required to scale the support of the distribution, and so the limit of the coherence-minimizing distributions for a basis of total-order p as $p \rightarrow \infty$ is not itself a distribution. In a practical sense, sampling uniformly from a d -dimensional hypersphere of radius $\sqrt{2p+1}$ yields reasonable coherence values [40] and is used here as a distribution for high-order expansions.

There is a practical method to sample from $g(\xi)$ so as to minimize (24.19) based on Markov chain Monte Carlo (MCMC) sampling [37], which does not require the computation of the normalizing constant c in (24.21). A Metropolis-Hastings [55] type version of MCMC sampling is presented in Algorithm 2 and uses random samples which are rejected and accepted in such a way that the distribution of samples converges to the desired distribution, which is the stationary distribution of a Markov chain. This is a particularly useful tool when the sampling distribution is accessible up to an unknown normalizing constant, as in the case of $g(\xi)$. There are several considerations [71] to take into account when using Algorithm 2 to sample from $g(\xi)$. One is that as MCMC samples are dependent, there may be significant serial correlation between samples, and so a number of intermediate samples, denoted by T in Algorithm 2, may need to be discarded to reduce this effect. Another consideration is that a number of initial discarded samples are required to insure that the samples are being drawn approximately from the desired distribution. Both of these considerations depend on the choice of proposal distribution $g_p(\xi)$ in Algorithm 2. Choices of proposal distributions depend on whether the PCE is of a higher dimension or order [40] and in the latter case can be derived from asymptotic considerations of the polynomials, leading to the asymptotic distributions shown in Figs. 24.4 and 24.5. For example, if a high-order Legendre approximation is used, $g_p(\xi)$ can be taken to be the Chebyshev distribution, while a low-order Legendre approximation would be better served by a uniformly distributed $g_p(\xi)$. Similarly, for a high-order Hermite approximation,

one may use a uniform distribution on a d -dimensional hypersphere of radius $\sqrt{2}\sqrt{2p+1}$, as in [40].

Algorithm 2 Metropolis-Hastings Sampler with Static Proposal Distribution

```

Let  $g(\xi)$  be the desired distribution from which to draw.
Draw  $x$  according to proposal distribution  $g_p(\xi)$ .
for The number of desired samples.
  Set  $k = 0$ .
  while  $k \leq T$ 
    Draw  $y$  according to  $g_p(\xi)$ .
    Let  $r = \frac{g(y)g_p(x)}{g(x)g_p(y)}$ . Note that this does not require a normalizing constant for  $g(\xi)$ .
    With probability  $\min\{1, r\}$ , set  $x$  to be  $y$ .
    Increment  $k$ .
  end while
  Save sample  $x$ , approximately distributed according to  $g(\xi)$ .
end for

```

Sampling in this way has been seen to lead to phase-transition diagrams as in Fig. 24.3 over a range of dimensions and orders for both Hermite and Legendre polynomials [40]. The effects of the various sampling methods on the phase-transition diagrams of randomly generated Legendre expansions are presented in Fig. 24.6.

4.1.2 Quadrature-Based Sampling

Random samples may not be ideal in all applications as the solution may depend, possibly largely in highly under-sampled cases, on the actual samples used. This has motivated the utilization of more *structured* samples. Quadratures for the computation of one-dimensional integrals have a rich history and structure [77], allowing a surprising level of accuracy with relatively few evaluations. A tensor product of one-dimensional quadrature rules can provide a d -dimensional quadrature, but this leads to a dense grid, growing exponentially in d , that is most appropriate for tensor order bases and undesirable for most applications. This tensor grid is often subsampled using the Smolyak sparse grid construction [35, 76], allowing for a significantly smaller number of evaluations that may still accurately integrate/interpolate the solution. In the context of compressive sampling, a random subsampling of the grid of quadrature nodes may be utilized to solve the ℓ_1 -minimization problem (24.8) [78].

4.2 Column Weighting

If a given, positive, diagonal, weight matrix W is added, (24.8) can be changed to

$$\hat{\mathbf{c}} = \arg \min_{\mathbf{c}} \|\mathbf{W}\mathbf{c}\|_1 \quad \text{subject to} \quad \Psi\mathbf{c} = \mathbf{u}. \quad (24.23)$$

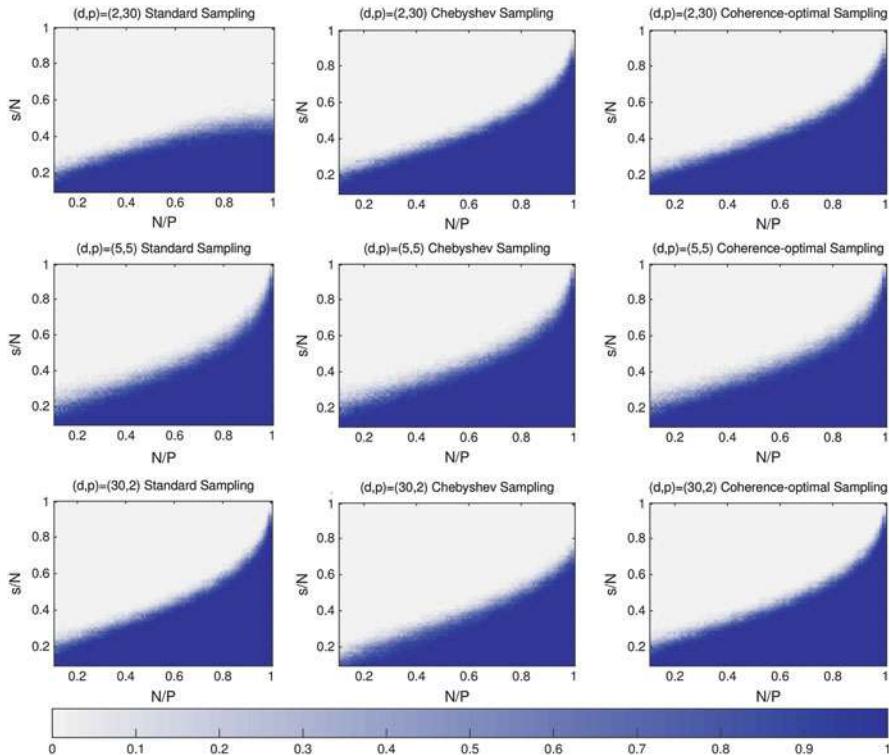

Fig. 24.6 Phase transition diagrams for Legendre PCE under various sampling strategies. Different rows correspond to different problems ranging from high dimensional to high order. Different columns correspond to different sampling distributions (Figure adapted from [40] with stricter ℓ_1 -minimization solver tolerance and larger number of iterations)

Notice that values $\mathbf{W}_{k,k}$ which are relatively large impose a higher penalty for larger \hat{c}_k , and so the corresponding values of \hat{c}_k will tend to be smaller than the solution to (24.8). Similarly, relatively small values of $\mathbf{W}_{k,k}$ will yield a smaller penalty for larger \hat{c}_k , and so the values of \hat{c}_k will tend to be larger than the solution to (24.8). In this way, \mathbf{W} distorts the ℓ_1 -ball and via the effect displayed in Fig. 24.7 may improve solution recovery [1, 17, 21, 42, 51, 61, 64, 70, 87, 90]. Weights may be adjusted iteratively and (24.23) recomputed, in a process called iteratively reweighted ℓ_1 -minimization [17, 90]. This adjustment is also related to a variant of (24.7) via the concept of weighted sparsity, as in [1, 70]. The choice of weights influences the computed solutions based on which coordinates are more heavily or lightly weighted, and so the weights must be identified carefully. Sometimes these weights can be derived by a careful analysis of decay rates [64], other times by a simplified or lower-fidelity model. In the context of function interpolation via solution of (24.8), column weighting is used to reduce aliasing, insuring that high-order basis functions are not overrepresented [1, 70].

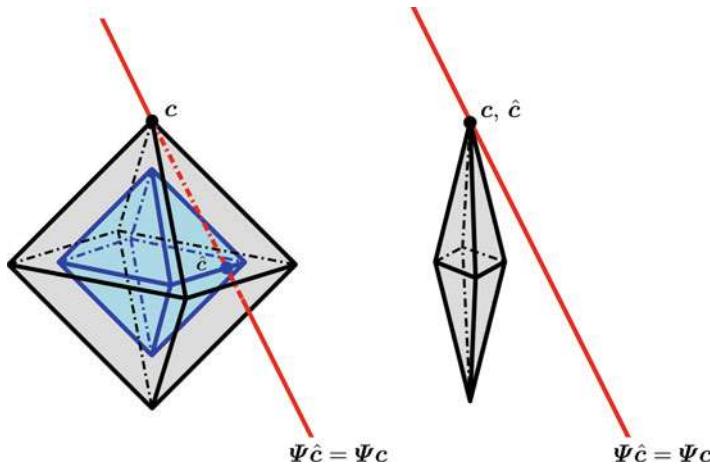

Fig. 24.7 Schematic of approximation of a sparse $c_0 \in \mathbb{R}^3$ via standard and weighted ℓ_1 -minimization. (a) Standard ℓ_1 -minimization for a particular solution, leading to a suboptimally sparse solution \hat{c} with more nonzero entries than c . (b) Weighted ℓ_1 -minimization for the same solution, leading to an optimally sparse computed solution, $\hat{c} = c$ [20]

4.3 Incorporating Derivative Evaluations

In practical applications the computation of a realized QoI may be accompanied with the computation of derivatives. These derivatives may be computed from automatic differentiation [67] or from direct or adjoint sensitivity equations [52]. These derivatives are often used to identify sensitivity, for design decisions, and for the solutions of inverse problems. Derivatives are also used to improve the quality of regression by insuring that the approximation is accurate not only for function values but also for its derivatives [44, 65], and this is how they are utilized here in the context of PCE. To change (24.8) and (24.9) appropriately, define

$$\mathbf{u}_\partial := \left(\frac{\partial u}{\partial \xi_1}(\xi^{(1)}), \dots, \frac{\partial u}{\partial \xi_d}(\xi^{(1)}), \dots, \frac{\partial u}{\partial \xi_1}(\xi^{(N)}), \dots, \frac{\partial u}{\partial \xi_d}(\xi^{(N)}) \right)^T \quad (24.24)$$

and

$$\Psi_\partial((i-1) \cdot d + k, j) := \frac{\partial \psi_j}{\partial \xi_k}(\xi^{(i)}), \quad k = 1, \dots, d. \quad (24.25)$$

In this way, \mathbf{u}_∂ contains all the partial derivative information for $u(\xi)$ with respect to each coordinate of ξ . Similarly, Ψ_∂ contains the partial derivatives of each basis function with respect to each coordinate of ξ . Whereas before Ψ had independent rows, here instead it has independent submatrices of size $(d+1) \times P$ for the

measurement matrix. Let the submatrix of independent information related with the k th sample be given by \mathbf{X}_k , with a generic realization given by \mathbf{X} . Specifically,

$$\begin{aligned}\mathbf{X}(i, j) &= \frac{\partial \psi_j}{\partial \xi_i}(\xi), \quad i = 1, \dots, d; \\ \mathbf{X}(d + 1, j) &= \psi_j(\xi).\end{aligned}$$

For simplicity of presentation, let

$$\boldsymbol{\Phi} = \begin{pmatrix} \boldsymbol{\Psi} \\ \boldsymbol{\Psi}_\partial \end{pmatrix}; \quad \mathbf{v} = \begin{pmatrix} \mathbf{u} \\ \mathbf{u}_\partial \end{pmatrix}. \quad (24.26)$$

With these definitions, \mathbf{c} can be approximated by the solution to the ℓ_1 -minimization problem

$$\mathbf{c} = \arg \min_{\mathbf{c}} \|\mathbf{c}\|_1 \quad \text{subject to} \quad \|\mathbf{v} - \boldsymbol{\Phi} \mathbf{W}_\partial \mathbf{c}\|_2 \leq \delta. \quad (24.27)$$

Here, \mathbf{W}_∂ is a fixed matrix depending on the basis functions and their derivatives chosen to insure that

$$\mathbf{W}_\partial^T \mathbb{E}(\mathbf{N}^{-1} \boldsymbol{\Phi}^T \boldsymbol{\Phi}) \mathbf{W}_\partial = \mathbf{I}. \quad (24.28)$$

It should be noted that $\mathbb{E}(\mathbf{N}^{-1} \boldsymbol{\Phi}^T \boldsymbol{\Phi}) = \mathbb{E}(\mathbf{X}^T \mathbf{X})$ is a symmetric positive definite matrix, admitting the Cholesky decomposition of $\mathbb{E}(\mathbf{X}^T \mathbf{X}) = \mathbf{L} \mathbf{L}^T$. With this decomposition $\mathbf{W}_\partial^T = \mathbf{L}^{-1}$. As a concrete example for identifying \mathbf{W}_∂ , consider the case of a d -dimensional Hermite polynomial basis. In this case, \mathbf{W}_∂ can be derived from Lemma 3.1 of [65], restated here.

Theorem 5 ([65]). *For d -dimensional orthonormal probabilists' Hermite polynomials ψ_i and ψ_j with order i_k, j_k in dimension k ,*

$$\mathbb{E} \left(\psi_i(\xi) \psi_j(\xi) + \sum_{k=1}^d \frac{\partial \psi_i}{\partial \xi_k}(\xi) \frac{\partial \psi_j}{\partial \xi_k}(\xi) \right) = \delta_{i,j} \left(1 + \sum_{k=1}^d i_k \right), \quad (24.29)$$

where $\delta_{i,j}$ is the Kronecker delta.

This theorem implies that \mathbf{W}_∂ is diagonal and having entries determined by the degree of the polynomial in each of the various dimensions. In general, \mathbf{W}_∂ will not be diagonal, for example, when considering d -dimensional Legendre polynomials.

It is possible to define coherence in the presence of derivative information in a manner that extends (24.14). Specifically, let

$$\mu_\nabla := \sup_{k \in \mathcal{K}_p, \xi \in \Omega} \|X(:, k)\|_2^2, \quad (24.30)$$

where the supremum is taken over all columns of X and potential realizations of X . From (24.30), μ_V represents the largest ℓ_2 -norm of a column of X evaluated at the domain of the random input. Stated another way, μ_V represents the largest ℓ_2 -contribution to Φ from any specific basis function over any potential realization. This definition of coherence is related to the recovery of solutions by (24.27), both directly and via the RIC in (24.12). As for (24.14), for Hermite polynomials, (24.30) is unbounded, and it is necessary to restrict the domain of Ξ to a smaller set as in [19, 40], giving a boundedness with high probability.

The same guarantees of Theorem 2 hold in this case [65]. The coherence in (24.30) is generally less than that of (24.14) [65] and is compatible with Theorem 3, implying that there is no need to increase sample sizes when including derivative information. In terms of the conditioning of the measurement matrix Ψ , relative to a comparable Φ , including derivative information as described does not reduce the ability of the matrix to uniformly recover solutions, although contributions from evaluation of the QoI and the appropriate derivatives may effect error in the solution computation [65]. In practice, the computational saving associated with including derivative information on the ℓ_1 -minimization solution depends on both the cost of computing the derivatives for the QoI and the benefit of including derivative information.

Note that the importance sampling to minimize (24.30) involves the weight function

$$w(\xi) := \left(\sup_{k \in \mathcal{K}_p} \|X(:, k)\|_2 \right)^{-1}. \quad (24.31)$$

Here, the realized weight function would multiply the entire submatrix for the corresponding sample. The associated sampling distribution is

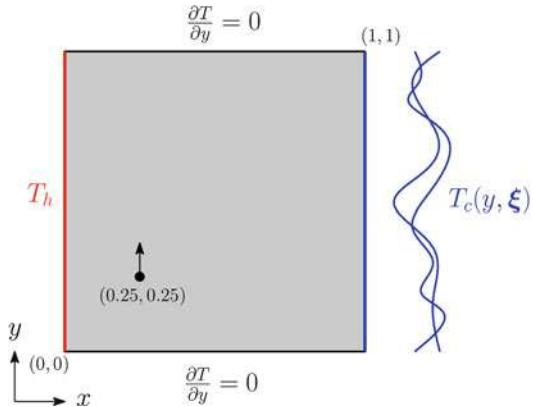

$$g(\xi) := c \left(\sup_{k \in \mathcal{K}_p} \|X(:, k)\|_2 \right)^2 f(\xi), \quad (24.32)$$

where c is a normalizing constant that need not be identified when samples from $g(\xi)$ are drawn via MCMC.

5 Thermally Driven Cavity Flow Example

Following [56, 64, 66], a 2-D heat-driven square cavity flow problem with uncertain wall temperature, as shown in Fig. 24.8, is considered. The left vertical wall has a deterministic, constant temperature \tilde{T}_h , while the right vertical wall has a stochastic temperature $\tilde{T}_c < \tilde{T}_h$ with constant mean $\bar{\tilde{T}}_c$. The superscript tilde (\sim) denotes the nondimensional quantities. Both the top and bottom walls are assumed to be adiabatic. The reference temperature and the reference temperature difference are

Fig. 24.8 Schematic for the cavity flow problem (Figure adapted from [64])

defined as $\tilde{T}_{ref} = (\tilde{T}_h + \tilde{T}_c)/2$ and $\Delta\tilde{T}_{ref} = \tilde{T}_h - \tilde{T}_c$, respectively. Under the assumption of small temperature differences, i.e., the Boussinesq approximation, the governing equations in dimensionless variables are given by

$$\begin{aligned} \frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} &= -\nabla p + \frac{\text{Pr}}{\sqrt{\text{Ra}}} \nabla^2 \mathbf{u} + \text{Pr} T \hat{\mathbf{y}}, \\ \nabla \cdot \mathbf{u} &= 0, \\ \frac{\partial T}{\partial t} + \nabla \cdot (\mathbf{u} T) &= \frac{1}{\sqrt{\text{Ra}}} \nabla^2 T, \end{aligned} \quad (24.33)$$

where $\hat{\mathbf{y}}$ is the unit vector $(0, 1)$, $\mathbf{u} = (u, v)$ is the velocity vector field, $T = (\tilde{T} - \tilde{T}_{ref})/\Delta\tilde{T}_{ref}$ is normalized temperature, p is pressure, and t is time. Nondimensional Prandtl and Rayleigh numbers are defined, respectively, as $\text{Pr} = \tilde{\mu}\tilde{c}_p/\tilde{\kappa}$ and $\text{Ra} = \tilde{\rho}g\beta\Delta\tilde{T}_{ref}\tilde{L}^3/(\tilde{\mu}\tilde{\kappa})$. Specifically, $\tilde{\mu}$ is molecular viscosity, $\tilde{\kappa}$ is thermal diffusivity, $\tilde{\rho}$ is density, g is gravitational acceleration, the coefficient of thermal expansion is given by β , and \tilde{L} is the reference length. In this example, the Prandtl and Rayleigh numbers are set to $\text{Pr} = 0.71$ and $\text{Ra} = 10^6$, respectively. For more details on the nondimensional variables in (24.33), the interested reader is referred to [56, Chapter 6.2]. On the right vertical wall, a (normalized) temperature distribution with stochastic fluctuations of the form

$$\begin{aligned} T_c(x = 1, y, \boldsymbol{\Xi}) &= \bar{T}_c + T'_c, \\ T'_c &= \sigma_T \sum_{i=1}^d \sqrt{\lambda_i} \varphi_i(y) \Xi_i \end{aligned} \quad (24.34)$$

is used, where \bar{T}_c is a constant mean temperature. In (24.34), Ξ_i , $i = 1, \dots, d$ are independent random variables uniformly distributed on $[-1, 1]$. $\{\lambda_i\}_{i=1}^d$ and $\{\varphi_i(y)\}_{i=1}^d$ are the d largest eigenvalues and the corresponding eigenfunctions of

the exponential covariance kernel $C_{T_c T_c}(y_1, y_2) = \exp\left(-\frac{|y_1 - y_2|}{l_c}\right)$, where l_c is the correlation length. In this setting, a (semi-)analytic representation of the eigenpairs $(\lambda_i, \varphi_i(y))$ in (24.34) is available; see, e.g., [36].

Here, $(T_h, \bar{T}_c) = (0.5, -0.5)$, $d = 20$, $l_c = 1/21$, and $\sigma_T = 11/100$. Our QoI is the vertical velocity component at $(x, y) = (0.25, 0.25)$ denoted by $u(\mathcal{E})$.

Figures 24.9a and 24.10a contrast the approximate PCE coefficients obtained via ℓ_1 -minimization, with $N = 200$ and $N = 1000$, respectively, against the reference solution, confirming an improved solution recovery when N is increased.

As an example of the improvement that can be achieved via weighted ℓ_1 -minimization, Figs. 24.9b and 24.10b display approximations to the solution, with and without weights as in Fig. 24.11, generated from a simplified model which does not require the solution to (24.33), [64]. Note that in Fig. 24.9, considerable improvement occurs even though the weights are not a very accurate representation of the solution decay. Figure 24.10 verifies that the weighted and unweighted

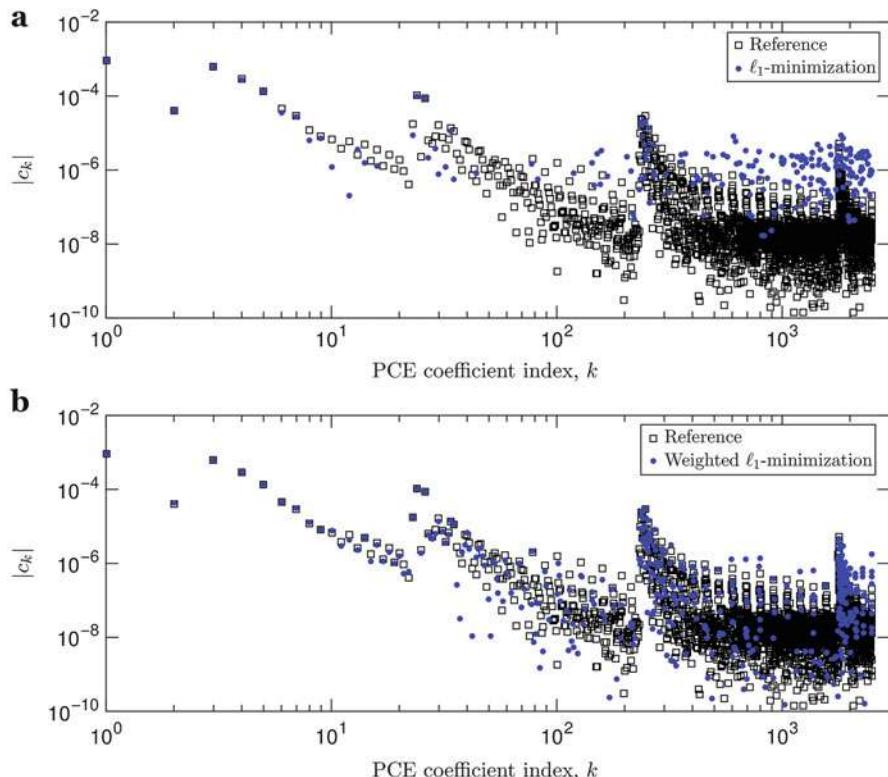

Fig. 24.9 Reference solution overlaid with a computed solution via standard ℓ_1 -minimization (a) and weighted ℓ_1 -minimization (b) using 200 realizations of the input random vector (Figure adapted from [64])

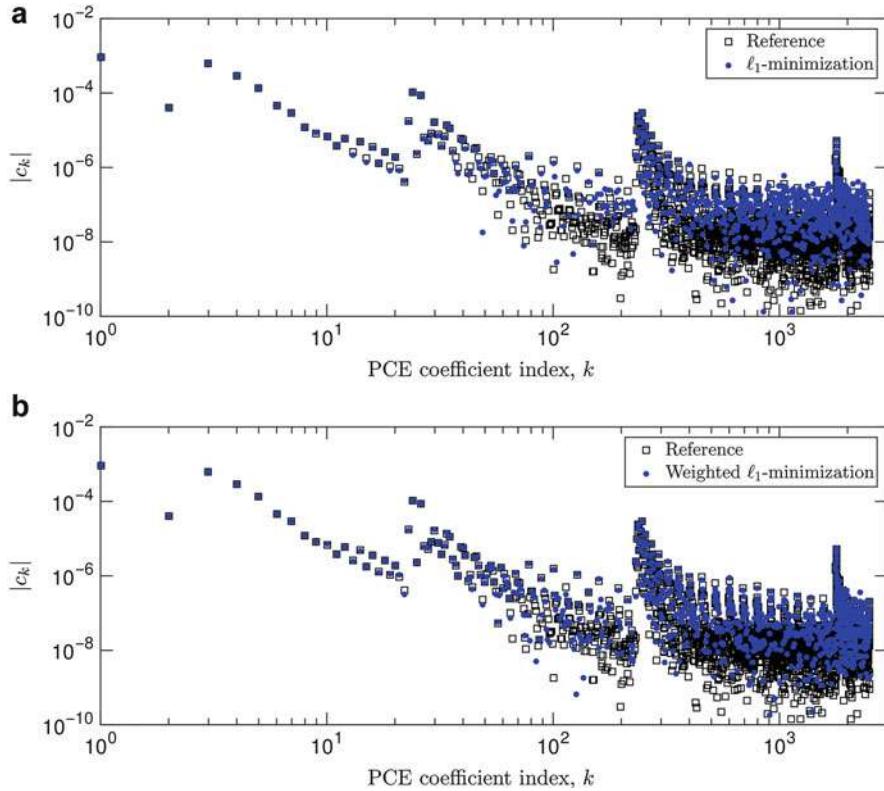

Fig. 24.10 Reference solution overlaid with a computed solution via standard ℓ_1 -minimization (a) and weighted ℓ_1 -minimization (b) using 1000 realizations of the input random vector (Figure adapted from [64])

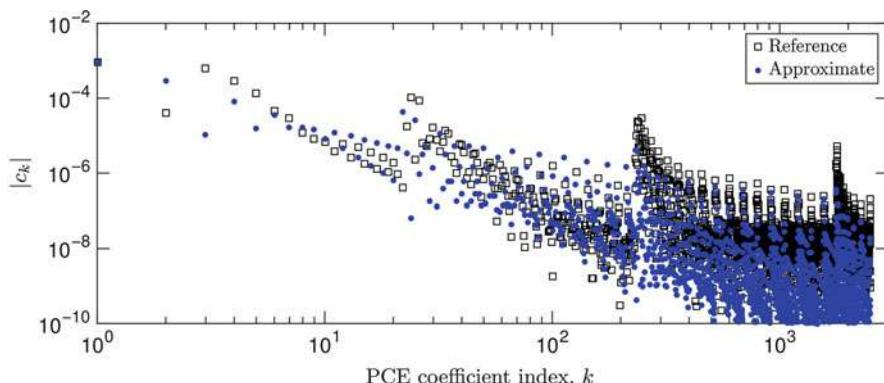

Fig. 24.11 Approximate PCE coefficient magnitudes of the QoI $v(0.25, 0.25)$ for the cavity problem of Fig. 24.8. The approximation is derived from a simplified model, [64], and is used to construct weights for solving (24.23) (Figure adapted from [64])

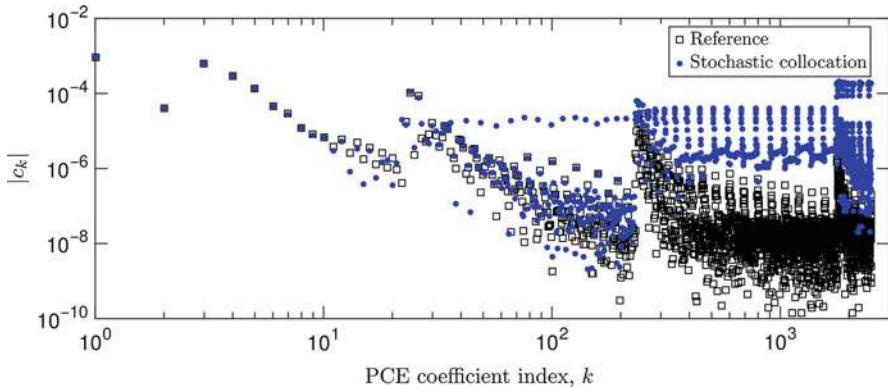

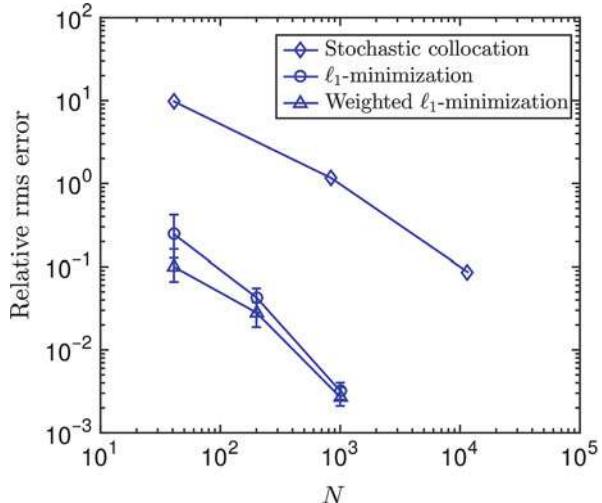

Fig. 24.12 Reference solution overlaid with a computed solution via stochastic collocation with Smolyak sparse grid based on Clenshaw-Curtis abscissas with $N = 841$ samples

Fig. 24.13 Comparison of relative error in statistics of $v(0.25, 0.25)$ computed via ℓ_1 -minimization, weighted ℓ_1 -minimization, and stochastic collocation. The error bars are generated using 100 independent replications with fixed samples size N (Figure adapted from [64])

solutions closely coincide when a sufficient number of samples is available, as also seen in Fig. 24.13. To compare the performance of standard and weighted ℓ_1 -minimization with that of the stochastic collocation, the relative root-mean-square error of the PCE solution as a function of the sample size N is displayed in Fig. 24.12. The stochastic collocation approximates c_k in (24.3) via numerical integration using Smolyak sparse grids [76] generated from Clenshaw-Curtis abscissas with multiple sizes. Two remarks are important to highlight. Firstly, unlike in the stochastic collocation, both standard and weighted ℓ_1 -minimization solutions are computed using random samples. To illustrate the associated variability, solutions with 100 independent replications of the same sample size N are used to establish the uncertainty bars in Fig. 24.13. As can be observed, the solution variability

reduces when larger number of samples are used. Secondly, improving the accuracy of the stochastic collocation (by using a larger sample size N) requires the simulation of an additional number of samples that is dictated by the Smolyak grid construction, as opposed to the available computational budget. This limitation, however, does not apply to the compressive sampling methods described above, as they rely on random samples.

6 Conclusion

The use of polynomial basis functions can impart a sparsity in solutions for many problems, allowing a tractable computation of solutions to a large number of problems. This chapter has looked at how a QoI is built from a computation of realized random variables, how orthogonal basis polynomials are identified in those random variables, and how coefficients for those basis functions are then computed. A variety of theoretical measures were investigated which are useful in gauging how well a solution may be recovered with a given number of samples. Adjustments to the standard approach were considered that may lead to an improvement of recovery.

Abstract

Parameter-dependent models arise in many contexts such as uncertainty quantification, sensitivity analysis, inverse problems, or optimization. Parametric or uncertainty analyses usually require the evaluation of an output of a model for many instances of the input parameters, which may be intractable for complex numerical models. A possible remedy consists in replacing the model by an approximate model with reduced complexity (a so-called reduced order model) allowing a fast evaluation of output variables of interest. This chapter provides an overview of low-rank methods for the approximation of functions that are identified either with order-two tensors (for vector-valued functions) or higher-order tensors (for multivariate functions). Different approaches are presented for the computation of low-rank approximations, either based on samples of the function or on the equations that are satisfied by the function, the latter approaches including projection-based model order reduction methods. For multivariate functions, different notions of ranks and the corresponding low-rank approximation formats are introduced.

1 Introduction

Parameter-dependent models arise in many contexts such as uncertainty quantification, sensitivity analysis, inverse problems, and optimization. These models are typically given under the form of a parameter-dependent equation:

$$R(u(\xi); \xi) = 0, \quad (25.1)$$

where ξ are parameters taking values in some set Ξ and where the solution $u(\xi)$ is in some vector space V , say \mathbb{R}^M . Parametric or uncertainty analyses usually require the evaluation of the solution for many instances of the parameters, which may be intractable for complex numerical models (with large M) for which one single solution requires hours or days of computation time. Therefore, one usually relies on approximations of the solution map $u : \Xi \rightarrow V$ allowing for a rapid evaluation of output quantities of interest. These approximations take on different names such as meta-model, surrogate model, or reduced order model. They are usually of the form

$$u_m(\xi) = \sum_{i=1}^m v_i s_i(\xi), \quad (25.2)$$

where the v_i are elements in V and the s_i are elements of some space S of functions defined on Ξ . Standard linear approximation methods rely on the introduction of generic bases (e.g., polynomials, wavelets, etc.) allowing an accurate approximation of a large class of models to be constructed but at the price of requiring expansions with a high number of terms m . These generic approaches usually result in a very high computational complexity.

Model order reduction methods aim at finding an approximation u_m with a small number of terms ($m \ll M$) that are adapted to the particular function u . One can distinguish approaches relying (i) on the construction of a reduced basis $\{v_1, \dots, v_m\}$ in V , (ii) on the construction of a reduced basis $\{s_1, \dots, s_m\}$ in S , or (iii) directly on the construction of an approximation under the form (25.2). These approaches are closely related. They all result in a *low-rank approximation* u_m , which can be interpreted as a rank- m element of the tensor space $V \otimes S$. Approaches of type (i) are usually named *projection-based model order reduction methods* since they define $u_m(\xi)$ as a certain projection of $u(\xi)$ onto a low-dimensional subspace of V . They include *reduced basis*, *proper orthogonal decomposition*, *Krylov subspace*, *balanced truncation methods*, and also subspace-based variants of *proper generalized decomposition* methods. Corresponding reduced order models usually take the form of a small system of equations which defines the projection $u_m(\xi)$ for each instance of ξ . Approaches (i) and (ii) are in some sense dual to each other. Approaches (ii) include *sparse approximation methods* which consist in selecting $\{s_1, \dots, s_m\}$ in a certain dictionary of functions (e.g., a polynomial basis), based on prior information on u or based on a posteriori error estimates (adaptive selection). They also include methods for the construction of reduced bases in S that exploit some prior information on u . *Low-rank tensor methods* enter the family of approaches (iii), where approximations of the form (25.2) directly result from an optimization on low-rank manifolds.

When one is interested not only in evaluating the solution $u(\xi)$ at a finite number of samples of ξ but in obtaining an explicit representation of the solution map $u : \Xi \rightarrow V$, approximations of functions of multiple parameters $\xi = (\xi_1, \dots, \xi_d)$ are required. This constitutes a challenging issue for high-dimensional problems. Naive approximation methods which consist in using tensorized bases yield an exponential increase in storage or computational complexity when the dimension d increases, which is the so-called curse of dimensionality. Specific structures of the functions have to be exploited in order to reduce the complexity. Standard structured approximations include additive approximations $u_1(\xi_1) + \dots + u_d(\xi_d)$, separated approximations $u_1(\xi_1) \dots u_d(\xi_d)$, sparse approximations, or rank-structured approximations. Rank-structured approximation methods include several types of approximation depending on the notion of rank.

The present chapter provides an overview of model order reduction methods based on low-rank tensor approximation methods. In a first section, we recall some basic notions about low-rank approximations of an order-two tensor $u \in V \otimes S$. In the second section, which is devoted to projection-based model reduction methods, we present different definitions of projections onto subspaces and different possible constructions of these subspaces. In the third section, we introduce the basic concepts of low-rank tensor methods for the approximation of a multivariate function, which is identified with a high-order tensor. The last two sections present different methods for the computation of low-rank approximations, either based on samples of the function (fourth section) or on the equations satisfied by the function (fifth section).

2 Low-Rank Approximation of Order-Two Tensors

Let us assume that $u : \mathcal{E} \rightarrow V$ with V a Hilbert space equipped with a norm $\|\cdot\|_V$ and inner product $(\cdot, \cdot)_V$. For the sake of simplicity, let us consider that $V = \mathbb{R}^M$. Let us further assume that u is in the Bochner space $L_\mu^p(\mathcal{E}; V)$ for some $p \geq 1$, where μ is a probability measure supported on \mathcal{E} . The space $L_\mu^p(\mathcal{E}; V)$ can be identified with the algebraic tensor space $V \otimes L_\mu^p(\mathcal{E})$ (or the completion of this space when V is infinite dimensional; see, e.g., [17]) which is the space of functions w that can be written under the form $w(\xi) = \sum_{i=1}^m v_i s_i(\xi)$ for some $v_i \in V$ and $s_i \in L_\mu^p(\mathcal{E})$ and some $m \in \mathbb{N}$. The rank of an element w , denoted $\text{rank}(w)$, is the minimal integer m such that w admits such an m -term representation. A rank- m approximation of u then takes the form

$$u_m(\xi) = \sum_{i=1}^m v_i s_i(\xi), \quad (25.3)$$

and can be interpreted as a certain projection of $u(\xi)$ onto an m -dimensional subspace V_m in V , where $\{v_1, \dots, v_m\}$ constitutes a basis of V_m .

2.1 Best Rank- m Approximation and Optimal Subspaces

The set of elements in $V \otimes L_\mu^p(\mathcal{E})$ with a rank bounded by m is denoted $\mathcal{R}_m = \{w \in V \otimes L_\mu^p(\mathcal{E}) : \text{rank}(w) \leq m\}$. The definition of a best approximation of u from \mathcal{R}_m requires the introduction of a measure of error. The best rank- m approximation with respect to the Bochner norm $\|\cdot\|_p$ in $L_\mu^p(\mathcal{E}; V)$ is the solution of

$$\min_{v \in \mathcal{R}_m} \|u - v\|_p = \min_{v \in \mathcal{R}_m} \|\|u(\xi) - v(\xi)\|_V\|_{L_\mu^p(\mathcal{E})} := d_m^{(p)}(\mathcal{E}). \quad (25.4)$$

The set \mathcal{R}_m admits the subspace-based parametrization $\mathcal{R}_m = \{w \in V_m \otimes L_\mu^p(\mathcal{E}) : V_m \subset V, \dim(V_m) = m\}$. Then the best rank- m approximation problem can be reformulated as an optimization problem over the set of m -dimensional spaces:

$$d_m^{(p)}(u) = \min_{\dim(V_m)=m} \min_{v \in V_m \otimes L_\mu^p} \|u - v\|_p = \min_{\dim(V_m)=m} \|u - P_{V_m} u\|_p, \quad (25.5)$$

where P_{V_m} is the orthogonal projection from V to V_m which provides the best approximation $P_{V_m} u(\xi)$ of $u(\xi)$ from V_m , defined by

$$\|u(\xi) - P_{V_m} u(\xi)\|_V = \min_{v \in V_m} \|u(\xi) - v\|_V. \quad (25.6)$$

That means that the best rank- m approximation problem is equivalent to the problem of finding an optimal subspace of dimension m for the projection of the solution.

2.2 Characterization of Optimal Subspaces

The numbers $d_m^{(p)}(u)$, which are the best rank- m approximation errors with respect to norms $\|\cdot\|_p$, are so-called linear widths of the *solution manifold*

$$\mathcal{K} := u(\Xi) = \{u(\xi) : \xi \in \Xi\},$$

and measure how well the set of solutions \mathcal{K} can be approximated by m -dimensional subspaces. They provide a quantification of the ideal performance of model order reduction methods.

For $p = \infty$, assuming that \mathcal{K} is compact, the number

$$d_m^{(\infty)}(u) = \min_{\dim(V_m)=m} \sup_{\xi \in \Xi} \|u(\xi) - P_{V_m} u(\xi)\|_V = \min_{\dim(V_m)=m} \sup_{v \in \mathcal{K}} \|v - P_{V_m} v\|_V \quad (25.7)$$

corresponds to the *Kolmogorov m -width* $d_m(\mathcal{K})_V$ of \mathcal{K} . This measure of error is particularly pertinent if one is interested in computing approximations that are uniformly accurate over the whole parameter set Ξ . For $p < \infty$, the numbers

$$d_m^{(p)}(u) = \min_{\dim(V_m)=m} \left(\int_{\Xi} \|u(\xi) - P_{V_m} u(\xi)\|_V^p \mu(d\xi) \right)^{1/p} \quad (25.8)$$

provide measures of the error that take into account the measure μ on the parameter set. This is particularly relevant for uncertainty quantification, where these numbers $d_m^{(p)}(u)$ directly control the error on the moments of the solution map u (such as mean, variance, or higher-order moments).

Some general results on the convergence of linear widths are available in approximation theory (see, e.g., [51]). More interesting results which are specific to some classes of parameter-dependent equations have been recently obtained [16, 38]. These results usually exploit smoothness and anisotropy of the solution map $u : \Xi \rightarrow V$ and are typically upper bounds deduced from results on polynomial approximation. Even if a priori estimates for $d_m^{(p)}(u)$ are usually not available, a challenging problem is to propose numerical methods that provide approximations u_m of the form (25.3) with an error $\|u - u_m\|_p$ of the order of the best achievable accuracy $d_m^{(p)}(u)$.

2.3 Singular Value Decomposition

Of particular importance is the case $p = 2$ where u is in the Hilbert space $L_\mu^2(\Xi; V) = V \otimes L_\mu^2(\Xi)$ and can be identified with a compact operator $U : v \in V \mapsto (u(\cdot), v)_V \in L_\mu^2(\Xi)$ which admits a *singular value decomposition*

$$U = \sum_{i \geq 1} \sigma_i v_i \otimes s_i,$$

where the σ_i are the singular values and where v_i and s_i are the corresponding normalized right and left singular vectors, respectively. Denoting by U^* the adjoint operator of U , defined by $U^* : s \in L^2_\mu(\Xi) \mapsto \int_\Xi u(\xi)s(\xi)d\mu(\xi) \in V$, the operator

$$U^*U := C(u) : v \in V \mapsto \int_\Xi u(\xi)(u(\xi), v)_V d\mu(\xi) \in V \quad (25.9)$$

is the correlation operator of u , with eigenvectors v_i and corresponding eigenvalues σ_i^2 . Assuming that singular values are sorted in decreasing order, $V_m = \text{span}\{v_1, \dots, v_m\}$ is a solution of (25.4) (which means an optimal subspace) and a best approximation of the form (25.2) is given by a rank- m truncated singular value decomposition $u_m(\xi) = \sum_{i=1}^m \sigma_i v_i s_i(\xi)$ which satisfies $\|u - u_m\|_2 = d_m^{(2)}(u) = (\sum_{i>m} \sigma_i^2)^{1/2}$.

3 Projection-Based Model Order Reduction Methods

Here we adopt a subspace point of view for the low-rank approximation of the solution map $u : \Xi \rightarrow V$. We first describe how to define projections onto a given subspace. Then we present methods for the practical construction of subspaces.

3.1 Projections on a Given Subspace

Here, we consider that a finite-dimensional subspace V_m is given to us. The best approximation of $u(\xi)$ from V_m is given by the projection $P_{V_m}u(\xi)$ defined by (25.6). However, in practice, projections of the solution $u(\xi)$ onto a given subspace V_m must be defined using computable information.

3.1.1 Interpolation

When the subspace V_m is the linear span of evaluations (samples) of the solution u at m given points $\{\xi^1, \dots, \xi^m\}$ in Ξ , i.e.,

$$V_m = \text{span}\{u(\xi^1), \dots, u(\xi^m)\}, \quad (25.10)$$

projections $u_m(\xi)$ of $u(\xi)$ onto V_m can be obtained by interpolation. An interpolation of u can be written in the form

$$u_m(\xi) = \sum_{i=1}^m u(\xi^i) s_i(\xi),$$

where functions s_i satisfy the interpolation conditions $s_i(\xi^j) = \delta_{ij}$, $1 \leq i, j \leq m$. The best approximation $P_{V_m} u(\xi)$ is a particular case of interpolation. However, its computation is not of practical interest since it requires the knowledge of $u(\xi)$. Standard polynomial interpolations can be used when Ξ is an interval in \mathbb{R} . In higher dimensions, polynomial interpolation can still be constructed for structured interpolation grids. For arbitrary sets of points, other interpolation formulae can be used, such as Kriging, nearest neighbor, Shepard, or radial basis interpolations. These standard interpolation formulae provide approximations $u_m(\xi)$ that only depend on the value of u at points $\{\xi^1, \dots, \xi^m\}$.

Generalized interpolation formulae that take into account the function over the whole parameter set can be defined by

$$u_m(\xi) = \sum_{i=1}^m u(\xi^i) \varphi_i(u(\xi)), \quad (25.11)$$

with $\{\varphi_i\}$ a dual system to $\{u(\xi^i)\}$ such that $\varphi_i(u(\xi^j)) = \delta_{ij}$ for $1 \leq i, j \leq m$. This yields an interpolation $u_m(\xi)$ depending not only on the value of u at the points $\{\xi^1, \dots, \xi^m\}$ but also on $u(\xi)$. This is of practical interest if $\varphi_i(u(\xi))$ can be efficiently computed without a complete knowledge of $u(\xi)$. For example, if the coefficients of $u(\xi)$ on some basis of V can be estimated without computing $u(\xi)$, then a possible choice consists in taking for $\{\varphi_1, \dots, \varphi_m\}$ a set of functions that associate to an element of V a set of m of its coefficients. This is the idea behind the *empirical interpolation method* [41] and its generalization [40].

3.1.2 Galerkin Projections

For models described by an equation of type (25.1), the most prominent methods are *Galerkin projections* which define the approximation $u_m(\xi)$ from the residual $R(u_m(\xi); \xi)$, e.g., by imposing orthogonality of the residual with respect to an m -dimensional space or by minimizing some residual norm. Galerkin projections do not provide the best approximation, but under some usual assumptions, they can provide quasi-best approximations $u_m(\xi)$ satisfying

$$\|u(\xi) - u_m(\xi)\|_V \leq c(\xi) \min_{v \in V_m} \|u(\xi) - v\|_V, \quad (25.12)$$

where $c(\xi) \geq 1$. As an example, let us consider the case of a linear problem where

$$R(v; \xi) = A(\xi)v - b(\xi), \quad (25.13)$$

with $A(\xi)$ a linear operator from V into some Hilbert space W , and let us consider a Galerkin projection defined by minimizing some residual norm, that means

$$\|A(\xi)u_m(\xi) - b(\xi)\|_W = \min_{v \in V_m} \|A(\xi)v - b(\xi)\|_W. \quad (25.14)$$

Assuming

$$\alpha(\xi)\|v\|_V \leq \|A(\xi)v\|_W \leq \beta(\xi)\|v\|_V, \quad (25.15)$$

the resulting projection $u_m(\xi)$ satisfies (25.12) with a constant $c(\xi) = \frac{\beta(\xi)}{\alpha(\xi)}$ which can be interpreted as the condition number of the operator $A(\xi)$. This reveals the interest of introducing efficient preconditioners in order to better exploit the approximation power of the subspace V_m (see, e.g., [13, 58] for the construction of parameter-dependent preconditioners). The resulting approximation can be written

$$u_m(\xi) = P_{V_m}^G(\xi)u(\xi),$$

where $P_{V_m}^G(\xi)$ is a parameter-dependent projection from V onto V_m . Note that if V_m is generated by samples of the solution, as in (25.10), then the Galerkin projection is also an interpolation which can be written under the form (25.11) with parameter-dependent functions φ_i that depend on the operator.

Some technical assumptions on the residual are required for a practical computation of Galerkin projections. More precisely, for $u_m(\xi) = \sum_{i=1}^m v_i s_i(\xi)$, the residual should admit a low-rank representation

$$R(u_m; \xi) = \sum_j R_j \gamma_j(s(\xi); \xi),$$

where the R_j are independent of $s(\xi) = (s_1(\xi), \dots, s_m(\xi))$ and where the γ_j can be computed with a complexity depending on m (the dimension of the reduced order model) but not on the dimension of V . This allows Galerkin projections to be computed by solving a reduced system of m equations on the unknown coefficients $s(\xi)$, with a computational complexity independent of the dimension of the full order model. For linear problems, such a property is obtained when the operator $A(\xi)$ and the right-hand side $b(\xi)$ admit low-rank representations (so-called affine representations)

$$A(\xi) = \sum_{i=1}^L A_i \alpha_i(\xi), \quad b(\xi) = \sum_{i=1}^R b_i \beta_i(\xi). \quad (25.16)$$

If $A(\xi)$ and $b(\xi)$ are not explicitly given under the form (25.16), then a preliminary approximation step is needed. Such expressions can be obtained by the empirical interpolation method [5, 11] or other low-rank truncation methods. Note that preconditioners for parameter-dependent operators should also have such representations in order to preserve a reduced order model with a complexity independent of the dimension of the full order model.

3.2 Construction of Subspaces

The computation of an optimal m -dimensional subspace V_m with respect to the natural norm in $L_\mu^p(\mathcal{E}; V)$, defined by (25.5), is not feasible in practice since it requires the knowledge of u . Practical constructions of subspaces must rely on computable information on u , which can be samples of the solution or the model equations (when available).

3.2.1 From Samples of the Function

Here, we present constructions of subspaces V_m which are based on evaluations of the function u at a set of points $\mathcal{E}_K = \{\xi^1, \dots, \xi^K\}$ in \mathcal{E} . Of course, V_m can be chosen as the span of evaluations of u at m points chosen independently of u , e.g., through random sampling. Here, we present methods for obtaining subspaces V_m that are closer to the optimal m -dimensional spaces, with $K \geq m$.

L^2 Optimality

When one is interested in optimal subspaces with respect to the norm $\|\cdot\|_2$, the definition (25.5) of optimal subspaces can be replaced by

$$\min_{\dim(V_m)=m} \frac{1}{K} \sum_{k=1}^K \|u(\xi^k) - P_{V_m} u(\xi^k)\|_V^2 = \min_{v \in \mathcal{R}_m} \frac{1}{K} \sum_{k=1}^K \|u(\xi^k) - v(\xi^k)\|_V^2, \quad (25.17)$$

where ξ^1, \dots, ξ^K are K independent random samples drawn according the probability measure μ . The resulting subspace V_m is the dominant eigenspace of the empirical correlation operator

$$C_K(u) = \frac{1}{K} \sum_{k=1}^K u(\xi^k)(u(\xi^k), \cdot)_V, \quad (25.18)$$

which is a statistical estimate of the correlation operator $C(u)$ defined by (25.9). This approach, which requires the computation of K evaluations of the solution u , corresponds to the classical *principal component analysis*. It is at the basis of proper orthogonal decomposition methods for parameter-dependent equations [33]. A straightforward generalization consists in defining the subspace V_m by

$$\min_{\dim(V_m)=m} \sum_{k=1}^K \omega_k \|u(\xi^k) - P_{V_m} u(\xi^k)\|_V^2 = \min_{v \in \mathcal{R}_m} \sum_{k=1}^K \omega_k \|u(\xi^k) - v(\xi^k)\|_V^2, \quad (25.19)$$

using a suitable quadrature rule for the integration over \mathcal{E} , e.g., exploiting the smoothness of the solution map $u : \mathcal{E} \rightarrow V$ in order to improvethe convergence

with K and therefore decrease the number of evaluations of u for a given accuracy. The resulting subspace V_m is obtained as the dominant eigenspace of the operator

$$C_K(u) = \sum_{k=1}^K \omega^k u(\xi^k)(u(\xi^k), \cdot)_V. \quad (25.20)$$

L^∞ Optimality

If one is interested in optimality with respect to the norm $\|\cdot\|_\infty$, the definition (25.5) of optimal spaces can be replaced by

$$\min_{\dim(V_m)=m} \sup_{\xi \in \Xi_K} \|u(\xi) - P_{V_m} u(\xi)\|_V = \min_{v \in \mathcal{R}_m} \sup_{\xi \in \Xi_K} \|u(\xi) - v(\xi)\|_V, \quad (25.21)$$

with $\Xi_K = \{\xi^1, \dots, \xi^K\}$ a set of K points in Ξ . A computationally tractable definition of subspaces can be obtained by adding the constraint that subspaces V_m are generated from m samples of the solution, that means $V_m = \text{span}\{u(\xi_*^1), \dots, u(\xi_*^m)\}$. Therefore, problem (25.21) becomes

$$\min_{\xi_*^1, \dots, \xi_*^m \in \Xi_K} \max_{\xi \in \Xi_K} \|u(\xi) - P_{V_m} u(\xi)\|_V,$$

where the m points are selected in the finite set of points Ξ_K . In practice, this combinatorial problem can be replaced by a *greedy algorithm*, which consists in selecting the points adaptively: given the first m points and the corresponding subspace V_m , a new interpolation point ξ_*^{m+1} is defined such that

$$\|u(\xi_*^{m+1}) - P_{V_m} u(\xi_*^{m+1})\|_V = \max_{\xi \in \Xi_K} \|u(\xi) - P_{V_m} u(\xi)\|_V. \quad (25.22)$$

This algorithm corresponds to the empirical interpolation method [5, 6, 41].

3.2.2 From Approximations of the Correlation Operator

An optimal m -dimensional space V_m for the approximation of u in $L_\mu^2(\Xi; V)$ is given by a dominant eigenspace of the correlation operator $C(u)$ of u . Approximations of optimal subspaces can then be obtained by computing dominant eigenspaces of an approximate correlation operator. These approximations can be obtained by using numerical integration in the definition of the correlation operator, yielding approximations (25.18) or (25.20) which require evaluations of u . Another approach consists in using the correlation operator $C(u_K)$ (or the singular value decomposition) of an approximation u_K of u which can be obtained by a projection of u onto a low-dimensional subspace $V \otimes S_K$ in $V \otimes L_\mu^2(\Xi)$. For example, an approximation can be sought after in the form $u_K(\xi) = \sum_{k=1}^K v_k \psi_k(\xi)$ where $\{\psi_k(\xi)\}_{k=1}^K$ is a

polynomial basis. Let us note that the statistical estimate $C_K(u)$ in (25.18) can be interpreted as the correlation operator $C(u_K)$ of a piecewise constant interpolation $u_K(\xi) = \sum_{k=1}^K u(\xi^k) 1_{\xi \in O_k}$ of $u(\xi)$, where the sets $\{O_1, \dots, O_K\}$ form a partition of Ξ such that $\xi^k \in O_k$ and $\mu(O_k) = 1/K$ for all k .

Remark 1. Let us mention that the optimal rank- m singular value decomposition of u can be equivalently obtained by computing the dominant eigenspace of the operator $\hat{C}(u) = UU^* : L_\mu^2(\Xi) \rightarrow L_\mu^2(\Xi)$. Then, a dual approach for model order reduction consists in defining a subspace S_m in $L_\mu^2(\Xi)$ as the dominant eigenspace of $\hat{C}(u_K)$, where u_K is an approximation of u . An approximation of u can then be obtained by a Galerkin projection onto the subspace $V \otimes S_m$ (see, e.g., [20] where an approximation u_K of the solution of a parameter-dependent partial differential equation is first computed using a coarse finite element approximation).

3.2.3 From the Model Equations

In the definition (25.5) of optimal spaces, $\|u(\xi) - v(\xi)\|$ can be replaced by a function $\Delta(v(\xi); \xi)$ which is computable without having $u(\xi)$ and such that $v \mapsto \Delta(v; \xi)$ has $u(\xi)$ as a minimizer over V . The choice for Δ is natural for problems where $u(\xi)$ is the minimizer of a functional $\Delta(\cdot; \xi) : V \rightarrow \mathbb{R}$. When $u(\xi)$ is solution of an equation of the form (25.1), a typical choice consists in taking for $\Delta(v(\xi); \xi)$ a certain norm of the residual $R(v(\xi); \xi)$.

L^2 Optimality (Proper Generalized Decomposition Methods)

When one is interested in optimality in the norm $\|\cdot\|_2$, an m -dimensional subspace V_m can be defined as the solution of the following optimization problem over the Grassmann manifold of subspaces of dimension m :

$$\min_{\dim(V_m)=m} \min_{v \in V_m \otimes L_\mu^2(\Xi)} \int_{\Xi} \Delta(v(\xi); \xi)^2 d\mu(\xi), \quad (25.23)$$

which can be equivalently written as an optimization problem over the set of m -dimensional bases in V :

$$\min_{v_1, \dots, v_m \in V} \min_{s_1, \dots, s_m \in L_\mu^2(\Xi)} \int_{\Xi} \Delta\left(\sum_{i=1}^m v_i s_i(\xi); \xi\right)^2 d\mu(\xi). \quad (25.24)$$

This problem is an optimization problem over the set \mathcal{R}_m of rank- m tensors which can be solved using optimization algorithms on low-rank manifolds such as an alternating minimization algorithm which consists in successively minimizing over the v_i and over the s_i . Assuming that $\Delta(\cdot; \xi)$ defines a distance to the solution $u(\xi)$ which is uniformly equivalent to the one induced by the norm $\|\cdot\|_V$, i.e.,

$$\alpha_\Delta \|u(\xi) - v\|_V \leq \Delta(v; \xi) \leq \beta_\Delta \|u(\xi) - v\|_V, \quad (25.25)$$

the resulting subspace V_m is quasi-optimal in the sense that

$$\|u - P_{V_m} u\|_2 \leq c_\Delta \min_{\dim(V_m)=m} \|u - P_{V_m} u\|_2 = c_\Delta d_m^{(2)}(u),$$

with $c_\Delta = \frac{\beta_\Delta}{\alpha_\Delta}$. For linear problems where $R(v; \xi) = A(\xi)v - b(\xi) \in W$ and $\Delta(v(\xi); \xi) = \|R(v(\xi); \xi)\|_W$, (25.25) results from the property (25.15) of the operator $A(\xi)$. A suboptimal but constructive variant of algorithm (25.24) is defined by

$$\min_{v_m \in V} \min_{s_1, \dots, s_m \in L^2_\mu(\Xi)} \int_{\Xi} \Delta\left(\sum_{i=1}^m v_i s_i(\xi; \xi)^2 d\mu(\xi)\right), \quad (25.26)$$

which is a greedy construction of the reduced basis $\{v_1, \dots, v_m\}$. It yields a nested sequence of subspaces V_m . This is one of the variants of proper generalized decomposition methods (see [44–46]).

Note that in practice, for solving (25.24) or (25.26) when Ξ is not a finite set, one has either to approximate functions s_i in a finite-dimensional subspace of $L^2_\mu(\Xi)$ [44, 45] or to approximate the integral over Ξ by using a suitable quadrature [26].

L^∞ Optimality (Reduced Basis Methods)

When one is interested in optimality in the norm $\|\cdot\|_\infty$, a subspace V_m could be defined by

$$\min_{\dim(V_m)=m} \max_{\xi \in \Xi} \Delta(u_m(\xi); \xi),$$

where $u_m(\xi)$ is some projection of $u(\xi)$ onto V_m (typically a Galerkin projection). A modification of the above definition consists in searching for spaces V_m that are generated from evaluations of the solution at m points selected in a subset Ξ_K of K points in Ξ (a training set). In practice, this combinatorial optimization problem can be replaced by a greedy algorithm for the selection of points: given a set of interpolation points $\{\xi_*^1, \dots, \xi_*^m\}$ and an approximation $u_m(\xi)$ in $V_m = \text{span}\{u(\xi_*^1), \dots, u(\xi_*^m)\}$, a new point ξ_*^{m+1} is selected such that

$$\Delta(u_m(\xi_*^{m+1}); \xi_*^{m+1}) = \max_{\xi \in \Xi_K} \Delta(u_m(\xi); \xi). \quad (25.27)$$

This results in an adaptive interpolation algorithm which was first introduced in [52]. It is the basic idea behind the so-called reduced basis methods (see, e.g., [50, 53]).

Assuming that Δ satisfies (25.25) and that the projection $u_m(\xi)$ verifies the quasi-optimality condition (25.12), the selection of interpolation points defined by (25.27) is quasi-optimal in the sense that

$$\|u(\xi_*^{m+1}) - P_{V_m} u(\xi_*^{m+1})\|_V \geq \gamma \max_{\xi \in \Xi_K} \|u(\xi) - P_{V_m} u(\xi)\|_V,$$

with $\gamma = c_{\Delta}^{-1} \inf_{\xi \in \Xi} c(\xi)^{-1}$. That makes (25.27) a suboptimal version of the greedy algorithm (25.22) (so-called weak greedy algorithm). Convergence results for this algorithm can be found in [8, 9, 18], where the authors provide explicit comparisons between the resulting error $\|u(\xi) - u_m(\xi)\|_V$ and the Kolmogorov m -width of $u(\Xi_K)$ which is the best achievable error by projections onto m -dimensional spaces.

The above definitions of interpolation points, and therefore of the resulting subspaces V_m , do not take into account explicitly the probability measure μ . However, this measure is taken into account implicitly when working with a sample set Ξ_K drawn according the probability measure μ . A construction that takes into account the measure explicitly has been proposed in [12], where $\Delta(v; \xi)$ is replaced by $\omega(\xi)\Delta(v; \xi)$, with $\omega(\xi)$ a weight function depending on the probability measure μ .

4 Low-Rank Approximation of Multivariate Functions

For the approximation of high-dimensional functions $u(\xi_1, \dots, \xi_d)$, a standard approximation tool consists in searching for an expansion on a multidimensional basis obtained by tensorizing univariate bases:

$$u(\xi_1, \dots, \xi_d) \approx \sum_{v_1=1}^{n_1} \dots \sum_{v_d=1}^{n_d} a_{v_1, \dots, v_d} \phi_{v_1}^1(\xi_1) \dots \phi_{v_d}^d(\xi_d). \quad (25.28)$$

This results in an exponential growth of storage and computational complexities with the dimension d . Low-rank tensor methods aim at reducing the complexity by exploiting high-order low-rank structures of multivariate functions, considered as elements of tensor product spaces. This section presents basic notions about low-rank approximations of high-order tensors. The reader is referred to the textbook [29] and the surveys [28, 34, 36] for further details on the subject. For simplicity, we consider the case of a real-valued function $u : \Xi \rightarrow \mathbb{R}$. The presentation naturally extends to the case $u : \Xi \rightarrow V$ by the addition of a new dimension.

Here, we assume that $\Xi = \Xi_1 \times \dots \times \Xi_d$ and that μ is a product measure $\mu_1 \otimes \dots \otimes \mu_d$. Let S_v denote a space of univariate functions defined on Ξ_v , $1 \leq v \leq d$. The elementary tensor product of functions $v^v \in S_v$ is defined by $(v^1 \otimes \dots \otimes v^d)(\xi_1, \dots, \xi_d) = v^1(\xi_1) \dots v^d(\xi_d)$. The algebraic tensor space $S = S_1 \otimes \dots \otimes S_d$ is defined as the set of elements that can be written as a finite sum of elementary tensors, which means

$$v(\xi_1, \dots, \xi_d) = \sum_{i=1}^r a_i v_i^1(\xi_1) \dots v_i^d(\xi_d), \quad (25.29)$$

for some $v_i^v \in S_v$, $a_i \in \mathbb{R}$, and $r \in \mathbb{N}$. For the sake of simplicity, we consider that S_v is a finite-dimensional approximation space in $L_{\mu_v}^2(\Xi_v)$ (e.g., a space of polynomials, wavelets, splines, etc.), with $\dim(S_v) = n_v \leq n$, so that S is a

subspace of the algebraic tensor space $L^2_{\mu_1}(\mathcal{E}_1) \otimes \dots \otimes L^2_{\mu_d}(\mathcal{E}_d)$ (whose completion is $L^2_\mu(\mathcal{E})$).

4.1 Tensor Ranks and Corresponding Low-Rank Formats

The *canonical rank* of a tensor v in S is the minimal integer m such that v can be written under the form (25.29). An approximation of the form (25.29) is called an approximation in *canonical tensor format*. It has a storage complexity in $O(rnd)$. For order-two tensors, this is the standard and unique notion of rank. For higher-order tensors, other notions of rank can be introduced, therefore yielding different types of rank-structured approximations. First, for a certain subset of dimensions $\alpha \subset D := \{1, \dots, d\}$ and its complementary subset $\alpha^c = D \setminus \alpha$, S can be identified with the space $S_\alpha \otimes S_{\alpha^c}$ of order-two tensors, where $S_\alpha = \bigotimes_{v \in \alpha} S_v$. The α -rank of a tensor v , denoted $\text{rank}_\alpha(v)$, is then defined as the minimal integer r_α such that

$$v(\xi_1, \dots, \xi_d) = \sum_{i=1}^{r_\alpha} v_i^\alpha(\xi_\alpha) v_i^{\alpha^c}(\xi_{\alpha^c}),$$

where $v_i^\alpha \in S_\alpha$ and $v_i^{\alpha^c} \in S_{\alpha^c}$ (here ξ_α denotes the collection of variables $\{\xi_v : v \in \alpha\}$), which is the standard and unique notion of rank for order-two tensors. Low-rank Tucker formats are then defined by imposing the α -rank for a collection of subsets $\alpha \subset D$. The *Tucker rank* (or *multilinear rank*) of a tensor is the tuple $(\text{rank}_{\{1\}}(v), \dots, \text{rank}_{\{d\}}(v))$ in \mathbb{N}^d . A tensor with Tucker rank bounded by (r_1, \dots, r_d) can be written as

$$v(\xi_1, \dots, \xi_d) = \sum_{i_1=1}^{r_1} \dots \sum_{i_d=1}^{r_d} a_{i_1 \dots i_d} v_{i_1}^1(\xi_1) \dots v_{i_d}^d(\xi_d), \quad (25.30)$$

where $v_{i_v}^v \in S_v$ and where $a \in \mathbb{R}^{r_1 \times \dots \times r_d}$ is a tensor of order d , called the *core tensor*. An approximation of the form (25.30) is called an approximation in *Tucker format*. It can be seen as an approximation in a tensor space $U_1 \otimes \dots \otimes U_d$, where $U_v = \text{span}\{v_{i_v}^v\}_{i_v=1}^{r_v}$ is a r_v -dimensional subspace of S_v . The storage complexity of this format is in $O(rnd + r^d)$ (with $r = \max_v r_v$) and grows exponentially with the dimension d . Additional constraints on the ranks of v (or of the core tensor a) have to be imposed in order to reduce this complexity. *Tree-based (or hierarchical) Tucker formats* [25, 30] are based on a notion of rank associated with a dimension partition tree T which is a tree-structured collection of subsets α in D , with D as the root of the tree and the singletons $\{1\}, \dots, \{d\}$ as the leaves of the tree (see Fig. 25.1). The *tree-based (or hierarchical) Tucker rank* associated with T is then defined as the tuple $(\text{rank}_\alpha(v))_{\alpha \in T}$. A particular case of interest is the *tensor train (TT) format* [47] which is associated with a simple rooted tree T with interior nodes $I = \{\{v, \dots, d\}, 1 \leq v \leq d\}$ (represented on Fig. 25.1b). The *TT-rank* of a

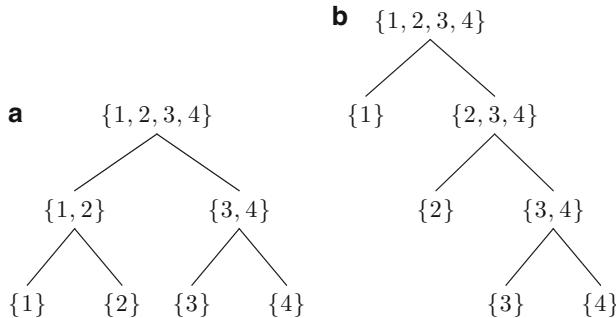

Fig. 25.1 Examples of dimension partition trees over $D = \{1, \dots, 4\}$. (a) Balanced tree. (b) Unbalanced tree

tensor v is defined as the tuple of ranks $(\text{rank}_{\{v+1, \dots, d\}}(v))_{1 \leq v \leq d-1}$. A tensor v with TT-rank bounded by (r_1, \dots, r_{d-1}) can be written under the form

$$v(\xi_1, \dots, \xi_d) = \sum_{i_1=1}^{r_1} \dots \sum_{i_{d-1}=1}^{r_{d-1}} v_{1,i_1}^1(\xi_1) v_{1,i_2}^2(\xi_2) \dots v_{i_{d-1},1}^d(\xi_d), \quad (25.31)$$

with $v_{i_{v-1}, i_v}^v \in S_v$, which is very convenient in practice (for storage, evaluations, and algebraic manipulations). The storage complexity for the TT format is in $O(dr^2n)$ (with $r = \max_v r_v$).

4.2 Relation with Other Structured Approximations

Sparse tensor methods consist in searching for approximations of the form (25.28) with only a few nonzero terms that means approximations $v(\xi) = \sum_{i=1}^m a_i s_i(\xi)$ where the m functions s_i are selected (with either adaptive or nonadaptive methods) in the collection (*dictionary*) of functions $\mathcal{D} = \{\phi_{k_1}^1(\xi_1) \dots \phi_{k_d}^d(\xi_d) : 1 \leq k_v \leq n_v, 1 \leq v \leq d\}$. A typical choice consists in taking for \mathcal{D} a basis of multivariate polynomials. Recently, theoretical results have been obtained on the convergence of sparse polynomial approximations of the solution of parameter-dependent equations (see [15]). Also, algorithms have been proposed that can achieve convergence rates comparable to the best m -term approximations. For such a dictionary \mathcal{D} containing rank-one functions, a sparse m -term approximation is a tensor with canonical rank bounded by m (usually lower than m , see [29, Section 7.6.5]). Therefore, an approximation in canonical tensor format (25.29) can be seen as a sparse m -term approximation where the m functions are selected in the dictionary of all rank-one (separated) functions $\mathcal{R}_1 = \{s(\xi) = s^1(\xi_1) \dots s^d(\xi_d) : s^v \in S^v\}$. Convergence results for best rank- m approximations can therefore be deduced from convergence results for sparse tensor approximation methods.

Let us mention some other standard structured approximations that are particular cases of low-rank tensor approximations. First, a function $v(\xi) = v(\xi_\nu)$ depending on a single variable ξ_ν is a rank-one (elementary) tensor. It has an α -rank equal to 1 for any subset α in D . A low-dimensional function $v(\xi) = v(\xi_\alpha)$ depending on a subset of variables ξ_α , $\alpha \subset D$, has a β -rank equal to 1 for any subset of dimensions β containing α or such that $\beta \cap \alpha = \emptyset$. An additive function $v(\xi) = v_1(\xi_1) + \dots + v_d(\xi_d)$, which is a sum of d elementary tensors, is a tensor with canonical rank d . Also, such an additive function has $\text{rank}_\alpha(v) \leq 2$ for any subset $\alpha \in D$, which means that it admits an exact representation in any hierarchical Tucker format (including TT format) with a rank bounded by $(2, \dots, 2)$.

Remark 2. Let us note that low-rank structures (as well as other types of structures) can be revealed only after a suitable change of variables. For example, let $\eta = (\eta_1, \dots, \eta_m)$ be the variables obtained by an affine transformation of variables ξ , with $\eta_i = \sum_{j=1}^d a_{ij} \xi_j + b_j$, $1 \leq j \leq m$. Then the function $v(\xi) = \sum_{i=1}^m v_i(\eta_i) := \hat{v}(\eta)$, as a function m variables, can be seen as an order- m tensor with canonical rank less than m . This type of approximation corresponds to the projection pursuit regression model.

4.3 Properties of Low-Rank Formats

Low-rank tensor approximation methods consist in searching for approximations in a subset of tensors

$$\mathcal{M}_{\leq r} = \{v : \text{rank}(v) \leq r\},$$

where different notions of rank yield different approximation formats. A first important question is to characterize the approximation power of low-rank formats, which means to quantify the best approximation error:

$$\inf_{v \in \mathcal{M}_{\leq r}} \|u - v\| := \sigma_r$$

for a given class of functions u and a given low-rank format. A few convergence results have been obtained for functions with standard Sobolev regularity (see, e.g., [55]). An open and challenging problem is to characterize approximation classes of the different low-rank formats, which means the class of functions u such that σ_r has a certain (e.g., algebraic or exponential) decay with r .

The characterization of topological and geometrical properties of subsets $\mathcal{M}_{\leq r}$ is important for different purposes such as proving the existence of best approximations in $\mathcal{M}_{\leq r}$ or deriving algorithms. For $d \geq 3$, the subsets $\mathcal{M}_{\leq r}$ associated with the notion of canonical rank are not closed and best approximation problems in $\mathcal{M}_{\leq r}$ are ill-posed. Subsets of tensors associated with the notions of tree-based (hierarchical) Tucker ranks have better properties. Indeed, they are closed sets,

which ensures the existence of best approximations. Also, they are differentiable manifolds [24, 32, 57]. This has useful consequences for optimization [57] or for the projection of dynamical systems on these manifolds [39].

For the different notions of rank introduced above, an interesting property of the corresponding low-rank subsets is that they admit simple parametrizations:

$$\mathcal{M}_{\leq r} = \{v = F(p_1, \dots, p_\ell) : p_k \in P_k\}, \quad (25.32)$$

where F is a multilinear map and P_k are vector spaces and where the number of parameters ℓ is in $O(d)$. An optimization problem on $\mathcal{M}_{\leq r}$ can then be reformulated as an optimization problem on $P_1 \times \dots \times P_\ell$, for which simple alternating minimization algorithms (block coordinate descent) can be used [23].

5 Low-Rank Approximation from Samples of the Function

Here we present some strategies for the construction of low-rank approximations of a multivariate function $u(\xi)$ from point evaluations of the function.

5.1 Least Squares

Let us assume that $u \in L^2_\mu(\mathcal{E})$. Given a set of K samples ξ^1, \dots, ξ^K of ξ drawn according the probability measure μ , a least-squares approximation of u in a low-rank subset $\mathcal{M}_{\leq r}$ is defined by

$$\min_{v \in \mathcal{M}_{\leq r}} \frac{1}{K} \sum_{k=1}^K (u(\xi^k) - v(\xi^k))^2. \quad (25.33)$$

Using a multilinear parametrization of low-rank tensor subsets (see (25.32)), the optimization problem (25.33) can be solved using alternating minimization algorithms, each iteration corresponding to a standard least-squares minimization for linear approximation [7, 14, 21]. An open question concerns the analysis of the number of samples which is required for a stable approximation in a given low-rank format. Also, standard regularizations can be introduced, such as sparsity-inducing regularizations [14]. In this statistical framework, cross-validation methods can be used for the selection of tensor formats, ranks, and approximation spaces S_k (see [14]).

Remark 3. Note that for other objectives in statistical learning (e.g., classification), (25.33) can be replaced by

$$\min_{v \in \mathcal{M}_{\leq r}} \frac{1}{K} \sum_{k=1}^K \ell(u(\xi^k), v(\xi^k)),$$

where ℓ is a so-called *loss function* measuring a certain distance between $u(\xi^k)$ and the approximation $v(\xi^k)$.

5.2 Interpolation/Projection

Here we present interpolation and projection methods for the approximation of u in $S = S_1 \otimes \dots \otimes S_d$. Let $\{\phi_{k_v}^v\}_{k_v \in \Lambda_{n_v}}$ be a basis of S_v , with $\Lambda_{n_v} = \{1, \dots, n_v\}$. If $\{\phi_{k_v}^v\}_{k_v \in \Lambda_{n_v}}$ is a set of interpolation functions associated with a set of points $\{\xi_v^{k_v}\}_{k_v \in \Lambda_{n_v}}$ in Ξ_v , then $\{\phi_k(\xi) = \phi_{k_1}^1(\xi_1) \dots \phi_{k_d}^d(\xi_d)\}_{k \in \Lambda}$, $\Lambda = \Lambda_{n_1} \times \dots \times \Lambda_{n_d}$, is a set of interpolation functions associated with the tensorized grid $\{\xi^k = (\xi_1^{k_1}, \dots, \xi_d^{k_d})\}_{k \in \Lambda}$ composed of $N = \prod_{v=1}^d n_v$ points. An interpolation u_N of u is then given by

$$u_N(\xi) = \sum_{k \in \Lambda} u(\xi^k) \phi_k(\xi),$$

so that u_N is completely characterized by the order- d tensor $U \in \mathbb{R}^{n_1} \otimes \dots \otimes \mathbb{R}^{n_d}$ whose components $U_{k_1, \dots, k_d} = u(\xi_1^{k_1}, \dots, \xi_d^{k_d})$ are the evaluations of u on the interpolation grid. Now, if $\{\phi_{k_v}^v\}_{k_v \in \Lambda_{n_v}}$ is an orthonormal basis of S_v (e.g., orthonormal polynomials) and if $\{(\xi_v^{k_v}, \omega_{k_v}^v)\}_{k_v \in \Lambda_{n_v}}$ is a quadrature rule on Ξ_v (associated with the measure μ_v), an approximate L^2 -projection of u can also be defined by

$$u_N(\xi) = \sum_{k \in \Lambda} u_k \phi_k(\xi), \quad u_k = \sum_{k \in \Lambda} \omega_k u(\xi^k) \phi_k(\xi^k),$$

with $\omega_k = \omega_{k_1}^1 \dots \omega_{k_d}^d$. Here again, u_N is completely characterized by the order- d tensor U whose components are the evaluations of u on the d -dimensional quadrature grid.

Then, low-rank approximation methods can be used in order to obtain an approximation of U using only a few entries of the tensor (i.e., a few evaluations of the function u). This is related to the problem of tensor completion. A possible approach consists in evaluating some entries of the tensor taken at random and then in reconstructing the tensor by the minimization of a least-squares functional (this is the algebraic version of the least-squares approach described in the previous section) or dual approaches using regularizations of rank minimization problems (see [54]). In this statistical framework, a challenging question is to determine the number of samples required for a stable reconstruction of low-rank approximations in different tensor formats (see [54] for first results). An algorithm has been introduced in [22] for the approximation in canonical format, using least-squares minimization with a structured set of entries selected adaptively. Algorithms have also been proposed for an adaptive construction of low-rank approximations of U in tensor train format [49] or hierarchical Tucker format [4]. These algorithms are extensions of adaptive

cross approximation (ACA) to high-order tensors and provide approximations that interpolate the tensor U at some adaptively chosen entries.

6 Low-Rank Tensor Methods for Parameter-Dependent Equations

Here, we present numerical methods for the direct computation of low-rank approximations of the solution u of a parameter-dependent equation $R(u(\xi); \xi) = 0$, where u is seen as a two-order tensor in $V \otimes L^2_\mu(\Xi)$ or as a higher-order tensor by exploiting an additional tensor space structure of $L^2_\mu(\Xi)$ (for a product measure μ).

Remark 4. When exploiting only the order-two tensor structure, the methods presented here are closely related to projection-based model reduction methods. Although they provide a directly exploitable low-rank approximation of u , they can also be used for the construction of a low-dimensional subspace in V (a candidate for projection-based model reduction) which is extracted from the obtained low-rank approximation.

6.1 Tensor-Structured Equations

Here, we describe how the initial equation can be reformulated as a tensor-structured equation. In practice, a preliminary discretization of functions defined on Ξ is required. A possible discretization consists in introducing an N -dimensional approximation space S in $L^2_\mu(\Xi)$ (e.g., a polynomial space) and a standard Galerkin projection of the solution onto $V \otimes S$ (see, e.g., [42, 46]). The resulting approximation can then be identified with a two-order tensor \mathbf{u} in $V \otimes \mathbb{R}^N$. When S is the tensor product of n_v -dimensional spaces S_v , $1 \leq v \leq d$, the resulting approximation can be identified with a higher-order tensor \mathbf{u} in $V \otimes \mathbb{R}^{n_1} \otimes \dots \otimes \mathbb{R}^{n_d}$. Another simple discretization consists in considering only a finite (possibly large) set of N points in Ξ (e.g., an interpolation grid) and the corresponding finite set of equations $R(u(\xi^k); \xi^k) = 0$, $1 \leq k \leq N$, on the set of samples of the solution $(u(\xi^k))_{k=1}^N \in V^N$, which can be identified with a tensor $\mathbf{u} \in V \otimes \mathbb{R}^N$. If the set of points is obtained by the tensorization of unidimensional grids with n_v points, $1 \leq v \leq d$, then $(u(\xi^k))_{k=1}^N$ can be identified with a higher-order tensor \mathbf{u} in $V \otimes \mathbb{R}^{n_1} \otimes \dots \otimes \mathbb{R}^{n_d}$. Both types of discretization yield an equation:

$$\mathbf{R}(\mathbf{u}) = 0, \tag{25.34}$$

with

$$\mathbf{u} \text{ in } V \otimes \mathbb{R}^N \text{ or } V \otimes \mathbb{R}^{n_1} \otimes \dots \otimes \mathbb{R}^{n_d}.$$

In order to clarify the structure of Eq. (25.34), let us consider the case of a linear problem where $R(v; \xi) = A(\xi)v - b(\xi)$ and assume that $A(\xi)$ and $b(\xi)$ have low-rank (or affine) representations of the form

$$A(\xi) = \sum_{i=1}^L A_i \alpha_i(\xi) \quad \text{and} \quad b(\xi) = \sum_{i=1}^R b_i \beta_i(\xi). \quad (25.35)$$

Then (25.34) takes the form of a tensor-structured equation $\mathbf{Au} - \mathbf{b} = 0$, with

$$\mathbf{A} = \sum_{i=1}^L A_i \otimes \tilde{A}_i \quad \text{and} \quad \mathbf{b} = \sum_{i=1}^R b_i \otimes \tilde{b}_i, \quad (25.36)$$

where, for the second type of discretization, $\tilde{A}_i \in \mathbb{R}^{N \times N}$ is a diagonal matrix whose diagonal is the vector of evaluations of $\alpha_i(\xi)$ at the sample points and $\tilde{b}_i \in \mathbb{R}^N$ is the vector of evaluations of $\beta_i(\xi)$ at the sample points. If $A(\xi)$ and $b(\xi)$ have higher-order low-rank representations of the form

$$A(\xi) = \sum_{i=1}^L A_i \alpha_i^1(\xi_1) \dots \alpha_i^d(\xi_d) \quad \text{and} \quad b(\xi) = \sum_{i=1}^R b_i \beta_i^1(\xi_1) \dots \beta_i^d(\xi_d), \quad (25.37)$$

then (25.34) takes the form of a tensor-structured equation $\mathbf{Au} - \mathbf{b} = 0$ on \mathbf{u} in $V \otimes \mathbb{R}^{n_1} \otimes \dots \otimes \mathbb{R}^{n_d}$, with

$$\mathbf{A} = \sum_{i=1}^L A_i \otimes \tilde{A}_i^1 \otimes \dots \otimes \tilde{A}_i^d \quad \text{and} \quad \mathbf{b} = \sum_{i=1}^R b_i \otimes \tilde{b}_i^1 \otimes \dots \otimes \tilde{b}_i^d, \quad (25.38)$$

where, for the second type of discretization (with a tensorized grid in $\mathcal{E}_1 \times \dots \times \mathcal{E}_d$), $\tilde{A}_i^\nu \in \mathbb{R}^{n_\nu \times n_\nu}$ is a diagonal matrix whose diagonal is the vector of evaluations of $\alpha_i^\nu(\xi_\nu)$ on the unidimensional grid in \mathcal{E}_ν and $\tilde{b}_i^\nu \in \mathbb{R}^{n_\nu}$ is the vector of evaluations of $\beta_i^\nu(\xi_\nu)$ on this grid (for the first type of discretization, see [46] for the definition of tensors \mathbf{A} and \mathbf{b}). Note that when $A(\xi)$ and $b(\xi)$ do not have low-rank representations (25.35) or (25.37) (or any other higher-order low-rank representation), then a preliminary approximation step is required in order to obtain such approximate representations (see, e.g., [5, 11, 19]). This is crucial for reducing the computational and storage complexities.

6.2 Iterative Solvers and Low-Rank Truncations

A first solution strategy consists in using standard iterative solvers (e.g., Richardson, conjugate gradient, Newton, etc.) with efficient low-rank truncation methods

of the iterates [1–3, 35, 37, 43]. A simple iterative algorithm takes the form $\mathbf{u}^{k+1} = M(\mathbf{u}^k)$, where M is an iteration map involving simple algebraic operations between tensors (additions, multiplications) which requires the implementation of a tensor algebra. Low-rank truncation methods can be systematically used for limiting the storage complexity and the computational complexity of algebraic operations. This results in approximate iterations $\mathbf{u}^{k+1} \approx M(\mathbf{u}^k)$, and the resulting algorithm can be analyzed as an inexact version (or perturbation) of the initial algorithm (see, e.g., [31]).

As an example, let us consider a linear tensor-structured problem $\mathbf{A}\mathbf{u} - \mathbf{b} = 0$. An approximate Richardson algorithm takes the form

$$\mathbf{u}^{k+1} = \Pi_\epsilon(\mathbf{u}^k + \alpha(\mathbf{b} - \mathbf{A}\mathbf{u}^k)),$$

where Π_ϵ is a map which associates to a tensor \mathbf{w} a low-rank approximation $\Pi_\epsilon(\mathbf{w})$ such that $\|\mathbf{w} - \Pi_\epsilon(\mathbf{w})\|_p \leq \epsilon \|\mathbf{w}\|_p$, with $p = 2$ or $p = \infty$ depending on the desired control of the error (mean-square or uniform error control over the parameter set). Provided some standard assumptions on the operator \mathbf{A} and the parameter α , the generated sequence \mathbf{u}^k is such that $\limsup_{k \rightarrow \infty} \|\mathbf{u} - \mathbf{u}^k\|_p \leq C(\epsilon)$ with $C(\epsilon) \rightarrow 0$ as $\epsilon \rightarrow 0$. For $p = 2$, efficient low-rank truncations of a tensor can be obtained using SVD for an order-two tensor or generalizations of SVD for higher-order tensor formats [27, 48]. A selection of the ranks based on the singular values of (matricizations of) the tensor allows a control of the error. In [2], the authors propose an alternative truncation strategy based on soft thresholding. For $p = \infty$, truncations can be obtained with an *adaptive cross approximation* algorithm (or empirical interpolation method) [6] for an order-two tensor or with extensions of this algorithm for higher-order tensors [49]. Note that low-rank representations of the form (25.36) or (25.38) for \mathbf{A} and \mathbf{b} are crucial since they ensure that algebraic operations between tensors can be done with a reduced complexity. Also, iterative methods usually require good preconditioners. In order to maintain a low computational complexity, these preconditioners must also admit low-rank representations.

6.3 Optimization on Low-Rank Manifolds

Another solution strategy consists in directly computing a low-rank approximation by minimizing some functional \mathcal{J} whose minimizer on $V \otimes \mathbb{R}^N$ (or $V \otimes \mathbb{R}^{n_1} \otimes \dots \otimes \mathbb{R}^{n_d}$) is the solution of Eq. (25.34), i.e., by solving

$$\min_{\mathbf{v} \in \mathcal{M}_{\leq r}} \mathcal{J}(\mathbf{v}), \quad (25.39)$$

where $\mathcal{M}_{\leq r}$ is a low-rank manifold. There is a natural choice of functional for problems where (25.34) corresponds to the stationary condition of a functional

\mathcal{J} [26]. Also, $\mathcal{J}(\mathbf{v})$ can be taken as a certain norm of the residual $\mathbf{R}(\mathbf{v})$. For linear problems, choosing

$$\mathcal{J}(\mathbf{v}) = \|\mathbf{Av} - \mathbf{b}\|^2$$

yields a quadratic optimization problem over a low-rank manifold. Optimization problems on low-rank manifolds can be solved either by using algorithms which exploit the manifold structure (e.g., Riemannian optimization) or by using simple alternating minimization algorithms given a parametrization (25.32) of the low-rank manifold. Under the assumption that \mathcal{J} satisfies $\alpha\|\mathbf{u} - \mathbf{v}\|_2 \leq \mathcal{J}(\mathbf{v}) \leq \beta\|\mathbf{u} - \mathbf{v}\|_2$, the solution \mathbf{u}_r of (25.39) is quasi-optimal in the sense that

$$\|\mathbf{u} - \mathbf{u}_r\|_2 \leq \frac{\beta}{\alpha} \min_{\mathbf{v} \in \mathcal{M}_{\leq r}} \|\mathbf{u} - \mathbf{v}\|_2,$$

where β/α is the condition number of the operator A . Here again, the use of preconditioners allows us to better exploit the approximation power of a given low-rank manifold $\mathcal{M}_{\leq r}$.

Constructive algorithms are also possible, the most prominent algorithm being a greedy algorithm which consists in computing a sequence of low-rank approximations u_m obtained by successive rank-one corrections, i.e.,

$$\mathcal{J}(\mathbf{u}_m) = \min_{w \in \mathcal{R}_1} \mathcal{J}(\mathbf{u}_{m-1} + w).$$

This algorithm is a standard greedy algorithm [56] with a dictionary of rank-one (elementary) tensors \mathcal{R}_1 , which was first introduced in [44] for the solution of parameter-dependent (stochastic) equations. Its convergence has been established under standard assumptions for convex optimization problems [10, 24]. The utility of this algorithm is that it is adaptive, and it only requires the solution of optimization problems on the low-dimensional manifold \mathcal{R}_1 . However, for many practical problems, greedy constructions of low-rank approximations in canonical low-rank format are observed to converge slowly. Improved constructive algorithms which better exploit the tensor structure of the problem have been proposed [46] and convergence results are also available for some general convex optimization problems [24].

Remark 5. The above algorithms can also be used within iterative algorithms for which an iteration takes the form

$$\mathbf{C}_k \mathbf{u}^{k+1} = \mathbf{F}_k(\mathbf{u}^k),$$

where $\mathbf{F}_k(\mathbf{u}^k)$ can be computed with a low complexity using low-rank tensor algebra (with potential low-rank truncations), but where the inverse of the operator \mathbf{C}_k is not known explicitly, so that $\mathbf{C}_k^{-1} \mathbf{F}_k(\mathbf{u}^k)$ cannot be obtained from simple algebraic

operations. Here, a low-rank approximation of \mathbf{u}^{k+1} can be computed using the above algorithms with the residual-based functional $\mathcal{J}(\mathbf{v}) = \|\mathbf{C}_k \mathbf{v} - \mathbf{F}_k(\mathbf{u}^k)\|^2$.

7 Concluding Remarks

Low-rank tensor methods have emerged as a very powerful tool for the solution of high-dimensional problems arising in many contexts and in particular in uncertainty quantification. However, there remain many challenging issues to address for a better understanding of this type of approximation and for a diffusion of these methods in a wide class of applications. From a theoretical point of view, open questions include the characterization of the approximation classes of a given low-rank tensor format, which means the class of functions for which a certain type of convergence (e.g., algebraic or exponential) can be expected, and also the characterization of the problems yielding solutions in these approximation classes. Also, quantitative results on the approximation of a low-rank function (or tensor) from samples of this function (or entries of this tensor) could allow us to answer some practical issues such as the determination of the number of samples required for a stable approximation in a given low-rank format or the design of sampling strategies which are adapted to particular low-rank formats. From a numerical point of view, challenging issues include the development of efficient algorithms for global optimization on low-rank manifolds, with guaranteed convergence properties, and the development of adaptive algorithms for the construction of controlled low-rank approximations, with an adaptive selection of ranks and potentially of the tensor formats (e.g., based on tree optimization for tree-based formats). From a practical point of view, low-rank tensor methods exploiting model equations (Galerkin-type methods) are often seen as “intrusive methods” in the sense that they require (a priori) the development of specific softwares. An important issue is then to develop weakly intrusive implementations of these methods which may allow the use of existing computational frameworks and which would therefore contribute to a large diffusion of these methods.

Random Vectors and Random Fields in High Dimension: Parametric Model-Based Representation, Identification from Data, and Inverse Problems

Christian Soize

Abstract

The statistical inverse problem for the experimental identification of a non-Gaussian matrix-valued random field, that is, the model parameter of a boundary value problem, using some partial and limited experimental data related to a model observation, is a very difficult and challenging problem. A complete advanced methodology and the associated tools are presented for solving such a problem in the following framework: the random field that must be identified is a non-Gaussian matrix-valued random field and is not simply a real-valued random field; this non-Gaussian random field is in high stochastic dimension and is identified in a general class of random fields; some fundamental algebraic properties of this non-Gaussian random field must be satisfied such as symmetry, positiveness, invertibility in mean square, boundedness, symmetry class, spatial-correlation lengths, etc.; and the available experimental data sets correspond only to partial and limited data for a model observation of the boundary value problem.

The developments presented are mainly related to the elasticity framework, but the methodology is general and can be used in many areas of computational sciences and engineering. The developments are organized as follows. The first part is devoted to the definition of the statistical inverse problem that has to be solved in high stochastic dimension and is focussed on stochastic elliptic operators such that the ones that are encountered in the boundary value problems of the linear elasticity. The second one deals with the construction of two possible parameterized representations for a non-Gaussian positive-definite matrix-valued random field that models the model parameter of a boundary value problem. A parametric model-based representation is then constructed in introducing a statistical reduced model and a polynomial chaos expansion, first with deterministic coefficients and after with random coefficients. This

parametric model-based representation is directly used for solving the statistical inverse problem. The third part is devoted to the description of all the steps of the methodology allowing the statistical inverse problem to be solved in high stochastic dimension. These steps are based on the identification of a prior stochastic model of the Non-Gaussian random field by using the maximum likelihood method and then, on the identification of a posterior stochastic model of the Non-Gaussian random field by using the Bayes method. The fourth part presents the construction of an algebraic prior stochastic model of the model parameter of the boundary value problem, for a non-Gaussian matrix-valued random field. The generator of realizations for such an algebraic prior stochastic model for a non-Gaussian matrix-valued random field is presented.

1 Introduction

The statistical inverse problem for the experimental identification of a non-Gaussian matrix-valued random field that is the model parameter of a boundary value problem, using some partial and limited experimental data related to a model observation, is a very difficult and challenging problem. The classical methodologies that are very efficient for Gaussian random fields cannot be used for non-Gaussian matrix-valued random fields in high stochastic dimension, in particular under the assumption that only partial and limited experimental data are available for the statistical inverse problem that has to be solved for identifying the non-Gaussian random field through a boundary value problem. This means that experimental data must be enriched in introducing adapted informative prior stochastic models for the non-Gaussian matrix-valued random fields in order to take into account fundamental algebraic properties such as symmetry, positiveness, invertibility in mean square, boundedness, symmetry class, spatial-correlation lengths, etc. The objective is then to present a complete advanced methodology and the associated tools for solving such a statistical inverse problem in high stochastic dimension and related to non-Gaussian matrix-valued random fields.

2 Notions on the High Stochastic Dimension and on the Parametric Model-Based Representations for Random Fields

2.1 What Is a Random Vector or a Random Field with a High Stochastic Dimension?

The *stochastic dimension* of a random vector or a random field is an important notion that allows for evaluating the level of complexity of a statistical inverse problem related to the identification of a random model parameter (random vector, random field) of a stochastic boundary value problem (for instance, the coefficients of a partial differential equation) using experimental data related to a random model observation (random variable, random vector, random field) of this boundary value problem.

Let us consider a random vector \mathbf{U} with values in \mathbb{R}^{N_U} in which N_U is an integer. The stochastic dimension of \mathbf{U} is not, in general, the value of integer N_U . For instance, if \mathbf{U} is written as $\mathbf{U} = \eta \mathbf{b}$, in which η is a real-valued random variable and where \mathbf{b} is a deterministic vector given in \mathbb{R}^{N_U} , then the stochastic dimension of \mathbf{U} is 1 for any value of integer N_U . If \mathbf{U} is written as $\mathbf{U} = \sum_{i=1}^m \eta_i \mathbf{b}^i$ with $m \leq N_U$, in which η_1, \dots, η_m are m independent real-valued random variables and where $\mathbf{b}^1, \dots, \mathbf{b}^m$ are m algebraically independent vectors given in \mathbb{R}^{N_U} , then the stochastic dimension of \mathbf{U} is m , and \mathbf{U} is in high stochastic dimension if m is large. If \mathbf{U} is a second-order random vector whose covariance matrix is known, then the use of the principal component analysis allows the reduced representation $\mathbf{U}^{(m)} = \sum_{i=1}^m \eta_i \sqrt{\lambda_i} \mathbf{b}^i$ of \mathbf{U} to be constructed with $m < N_U$ and where m is calculated

in order that the mean-square error of $\mathbf{U} - \mathbf{U}^{(m)}$ is sufficiently small. It can thus be written $\mathbf{U} \sim \mathbf{U}^{(m)}$ (in mean square). In such a reduced representation, $\lambda_1 \geq \dots > \lambda_m > 0$ are the dominant eigenvalues of the covariance matrix of \mathbf{U} and $\mathbf{b}^1, \dots, \mathbf{b}^m$ are the associated orthonormal eigenvectors in \mathbb{R}^{N_U} . The components η_1, \dots, η_m are m centered and uncorrelated real-valued random variables. If random vector \mathbf{U} is a Gaussian random vector, then η_1, \dots, η_m are m independent Gaussian real-valued random variables, and, for this particular Gaussian case, the stochastic dimension of \mathbf{U} is m . However, for the general case, \mathbf{U} is a non-Gaussian random vector, and consequently, the real-valued random variables η_1, \dots, η_m (that are centered and uncorrelated) are not independent but are statistically dependent. In such a case, m is not the stochastic dimension of \mathbf{U} , but clearly the stochastic dimension is less or equal to m (the equality is obtained for the Gaussian case). Let us assume that there exists a deterministic nonlinear mapping \mathcal{Y} from \mathbb{R}^{N_g} into \mathbb{R}^m such that the random vector $\boldsymbol{\eta} = (\eta_1, \dots, \eta_m)$ can be written as $\boldsymbol{\eta} = \mathcal{Y}(\mathcal{E}_1, \dots, \mathcal{E}_{N_g})$ in which $N_g < m$ and where $\mathcal{E}_1, \dots, \mathcal{E}_{N_g}$ are N_g independent real-valued random variables (for instance, \mathcal{Y} can be constructed using the polynomial chaos expansion of the second-order random vector $\boldsymbol{\eta}$). In such a case, the stochastic dimension of \mathbf{U} is less or equal to N_g . If among all the possible nonlinear mappings and all the possible integers N_g such that $1 \leq N_g < m$, the mapping \mathcal{Y} and the integer N_g correspond to the smallest possible value of N_g such as $\boldsymbol{\eta} = \mathcal{Y}(\mathcal{E}_1, \dots, \mathcal{E}_{N_g})$, then N_g is the stochastic dimension of \mathbf{U} , and \mathbf{U} has a high stochastic dimension if N_g is large.

If $\{\mathbf{u}(\mathbf{x}), \mathbf{x} \in \Omega\}$ is a second-order random field indexed by $\Omega \subset \mathbb{R}^d$ with values in \mathbb{R}^{N_u} , for which its cross covariance function is square integrable $\Omega \times \Omega$, then a reduced representation $\mathbf{u}^{(m)}(\mathbf{x}) = \sum_{i=1}^m \eta_i \sqrt{\lambda_i} \mathbf{b}^i(\mathbf{x})$ of \mathbf{u} can be constructed using the Karhunen-Loève expansion of \mathbf{u} , in which m is calculated in order that the mean-square error of $\mathbf{u} - \mathbf{u}^{(m)}$ is sufficiently small. Therefore, the explanations given before can be applied to the random vector $\boldsymbol{\eta} = (\eta_1, \dots, \eta_m)$ in order to estimate the stochastic dimension of random field \mathbf{u} .

2.2 What Is a Parametric Model-Based Representation for the Statistical Identification of a Random Model Parameter from Experimental Data?

In order to simply explain what is a parametric model-based representation for the statistical identification of a random model parameter from experimental data, let us consider the stochastic elliptic boundary value problem formulated for a real-valued random field $u(\mathbf{x})$ indexed by $\mathbf{x} = (x_1, \dots, x_d)$ belonging to a subset Ω of \mathbb{R}^d and which is assumed to have a unique second-order stochastic solution u . The stochastic elliptic operator of the boundary value problem is written as $-\sum_{j=1}^d \frac{\partial}{\partial x_j} \{K(\mathbf{x}) \frac{\partial}{\partial x_j} u(\mathbf{x})\}$ in which the random field $K = \{K(\mathbf{x}), \mathbf{x} \in \Omega\}$, indexed by Ω , with values in $\mathbb{R}^+ = [0, +\infty[$, is defined as the *model parameter* of the boundary value problem. Let \mathbf{U} be a random *model observation* that is assumed to be a random vector with values in \mathbb{R}^{N_U} , which is deduced from random field u by a

deterministic observation operator \mathcal{O} , such that $\mathbf{U} = \mathcal{O}(u)$. Consequently, random model observation \mathbf{U} can be written as $\mathbf{U} = \mathcal{H}(K)$ in which \mathcal{H} is a deterministic nonlinear functional of K . For all \mathbf{x} in Ω , a representation of K is assumed to be written as $K(\mathbf{x}) = \mathcal{G}(G(\mathbf{x}))$ with $G(\mathbf{x}) = G_0(\mathbf{x}) + \sum_{i=1}^m \eta_i \sqrt{\lambda_i} G_i(\mathbf{x})$. The deterministic nonlinear mapping \mathcal{G} is independent of \mathbf{x} and is assumed to be from \mathbb{R} into \mathbb{R}^+ . With the introduction of such a deterministic mapping \mathcal{G} , for all \mathbf{x} fixed in Ω , the support of the probability distribution of the random variable $G(\mathbf{x})$ is \mathbb{R} instead of \mathbb{R}^+ for $K(\mathbf{x})$. In the reduced representation of the random field G indexed by Ω , with values in \mathbb{R} , the quantities $G_0(\mathbf{x})$, λ_i , and $G_i(\mathbf{x})$ are some real numbers. The random vector $\boldsymbol{\eta} = (\eta_1, \dots, \eta_m)$ is written as $\boldsymbol{\eta} = \mathcal{Y}(\boldsymbol{\Xi}; [z])$ in which $\boldsymbol{\Xi} = (\Xi_1, \dots, \Xi_{N_g})$ is a given vector-valued random variable, where \mathcal{Y} is a deterministic nonlinear mapping representing the truncated polynomial chaos expansion of $\boldsymbol{\eta}$ with respect to $\boldsymbol{\Xi}$ and where $[z]$ is the real matrix of the \mathbb{R}^m -valued coefficients of the truncated polynomial chaos expansion of $\boldsymbol{\eta}$. It can then be deduced that random model observation \mathbf{U} can be rewritten as $\mathbf{U} = \mathcal{B}(\boldsymbol{\Xi}, [z])$ in which \mathcal{B} is a deterministic nonlinear mapping depending on \mathcal{H} , \mathcal{G} , and \mathcal{Y} . This last representation is defined as a *parametric model-based representation* of the random model observation \mathbf{U} in which the real matrix $[z]$ is the hyperparameter of the representation. Let us assume that some experimental data $\mathbf{u}^{\text{exp},1}, \dots, \mathbf{u}^{\text{exp},n_{\text{exp}}}$ related to random model observation \mathbf{U} are available. The *identification of the model parameter* K using the *experimental data* consists in identifying the real matrix $[z]$ using the parametric model-based representation $\mathbf{U} = \mathcal{B}(\boldsymbol{\Xi}, [z])$ of the random model observation and the corresponding experimental data.

3 Brief History

3.1 Classical Methods for Statistical Inverse Problems

The problem related to the identification of a model parameter (scalar, vector, field) of a boundary value problem (BVP) (for instance, the coefficients of a partial differential equation) using experimental data related to a model observation (scalar, vector, field) of this BVP is a problem for which there exists a rich literature, including numerous textbooks. In general and in the deterministic context, there is not a unique solution because the function, which maps the model parameter (that belongs to an admissible set) to the model observation (that belongs to another admissible set) is not a one-to-one mapping and, consequently, cannot be inverted. It is an ill-posed problem. However, such a problem can be reformulated in terms of an optimization problem consisting in calculating an optimal value of the model parameter, which minimizes a certain distance between the observed experimental data and the model observation that is computed with the BVP and that depends on the model parameter (see, for instance, [76] for an overview concerning the general methodologies and [36] for some mathematical aspects related to the inverse problems for partial differential equations). In many cases, the analysis of such an inverse problem can have a unique solution in the framework of statistics,

that is to say when the model parameter is modeled by a random quantity, with or without external noise on the model observation (observed output). In such a case, the random model observation is completely defined by its probability distribution (in finite or in infinite dimension) that is the unique transformation of the probability distribution of the random model parameter. This transformation is defined by the functional that maps the model parameter to the model observation. Such a formulation is constructed for obtaining a well-posed problem that has a unique solution in the probability theory framework. We refer the reader to [38] and [72] for an overview concerning the general methodologies for statistical and computational inverse problems, including general least-square inversion and the maximum likelihood method [54, 67] and including the Bayesian approach [8, 9, 67, 68].

3.2 Case of a Gaussian Random Model Parameter

A Gaussian second-order random vector is completely defined by its second-order moments, that is to say, by its mean vector and by its covariance matrix. Similarly, a Gaussian second-order random field is completely defined by its mean function and by its cross covariance function or, if the random field is homogeneous (stationary) and mean-square continuous, by its spectral measure [17]. If the model parameter is Gaussian (random vector or random field), then the statistical inverse problem (identification of the system parameter using experimental data related to the model observation of the system) consists in identifying the second-order moments, which is relatively easy for a low or a high stochastic dimension. Concerning the description of the Gaussian random fields, we refer the reader to the abundant existing literature (see, for instance, [41, 53, 74]).

3.3 Case for Which the Model Parameter Is a Non-Gaussian Second-Order Random Field

A non-Gaussian second-order random field is completely defined by its system of marginal probability distributions, which is an uncountable family of probability distributions on sets of finite dimension and not only by its mean function and its covariance function as for a Gaussian random field. The experimental identification of such a non-Gaussian random field then requires the introduction of an adapted representation in order to be in capability to solve the statistical inverse problem. For any non-Gaussian second-order random field, an important type of representation is based on the use of the polynomial chaos expansion [7], for which the development and the use in computational sciences and engineering have been pioneered by Roger Ghanem in 1990–1991 [23]. An efficient construction is proposed, which consists in combining a Karhunen-Loëve expansion (that allows using a statistical reduced model) with a polynomial chaos expansion of the statistical reduced model. This type of construction has then been reanalyzed and used for solving boundary value problems using the spectral approach (see, for instance, [13, 18, 22, 24, 25, 42,

[46, 47, 52]). The polynomial chaos expansion has also been extended for an arbitrary probability measure [20, 43, 44, 57, 77, 78] and for sparse representation [5]. New algorithms have been proposed for obtaining a robust computation of realizations of high degrees of polynomial chaos [49, 65]. This type of representation has also been extended for the case of the polynomial chaos expansion with random coefficients [66], for the construction of a basis adaptation in homogeneous chaos spaces [73], and for an arbitrary multimodal multidimensional probability distribution [64].

3.4 Finite-Dimension Approximation of the BVP and Finite-Dimension Parameterization of the Random Field

A finite-dimension parameterized representation of the non-Gaussian random field must be constructed in order to be able to solve the statistical inverse problem. In addition and in general, an explicit solution of the BVP cannot be obtained and consequently, a finite-dimension approximation of the solution of the BVP must also be constructed (using, for instance, the finite element method), accompanied by a convergence analysis. The combination of these two approximations leads us to introduce a non-Gaussian second-order random vector η with values in \mathbb{R}^m , which is the finite-dimension parameterized representation of the random model parameter of the system. Consequently, the statistical inverse problem consists in identifying the non-Gaussian second-order random vector η that is completely defined by its probability distribution on \mathbb{R}^m . Nevertheless, as η corresponds to a finite-dimension parameterization of the finite discretization of a random field, it is necessary to construct, first, a good mathematical representation of the random field and of its finite-dimension parameterization, before performing its spatial discretization.

3.5 Parameterization of the Non-Gaussian Second-Order Random Vector η

Since it is assumed that the experimental data that are available for the statistical inverse problem are partial and limited, the parametric statistics must be used instead of the nonparametric statistics that cannot be used. This implies that a parameterized representation of the non-Gaussian second-order random vector η must be constructed. There are two main methods for constructing such a parameterization.

- (i) The first one is a direct approach that consists in constructing a algebraic prior representation of the non-Gaussian probability distribution of η in using the maximum entropy principle (MaxEnt) [37, 63] under the constraints defined by the available information. A general computational methodology, for the problems in high stochastic dimension, is proposed in [4, 59] and is synthesized in Sect. 11 of ▶ Chap. 8, “Random Matrix Models and Nonparametric Method for Uncertainty Quantification” in part II of the present Handbook on Uncertainty Quantification. Such a construction allows a low-dimension

hyperparameterization to be obtained for the non-Gaussian probability distribution on \mathbb{R}^m . Therefore, the parametric statistics [54, 67, 76] can be used for solving the statistical inverse problem consisting in identifying the vector-valued hyperparameter of the probability distribution constructed with the MaxEnt. In counterpart, the “distance” between the observed experimental data and the random model observation cannot be, in general, reduced to zero. A residual error exists. If there are a sufficient amount of experimental data, this error can be reduced by identifying a posterior probability distribution of η using the Bayesian approach [8, 9, 67].

- (ii) The second method is an indirect approach which consists in introducing a representation $\eta = \mathcal{Y}(\Xi)$ in which \mathcal{Y} is an unknown deterministic nonlinear (measurable) mapping from \mathbb{R}^{N_g} into \mathbb{R}^m (which has to be constructed) and where Ξ is a given random vector with values in \mathbb{R}^{N_g} , for which its probability distribution is known (for instance, a normalized Gaussian random vector). The statistical inverse problem then consists in identifying the nonlinear mapping \mathcal{Y} . Consequently, a parameterization of mapping \mathcal{Y} must be introduced in order to use parametric statistics, and there are two main approaches.
 1. The first one corresponds to the truncated polynomial chaos expansion of second-order random vector η with respect to the normalized Gaussian measure. In this case, Ξ is a normalized Gaussian random vector, and the orthogonal polynomials are the normalized Hermite polynomials [23]). If an arbitrary probability measure is used instead of the normalized Gaussian measure, then Ξ is a normalized random vector with this arbitrary probability distribution, and the orthogonal polynomials are constructed with respect to this arbitrary probability distribution [49, 57, 64, 77, 78]. Such a polynomial expansion defines a parameterization, noted as $\mathcal{Y}(\Xi, [z])$, of mapping \mathcal{Y} , in which the real matrix $[z]^T$ represents the \mathbb{R}^m -valued coefficients of the polynomial chaos expansion of η , and the identification of \mathcal{Y} is replaced by the identification of the hyperparameter $[z]$.
 2. The second approach consists in introducing an algebraic prior representation $\eta = \mathcal{Y}(\Xi, s)$ in which s is a vector-valued hyperparameter that has a small dimension and which must be identified using parametric statistics [54, 67, 76]. Similar to the method (i) presented before, if there is a sufficient amount of experimental data, the prior model can be updated in constructing a posterior probability distribution using the Bayesian approach [22, 45].

3.6 Statistical Inverse Problem for Identifying a Non-Gaussian Random Field as a Model Parameter of a BVP, Using Polynomial Chaos Expansion

The use of the polynomial chaos expansion for constructing a parameterized representation of a non-Gaussian random field that models the model parameter of a boundary value problem, in order to identify it using a statistical inverse method, has been initialized in [14, 15], used in [30], and revisited in [12]. In [11], the

construction of the probability model of the random coefficients of the polynomial chaos expansion is proposed by using the asymptotic sampling Gaussian distribution constructed with the Fisher information matrix and is used for model validation [24]. This work has been developed for statistical inverse problems that are rather in low stochastic dimension, and new ingredients have been introduced in [49, 61, 63] for statistical inverse problems in high stochastic dimension. In using the reduced chaos decomposition with random coefficients of random fields [66], a Bayesian approach for identifying the posterior probability model of the random coefficients of the polynomial chaos expansion of the model parameter of the BVP has been proposed in [2] for the low stochastic dimension and in [62] for the high stochastic dimension. The experimental identification of a non-Gaussian positive matrix-valued random field in high stochastic dimension, using partial and limited experimental data for a model observation related to the random solution of a stochastic BVP, is a difficult problem that requires both adapted representations and methodologies [48, 61–63].

3.7 Algebraic Prior Stochastic Models of the Model Parameters of BVP

In the methodology devoted to the identification of a non-Gaussian random field in high stochastic dimension, an important step is the construction of a parameterized representation for which the number of hyperparameters (in the parameterized representation) is generally very large due to the high stochastic dimension. In the framework of hypotheses for which only partial and limited data are available, such an identification is difficult if there is no information concerning the region of the admissible set (in high dimension), in which the optimal values of these hyperparameters must be searched. The optimization process, related to the statistical inverse problem, requires to localize the region in which the algorithms must search for an optimal value. The method consists in previously identifying the “center” of such a region, which corresponds to the value of the hyperparameters of the parameterized representation using a set of realizations generated with an algebraic prior stochastic model (APSM) that is specifically constructed on the basis of the available information associated with all the mathematical properties of the non-Gaussian random field that has to be identified. This APSM allows for enriching the information in order to overcome the lack of experimental data (since only partial experimental data are assumed to be available). This is particularly crucial for the identification of the non-Gaussian matrix-valued random field encountered, for instance, in three-dimensional linear elasticity, for which some works have been performed in order to introduce the symmetry, the positiveness and invertibility properties [56, 58, 60], the boundedness [27, 32], a capability of the prior stochastic model to exhibit a capability to generate simultaneously anisotropic statistical fluctuations and some statistical fluctuations in a symmetry class such as isotropic, cubic, transversely isotropic, orthotropic, etc. [26, 28, 29, 33, 69], and to develop the corresponding generators of realizations [26, 28, 29, 58, 61].

4 Overview

A complete methodology and the associated tools are presented for the experimental identification of a non-Gaussian matrix-valued random field that is the model parameter of a boundary value problem, using some experimental data related to a model observation. The difficulties of the statistical inverse problem that are presented are due to the following chosen framework that corresponds to many practical situations in computational sciences and engineering:

- A non-Gaussian matrix-valued random field must be identified, not simply a real-valued random field.
- The non-Gaussian random field that has to be identified is in high stochastic dimension and must be identified in a general class of random fields.
- Some fundamental algebraic properties of the non-Gaussian random field must be satisfied such as symmetry, positiveness, invertibility in mean square, boundedness, symmetry class, spatial-correlation lengths, etc.
- The available experimental data sets correspond only to partial and limited data for a model observation of the boundary value problem.

For such a statistical inverse problem, the above framework implies the use of an adapted and advanced methodology. The developments presented hereinafter are mainly related to the elasticity framework, but the methodology is general and can be used in many areas of computational sciences and engineering. The developments are organized as follows.

- The first one is devoted to the definition of the statistical inverse problem that has to be solved in high stochastic dimension and is focused on stochastic elliptic operators such as the ones that are encountered in the boundary value problems of the linear elasticity.
- The second one deals with the construction of two possible parameterized representations for a non-Gaussian positive-definite matrix-valued random field that models the model parameter of a boundary value problem. A parametric model-based representation is then constructed in introducing a statistical reduced model and a polynomial chaos expansion, first with deterministic coefficients and after with random coefficients. This parametric model-based representation is directly used for solving the statistical inverse problem.
- The third part is devoted to the description of all the steps of the methodology allowing the statistical inverse problem to be solved in high stochastic dimension. This methodology corresponds to the work initialized in [61], extended in [62] for constructing a posterior stochastic model using the Bayesian approach, and revisited in [48, 49].
- The fourth part presents the construction of an algebraic prior stochastic model of the model parameter of the boundary value problem, for a non-Gaussian matrix-valued random field. This construction is based on the works [27, 28, 58, 60] and reuses the formalism and the results introduced in the developments presented in

Sect. 12 of ▶ Chap. 8, “Random Matrix Models and Nonparametric Method for Uncertainty Quantification” in part II of the present Handbook on Uncertainty Quantification. The generator of realizations for such an algebraic prior stochastic model for a non-Gaussian matrix-valued random field is presented [28, 58, 61].

5 Notations

The following algebraic notations are used.

5.1 Euclidean Space

Let $\mathbf{x} = (x_1, \dots, x_n)$ be a vector in \mathbb{R}^n . The Euclidean space \mathbb{R}^n is equipped with the usual inner product $\langle \mathbf{x}, \mathbf{y} \rangle = \sum_{j=1}^n x_j y_j$ and the associated norm $\|\mathbf{x}\| = \sqrt{\langle \mathbf{x}, \mathbf{x} \rangle}$.

5.2 Sets of Matrices

Let $\mathbb{M}_{n,m}(\mathbb{R})$ be the set of all the $(n \times m)$ real matrices,

$\mathbb{M}_n(\mathbb{R}) = \mathbb{M}_{n,n}(\mathbb{R})$ the square matrices,

$\mathbb{M}_n^S(\mathbb{R})$ be the set of all the symmetric $(n \times n)$ real matrices,

$\mathbb{M}_n^U(\mathbb{R})$ be the set of all the upper triangular $(n \times n)$ real matrices with positive diagonal entries,

$\mathbb{M}_n^+(\mathbb{R})$ be the set of all the positive-definite symmetric $(n \times n)$ real matrices.

The ensembles of real matrices are such that

$$\mathbb{M}_n^+(\mathbb{R}) \subset \mathbb{M}_n^S(\mathbb{R}) \subset \mathbb{M}_n(\mathbb{R}).$$

5.3 Kronecker Symbol, Unit Matrix, and Indicator Function

The Kronecker symbol is denoted by δ_{jk} and is such that $\delta_{jk} = 0$ if $j \neq k$ and $\delta_{jj} = 1$. The unit (or identity) matrix in $\mathbb{M}_n(\mathbb{R})$ is denoted by $[I_n]$ and is such that $[I_n]_{jk} = \delta_{jk}$. Let \mathbb{S} be any subset of any set \mathbb{M} , possibly with $\mathbb{S} = \mathbb{M}$. The indicator function $M \mapsto \mathbb{1}_{\mathbb{S}}(M)$ defined on set \mathbb{M} is such that $\mathbb{1}_{\mathbb{S}}(M) = 1$ if $M \in \mathbb{S} \subset \mathbb{M}$, and $\mathbb{1}_{\mathbb{S}}(M) = 0$ if $M \notin \mathbb{S}$.

5.4 Norms and Usual Operators

- (i) The determinant of a matrix $[G]$ in $\mathbb{M}_n(\mathbb{R})$ is denoted by $\det[G]$, and its trace is denoted by $\text{tr}[G] = \sum_{j=1}^n G_{jj}$.
- (ii) The transpose of a matrix $[G]$ in $\mathbb{M}_{n,m}(\mathbb{R})$ is denoted by $[G]^T$, which is in $\mathbb{M}_{m,n}(\mathbb{R})$.

- (iii) The operator norm of a matrix $[G]$ in $\mathbb{M}_{n,m}(\mathbb{R})$ is denoted by $\|G\| = \sup_{\|\mathbf{x}\| \leq 1} \| [G] \mathbf{x} \|$ for all \mathbf{x} in \mathbb{R}^m , which is such that $\| [G] \mathbf{x} \| \leq \|G\| \|\mathbf{x}\|$ for all \mathbf{x} in \mathbb{R}^m .
- (iv) For $[G]$ and $[H]$ in $\mathbb{M}_{n,m}(\mathbb{R})$, we denote $\ll [G], [H] \gg = \text{tr}\{[G]^T [H]\}$ and the Frobenius norm (or Hilbert-Schmidt norm) $\|G\|_F$ of $[G]$ is such that $\|G\|_F^2 = \ll [G], [G] \gg = \text{tr}\{[G]^T [G]\} = \sum_{j=1}^n \sum_{k=1}^m G_{jk}^2$, which is such that $\|G\| \leq \|G\|_F \leq \sqrt{n} \|G\|$.
- (v) The gradient $\nabla_{\mathbf{x}} u(\mathbf{x})$ at point \mathbf{x} in \mathbb{R}^n of the real-valued function $\mathbf{x} \mapsto u(\mathbf{x})$ is the vector in \mathbb{R}^n such that $\{\nabla_{\mathbf{x}} u(\mathbf{x})\}_j = \partial u(\mathbf{x}) / \partial x_j$ for $j = 1, \dots, n$. The divergence $\text{div}_{\mathbf{x}}(\mathbf{u}(\mathbf{x}))$ at point \mathbf{x} in \mathbb{R}^n of the \mathbb{R}^n -valued function $\mathbf{x} \mapsto \mathbf{u}(\mathbf{x}) = (u_1(\mathbf{x}), \dots, u_n(\mathbf{x}))$ is the real number such that $\text{div}_{\mathbf{x}}(\mathbf{u}(\mathbf{x})) = \sum_{j=1}^n \partial u_j(\mathbf{x}) / \partial x_j$.

5.5 Order Relation in the Set of All the Positive-Definite Real Matrices

Let $[G]$ and $[H]$ be two matrices in $\mathbb{M}_n^+(\mathbb{R})$. The notation $[G] > [H]$ means that the matrix $[G] - [H]$ belongs to $\mathbb{M}_n^+(\mathbb{R})$.

5.6 Probability Space, Mathematical Expectation, and Space of Second-Order Random Vectors

The mathematical expectation relative to a probability space (Θ, \mathcal{T}, P) is denoted by E . The space of all the second-order random variables, defined on (Θ, \mathcal{T}, P) , with values in \mathbb{R}^n , equipped with the inner product $((\mathbf{X}, \mathbf{Y})) = E\{\langle \mathbf{X}, \mathbf{Y} \rangle\}$ and with the associated norm $|||\mathbf{X}||| = ((\mathbf{X}, \mathbf{X}))^{1/2}$, is a Hilbert space denoted by \mathcal{L}_n^2 .

6 Setting the Statistical Inverse Problem to be Solved in High Stochastic Dimension

Let d be an integer such that $1 \leq d \leq 3$. Let n be another finite integer such that $n \geq 1$, and let N_u be an integer such that $1 \leq N_u \leq n$. Let Ω be a bounded open domain of \mathbb{R}^d , with generic point $\mathbf{x} = (x_1, \dots, x_d)$, with boundary $\partial\Omega$, and let be $\bar{\Omega} = \Omega \cup \partial\Omega$.

6.1 Stochastic Elliptic Operator and Boundary Value Problem

Let $[\mathbf{K}] = \{[\mathbf{K}(\mathbf{x})], \mathbf{x} \in \bar{\Omega}\}$ be a non-Gaussian random field, in high stochastic dimension, defined on a probability space $(\Theta, \mathcal{T}, \mathcal{P})$, indexed by $\bar{\Omega}$, with values in $\mathbb{M}_n^+(\mathbb{R})$. It should be noted that random field $[\mathbf{K}]$ being with values in $\mathbb{M}_n^+(\mathbb{R})$,

random field $[\mathbf{K}]$ cannot be a Gaussian field. Such a random field $[\mathbf{K}]$ allows for constructing the coefficients of a given stochastic elliptic operator $\mathbf{u} \mapsto \mathcal{D}_{\mathbf{x}}(\mathbf{u})$ that applies to the random field $\mathbf{u}(\mathbf{x}) = (u_1(\mathbf{x}), \dots, u_{N_u}(\mathbf{x}))$, indexed by Ω , with values in \mathbb{R}^{N_u} .

The boundary value problem that is formulated in \mathbf{u} involves the stochastic elliptic operator $\mathcal{D}_{\mathbf{x}}$, and some Dirichlet and Neumann boundary conditions are given on $\partial\Omega$ that is written as the union of three parts, $\partial\Omega = \Gamma_0 \cup \Gamma \cup \Gamma_1$. On the part Γ_0 , a Dirichlet condition is given. The part Γ corresponds to the part of the boundary on which there is a zero Neumann condition and on which experimental data are available for \mathbf{u} . On the part Γ_1 , a Neumann condition is given. The boundary value problems, involving such a stochastic elliptic operator $\mathcal{D}_{\mathbf{x}}$, are encountered in many problems of computational sciences and engineering.

■ *Examples of stochastic elliptic operators.*

- (i) For a three-dimensional anisotropic diffusion problem, the stochastic elliptic differential operator $\mathcal{D}_{\mathbf{x}}$ relative to the density u of the diffusing medium is written as

$$\{\mathcal{D}_{\mathbf{x}}(u)\}(\mathbf{x}) = -\operatorname{div}_{\mathbf{x}}([\mathbf{K}(\mathbf{x})] \nabla_{\mathbf{x}} u(\mathbf{x})), \quad \mathbf{x} \in \Omega, \quad (26.1)$$

in which $d = n = 3$ and $N_u = 1$ and where $\{[\mathbf{K}(\mathbf{x})], \mathbf{x} \in \Omega\}$ is the $\mathbb{M}_n^+(\mathbb{R})$ -valued random field of the medium.

- (ii) For the wave propagation inside a three-dimensional random heterogeneous anisotropic linear elastic medium, we have $d = 3$, $n = 6$, and $N_u = 3$, and the stochastic elliptic differential operator $\mathcal{D}_{\mathbf{x}}$ relative to the displacement field \mathbf{u} is written as

$$\{\mathcal{D}_{\mathbf{x}}(\mathbf{u})\}(\mathbf{x}) = -[D_{\mathbf{x}}]^T [\mathbf{K}(\mathbf{x})] [D_{\mathbf{x}}] \mathbf{u}(\mathbf{x}), \quad \mathbf{x} \in \Omega, \quad (26.2)$$

in which $\{[\mathbf{K}(\mathbf{x})], \mathbf{x} \in \Omega\}$ is the $\mathbb{M}_n^+(\mathbb{R})$ -valued elasticity random field of the medium deduced from the fourth-order tensor-valued elasticity field $\{\mathbf{C}_{ijkl}(\mathbf{x}), \mathbf{x} \in \Omega\}$ by the following equation,

$$[\mathbf{K}] = \begin{bmatrix} \mathbf{C}_{1111} & \mathbf{C}_{1122} & \mathbf{C}_{1133} & \sqrt{2}\mathbf{C}_{1112} & \sqrt{2}\mathbf{C}_{1113} & \sqrt{2}\mathbf{C}_{1123} \\ \mathbf{C}_{2211} & \mathbf{C}_{2222} & \mathbf{C}_{2233} & \sqrt{2}\mathbf{C}_{2212} & \sqrt{2}\mathbf{C}_{2213} & \sqrt{2}\mathbf{C}_{2223} \\ \mathbf{C}_{3311} & \mathbf{C}_{3322} & \mathbf{C}_{3333} & \sqrt{2}\mathbf{C}_{3312} & \sqrt{2}\mathbf{C}_{3313} & \sqrt{2}\mathbf{C}_{3323} \\ \sqrt{2}\mathbf{C}_{1211} & \sqrt{2}\mathbf{C}_{1222} & \sqrt{2}\mathbf{C}_{1233} & 2\mathbf{C}_{1212} & 2\mathbf{C}_{1213} & 2\mathbf{C}_{1223} \\ \sqrt{2}\mathbf{C}_{1311} & \sqrt{2}\mathbf{C}_{1322} & \sqrt{2}\mathbf{C}_{1333} & 2\mathbf{C}_{1312} & 2\mathbf{C}_{1313} & 2\mathbf{C}_{1323} \\ \sqrt{2}\mathbf{C}_{2311} & \sqrt{2}\mathbf{C}_{2322} & \sqrt{2}\mathbf{C}_{2333} & 2\mathbf{C}_{2312} & 2\mathbf{C}_{2313} & 2\mathbf{C}_{2323} \end{bmatrix}, \quad (26.3)$$

in which $[D_{\mathbf{x}}]$ is the differential operator,

$$[D_{\mathbf{x}}] = [M^{(1)}] \frac{\partial}{\partial x_1} + [M^{(2)}] \frac{\partial}{\partial x_2} + [M^{(3)}] \frac{\partial}{\partial x_3}, \quad (26.4)$$

where $[M^{(1)}]$, $[M^{(2)}]$ and $[M^{(3)}]$ are the $(n \times N_u)$ real matrices defined by

$$[M^{(1)}] = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & \frac{1}{\sqrt{2}} & 0 \\ 0 & 0 & \frac{1}{\sqrt{2}} \\ 0 & 0 & 0 \end{bmatrix}, [M^{(2)}] = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \\ \frac{1}{\sqrt{2}} & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \frac{1}{\sqrt{2}} \end{bmatrix}, [M^{(3)}] = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \\ \frac{1}{\sqrt{2}} & 0 & 0 \\ 0 & \frac{1}{\sqrt{2}} & 0 \end{bmatrix}. \quad (26.5)$$

■ *Example of a time-independent stochastic boundary value problem in linear elasticity.*

Let be $d = 3$, $n = 6$, and $N_u = 3$. Let us consider the boundary value problem related to the linear elastostatic deformation of a three-dimensional random heterogeneous anisotropic linear elastic medium occupying domain Ω , for which an experimental displacement field $\mathbf{u}^{\text{exp},\ell}$ is measured on Γ . Let $\mathbf{n}(\mathbf{x}) = (n_1(\mathbf{x}), n_2(\mathbf{x}), n_3(\mathbf{x}))$ be the unit normal to $\partial\Omega$, exterior to Ω . The stochastic boundary value problem is written as

$$\mathcal{D}_{\mathbf{x}}(\mathbf{u}) = \mathbf{0} \quad \text{in } \Omega, \quad (26.6)$$

in which the stochastic operator $\mathcal{D}_{\mathbf{x}}$ is defined by Eq. (26.2), where the Dirichlet condition is

$$\mathbf{u} = \mathbf{0} \quad \text{on } \Gamma_0, \quad (26.7)$$

and where the Neumann condition is written as

$$[\mathcal{M}_{\mathbf{n}}(\mathbf{x})]^T [\mathbf{K}(\mathbf{x})][D_{\mathbf{x}}] \mathbf{u}(\mathbf{x}) = \mathbf{0} \quad \text{on } \Gamma, \text{ and } = \mathbf{f}_{\Gamma_1} \quad \text{on } \Gamma_1, \quad (26.8)$$

in which $[\mathcal{M}_{\mathbf{n}}(\mathbf{x})] = [M^{(1)}] n_1(\mathbf{x}) + [M^{(2)}] n_2(\mathbf{x}) + [M^{(3)}] n_3(\mathbf{x})$ and where \mathbf{f}_{Γ_1} is a given surface force field applied to Γ_1 . The boundary value problem defined by Eqs. (26.6), (26.7) and (26.8) is typically the one for which the random field $\{\mathbf{K}(\mathbf{x}), \mathbf{x} \in \Omega\}$ has to be identified by solving a statistical inverse problem in high stochastic dimension with the partial and limited experimental data $\{\mathbf{u}^{\text{exp},\ell}, \ell = 1, \dots, v_{\text{exp}}\}$.

6.2 Stochastic Finite Element Approximation of the Stochastic Boundary Value Problem

Let us assume that the weak formulation of the stochastic boundary value problem involving stochastic elliptic operator $\mathcal{D}_{\mathbf{x}}$ is discretized by using the finite element method. Let $\mathcal{I} = \{\mathbf{x}^1, \dots, \mathbf{x}^{N_p}\} \subset \Omega$ be the finite subset of Ω made up of all the

integrating points in the numerical integration formulae for the finite elements [79] used in the mesh of Ω . Let $\mathbf{U} = (U_1, \dots, U_{N_U})$ be the random model observation with values in \mathbb{R}^{N_U} , constituted of the N_U observed degrees of freedom for which there are available experimental data (corresponding to some degrees of freedom of the nodal values of \mathbf{u} at all the nodes in Γ). The random observation vector \mathbf{U} is the unique deterministic nonlinear transformation of the finite family of the N_p dependent random matrices $[\mathbf{K}(\mathbf{x}^1)], \dots, [\mathbf{K}(\mathbf{x}^{N_p})]$ such that

$$\mathbf{U} = \mathbf{h}([\mathbf{K}(\mathbf{x}^1)], \dots, [\mathbf{K}(\mathbf{x}^{N_p})]), \quad (26.9)$$

in which

$$([K^1], \dots, [K^{N_p}]) \mapsto \mathbf{h}([K^1], \dots, [K^{N_p}]) : \mathbb{M}_n^+(\mathbb{R}) \times \dots \times \mathbb{M}_n^+(\mathbb{R}) \longrightarrow \mathbb{R}^{N_U}, \quad (26.10)$$

is a deterministic nonlinear transformation that is constructed by solving the discretized boundary value problem.

6.3 Experimental Data Sets

It is assumed that v_{exp} experimental data sets are available for the random observation vector \mathbf{U} . Each experimental data set corresponds to partial experimental data (only some degrees of freedom of the nodal values of the displacement field on Γ are observed) with a limited length (v_{exp} is relatively small). These v_{exp} experimental data sets correspond to measurements of v_{exp} experimental configurations associated with the same boundary value problem. For configuration ℓ , with $\ell = 1, \dots, v_{\text{exp}}$, the observation vector (corresponding to \mathbf{U} for the computational model) is denoted by $\mathbf{u}^{\text{exp},\ell}$ and belongs to \mathbb{R}^{N_U} . Therefore, the available data are made up of the v_{exp} vectors $\mathbf{u}^{\text{exp},1}, \dots, \mathbf{u}^{\text{exp},v_{\text{exp}}}$ in \mathbb{R}^{N_U} . It is assumed that $\mathbf{u}^{\text{exp},1}, \dots, \mathbf{u}^{\text{exp},v_{\text{exp}}}$ correspond to v_{exp} independent realizations of a random vector \mathbf{U}^{exp} defined on a probability space $(\Theta^{\text{exp}}, \mathcal{T}^{\text{exp}}, \mathcal{P}^{\text{exp}})$ and correspond to random observation vector \mathbf{U} of the stochastic computational model (random vectors \mathbf{U}^{exp} and \mathbf{U} are not defined on the same probability space). It should be noted that the experimental data do not correspond to a field measurement in $\overline{\Omega}$ but only to a field measurement on the part Γ of the boundary $\partial\Omega$ of domain Ω . This is the reason why the experimental data are called “partial”.

6.4 Statistical Inverse Problem to be Solved

The problem that must be solved is the identification of non-Gaussian matrix-valued random field $[\mathbf{K}]$, using the partial and limited experimental data $\mathbf{u}^{\text{exp},1}, \dots, \mathbf{u}^{\text{exp},v_{\text{exp}}}$ relative to the random observation vector \mathbf{U} of the stochastic computational model and defined by Eq. (26.9).

7 Parametric Model-Based Representation for the Model Parameters and Model Observations

As explained in the previous paragraph entitled Sect. 2.2, a parametric model-based representation $\mathbf{U} = \mathcal{B}(\boldsymbol{\Xi}, [z])$ must be constructed in order to be able to solve the statistical inverse problem allowing random model parameter $[\mathbf{K}]$ to be identified using the experimental data sets. For that, it is needed to introduce:

- a representation of the non-Gaussian positive-definite matrix-valued random field $[\mathbf{K}]$ that is expressed as a transformation \mathcal{G} of a non-Gaussian second-order symmetric matrix-valued random field $[\mathbf{G}]$, such that for all \mathbf{x} in Ω , $[\mathbf{K}(\mathbf{x})] = \mathcal{G}([\mathbf{G}(\mathbf{x})])$, where \mathcal{G} is independent of \mathbf{x} (in fact, two types of representation are proposed),
- a truncated reduced representation of random field $[\mathbf{G}]$,
- a parameterized representation for non-Gaussian random field $[\mathbf{K}]$,
- the parametric model-based representation $\mathbf{U} = \mathcal{B}(\boldsymbol{\Xi}, [z])$.

7.1 Introduction a Class of Lower-Bounded Random Fields for $[\mathbf{K}]$ and Normalization

In order to normalize random field $[\mathbf{K}]$, a deterministic function $\mathbf{x} \mapsto [\underline{K}(\mathbf{x})]$ from Ω into $\mathbb{M}_n^+(\mathbb{R})$ is introduced such that, for all \mathbf{x} in Ω and for all \mathbf{z} in \mathbb{R}^n , $\langle [\underline{K}(\mathbf{x})] \mathbf{z}, \mathbf{z} \rangle \geq \underline{k}_0 \|\mathbf{z}\|^2$ and $\langle [\underline{K}(\mathbf{x})] \mathbf{z}, \mathbf{z} \rangle \leq \underline{k}_1 \|\mathbf{z}\|^2$ in which \underline{k}_0 and \underline{k}_1 are positive real constants, independent of \mathbf{x} , such that $0 < \underline{k}_0 < \underline{k}_1 < +\infty$. These two technical inequalities correspond to the mathematical hypotheses that are required for obtaining a uniform deterministic elliptic operator whose coefficient is $[\underline{K}]$.

We introduce the following class of non-Gaussian positive-definite matrix-valued random fields $[\mathbf{K}]$, which admit a positive-definite matrix-valued lower bound, defined by

$$[\mathbf{K}(\mathbf{x})] = \frac{1}{1+\varepsilon} [\underline{L}(\mathbf{x})]^T \{ \varepsilon[I_n] + [\mathbf{K}_0(\mathbf{x})] \} [\underline{L}(\mathbf{x})], \quad \forall \mathbf{x} \in \Omega, \quad (26.11)$$

in which $\varepsilon > 0$ is any fixed positive real number, where $[\underline{L}(\mathbf{x})]$ is the upper triangular $(n \times n)$ real matrix such that $[\underline{K}(\mathbf{x})] = [\underline{L}(\mathbf{x})]^T [\underline{L}(\mathbf{x})]$ and where $[\mathbf{K}_0] = \{[\mathbf{K}_0(\mathbf{x})], \mathbf{x} \in \Omega\}$ is any random field indexed by Ω , with values in $\mathbb{M}_n^+(\mathbb{R})$. Equation (26.11) can be inverted,

$$[\mathbf{K}_0(\mathbf{x})] = (1+\varepsilon)[\underline{L}(\mathbf{x})]^{-T} [\mathbf{K}(\mathbf{x})] [\underline{L}(\mathbf{x})]^{-1} - \varepsilon[I_n], \quad \forall \mathbf{x} \in \Omega. \quad (26.12)$$

We have the following important properties for the class defined:

- Random field $[\mathbf{K}]$ is effective with values in $\mathbb{M}_n^+(\mathbb{R})$. For all \mathbf{x} fixed in Ω , the lower bound is the matrix belonging to $\mathbb{M}_n^+(\mathbb{R})$ defined by $[K_\varepsilon(\mathbf{x})] = \frac{\varepsilon}{1+\varepsilon} [\underline{K}(\mathbf{x})]$,

and for all random matrix $[\mathbf{K}_0(\mathbf{x})]$ with values in $\mathbb{M}_n^+(\mathbb{R})$, $[\mathbf{K}(\mathbf{x})]$, defined by Eq. (26.12), is a random matrix with values in a subset of $\mathbb{M}_n^+(\mathbb{R})$ such that $[\mathbf{K}(\mathbf{x})] \geq [K_\varepsilon(\mathbf{x})]$ almost surely.

- For all integer $p \geq 1$, $\{[\mathbf{K}(\mathbf{x})]^{-1}, \mathbf{x} \in \Omega\}$ is a p -order random field with values in $\mathbb{M}_n^+(\mathbb{R})$, i.e., for all \mathbf{x} in Ω , $E\{\|[\mathbf{K}(\mathbf{x})]^{-1}\|_F^p\} < +\infty$ and, in particular, is a second-order random field.
- If $[\mathbf{K}_0]$ is a second-order random field, i.e., for all \mathbf{x} in Ω , $E\{\|\mathbf{K}_0(\mathbf{x})\|_F^2\} < +\infty$, then $[\mathbf{K}]$ is a second-order random field, i.e., for all \mathbf{x} in Ω , $E\{\|\mathbf{K}(\mathbf{x})\|_F^2\} < +\infty$.
- If function $[K]$ is chosen as the mean function of random field $[\mathbf{K}]$, i.e., $[K(\mathbf{x})] = E\{[\mathbf{K}(\mathbf{x})]\}$ for all \mathbf{x} , then $E\{[\mathbf{K}_0(\mathbf{x})]\}$ is equal to $[I_n]$, which shows that random field $[\mathbf{K}_0]$ is normalized.
- The class of random fields defined by Eq. (26.11) yields a uniform stochastic elliptic operator $\mathcal{D}_{\mathbf{x}}$ that allows for studying the existence and uniqueness of a second-order random solution of a stochastic boundary value problem involving $\mathcal{D}_{\mathbf{x}}$.

7.2 Construction of the Nonlinear Transformation \mathcal{G}

Two types of representation of random field $[\mathbf{K}_0]$ is proposed hereinafter: An “exponential-type representation” and a “square-type representation”.

■ *Exponential-type representation of random field $[\mathbf{K}_0]$.*

For all second-order random field $[\mathbf{G}] = \{[\mathbf{G}(\mathbf{x})], \mathbf{x} \in \Omega\}$ with values in $\mathbb{M}_n^S(\mathbb{R})$, which is not assumed to be Gaussian, the random field $[\mathbf{K}_0]$ defined by

$$[\mathbf{K}_0(\mathbf{x})] = \exp_{\mathbb{M}}([\mathbf{G}(\mathbf{x})]), \quad \forall \mathbf{x} \in \Omega, \quad (26.13)$$

in which $\exp_{\mathbb{M}}$ denotes the exponential of symmetric square real matrices, is a random field with values in $\mathbb{M}_n^+(\mathbb{R})$. If $[\mathbf{K}_0]$ is any random field with values in $\mathbb{M}_n^+(\mathbb{R})$, then there exists a unique random field $[\mathbf{G}]$ with values in $\mathbb{M}_n^S(\mathbb{R})$ such that

$$[\mathbf{G}(\mathbf{x})] = \log_{\mathbb{M}}([\mathbf{K}_0(\mathbf{x})]), \quad \forall \mathbf{x} \in \Omega, \quad (26.14)$$

in which $\log_{\mathbb{M}}$ is the reciprocity mapping of $\exp_{\mathbb{M}}$, which is defined on $\mathbb{M}_n^+(\mathbb{R})$ with values in $\mathbb{M}_n^S(\mathbb{R})$, but in general, random field $[\mathbf{G}]$ is not a second-order random field. If $[\mathbf{G}]$ is any second-order random field with values in $\mathbb{M}_n^+(\mathbb{R})$, in general, the random field $[\mathbf{K}_0] = \exp_{\mathbb{M}}([\mathbf{G}])$ is not a second-order random field. Nevertheless, it can be proved that, if $[\mathbf{K}_0]$ and $[\mathbf{K}_0]^{-1}$ are second-order random fields with values in $\mathbb{M}_n^+(\mathbb{R})$, then there exists a second-order random field $[\mathbf{G}]$ with values in $\mathbb{M}_n^S(\mathbb{R})$ such that $[\mathbf{K}_0] = \exp_{\mathbb{M}}([\mathbf{G}])$.

■ *Square-type representation of random field $[\mathbf{K}_0]$.*

Let $g \mapsto h(g; a)$ be a given function from \mathbb{R} in \mathbb{R}^+ , depending on one positive real parameter a . For all fixed a , it is assumed that:

- $h(\cdot; a)$ is a strictly monotonically increasing function on \mathbb{R} , which means that $h(g; a) < h(g'; a)$ if $-\infty < g < g' < +\infty$;

- (ii) there are real numbers $0 < c_h < +\infty$ and $0 < c_a < +\infty$, such that, for all g in \mathbb{R} , we have $h(g; a) \leq c_a + c_h g^2$.

The introduced hypotheses imply that, for all $a > 0$, $g \mapsto h(g; a)$ is a one-to-one mapping from \mathbb{R} onto \mathbb{R}^+ and consequently, the reciprocity mapping, $v \mapsto h^{-1}(v; a)$, is a strictly monotonically increasing function from \mathbb{R}^+ onto \mathbb{R} . The square-type representation of random field $[\mathbf{K}_0]$, indexed by Ω , with values in $\mathbb{M}_n^+(\mathbb{R})$, is defined by

$$[\mathbf{K}_0(\mathbf{x})] = \mathbb{L}([\mathbf{G}(\mathbf{x})]), \quad \forall \mathbf{x} \in \Omega, \quad (26.15)$$

in which $[\mathbf{G}] = \{[\mathbf{G}(\mathbf{x})], \mathbf{x} \in \Omega\}$ is a second-order random field with values in $\mathbb{M}_n^S(\mathbb{R})$ and where $[G] \mapsto \mathbb{L}([G])$ is a measurable mapping from $\mathbb{M}_n^S(\mathbb{R})$ into $\mathbb{M}_n^+(\mathbb{R})$ which is defined as follows. The matrix $[K_0] = \mathbb{L}([G]) \in \mathbb{M}_n^+(\mathbb{R})$ is written as $[K_0] = [L]^T [L]$ in which $[L]$ belongs to $\mathbb{M}_n^U(\mathbb{R})$, which is written as $[L] = \mathcal{L}([G])$ where $[G] \mapsto \mathcal{L}([G])$ is the measurable mapping from $\mathbb{M}_n^S(\mathbb{R})$ into $\mathbb{M}_n^U(\mathbb{R})$ defined by

$$[\mathcal{L}([G])]_{jk} = [G]_{jk}, \quad 1 \leq j < k \leq n, \quad [\mathcal{L}([G])]_{jj} = \sqrt{h([G]_{jj}; a_j)}, \quad 1 \leq j \leq n, \quad (26.16)$$

in which a_1, \dots, a_n are positive real numbers. If $[\mathbf{K}_0]$ is any random field indexed by Ω with values in $\mathbb{M}_n^+(\mathbb{R})$, then there exists a unique random field $[\mathbf{G}]$ with values in $\mathbb{M}_n^S(\mathbb{R})$ such that

$$[\mathbf{G}(\mathbf{x})] = \mathbb{L}^{-1}([\mathbf{K}_0(\mathbf{x})]), \quad \forall \mathbf{x} \in \Omega, \quad (26.17)$$

in which \mathbb{L}^{-1} is the reciprocity function of \mathbb{L} , from $\mathbb{M}_n^+(\mathbb{R})$ into $\mathbb{M}_n^S(\mathbb{R})$, which is explicitly defined as follows. For all $1 \leq j \leq k \leq n$,

$$[\mathbf{G}(\mathbf{x})]_{jk} = [\mathbb{L}^{-1}([\mathbf{L}(\mathbf{x})])]_{jk}, \quad [\mathbf{G}(\mathbf{x})]_{kj} = [\mathbf{G}(\mathbf{x})]_{jk}, \quad (26.18)$$

in which $[L] \mapsto \mathbb{L}^{-1}([L])$ is the unique reciprocity mapping of \mathbb{L} (due to the existence of $v \mapsto h^{-1}(v; a)$) defined on $\mathbb{M}_n^U(\mathbb{R})$ and where $[\mathbf{L}(\mathbf{x})]$ follows from the Cholesky factorization of random matrix $[\mathbf{K}_0(\mathbf{x})] = [\mathbf{L}(\mathbf{x})]^T [\mathbf{L}(\mathbf{x})]$ (see Eq. (26.15)).

Example of function h . An example of such a function is given in *An algebraic prior stochastic model $[\mathbf{K}^{\text{APSM}}]$ for the case of anisotropic statistical fluctuations* of the present section. Nevertheless, for the sake of clarity, we detail it hereinafter. Let $h = h^{\text{APSM}}$ be the function h^{APSM} defined in [58] as follows. Let be $s = \delta/\sqrt{n+1}$ in which δ is a parameter such that $0 < \delta < \sqrt{(n+1)/(n-1)}$ and which allows the statistical fluctuations level to be controlled. Let be $a_j = 1/(2s^2) + (1-j)/2 > 0$ and $h^{\text{APSM}}(g; a) = 2s^2 F_{\Gamma_a}^{-1}(F_W(g/s))$ with $F_W(\tilde{w}) = \int_{-\infty}^{\tilde{w}} \frac{1}{\sqrt{2\pi}} \exp(-\frac{1}{2}w^2) dw$ and $F_{\Gamma_a}^{-1}(u) = \gamma$ the reciprocal function such that $F_{\Gamma_a}(\gamma) = u$ with $F_{\Gamma_a}(\gamma) = \int_0^\gamma \frac{1}{\Gamma(a)} t^{a-1} e^{-t} dt$ and $\Gamma(a) = \int_0^{+\infty} t^{a-1} e^{-t} dt$. Then, for all $j = 1, \dots, n$, it can be proved that $g \mapsto h^{\text{APSM}}(g; a_j)$ is a strictly monotonically increasing function

from \mathbb{R} into \mathbb{R}^+ and there are positive real numbers c_h and c_{a_j} such that, for all g in \mathbb{R} , we have $h^{\text{APSM}}(g; a_j) \leq c_{a_j} + c_h g^2$. In addition, it can easily be seen that the reciprocity function is written as $h^{\text{APSM}^{-1}}(v; a) = s F_W^{-1}(F_{\Gamma_a}(v/(2s^2)))$.

■ *Construction of the transformation \mathcal{G} and its inverse \mathcal{G}^{-1} .*

For the *exponential-type representation*, the transformation \mathcal{G} is defined by Eq. (26.11) with Eq. (26.13), and its inverse \mathcal{G}^{-1} is defined by Eq. (26.14) with Eq. (26.12), and is such that, for all \mathbf{x} in Ω ,

$$[\mathbf{K}(\mathbf{x})] = \mathcal{G}([\mathbf{G}(\mathbf{x})]) := \frac{1}{1 + \varepsilon} [\underline{L}(\mathbf{x})]^T \{ \varepsilon [I_n] + \exp_{\mathbb{M}}([\mathbf{G}(\mathbf{x})]) \} [\underline{L}(\mathbf{x})], \quad (26.19)$$

$$[\mathbf{G}(\mathbf{x})] = \mathcal{G}^{-1}([\mathbf{K}(\mathbf{x})]) := \log_{\mathbb{M}}\{ (1 + \varepsilon)[\underline{L}(\mathbf{x})]^{-T} [\mathbf{K}(\mathbf{x})] [\underline{L}(\mathbf{x})]^{-1} - \varepsilon [I_n] \}. \quad (26.20)$$

For the *square-type representation*, the transformation \mathcal{G} is defined by Eq. (26.11) with Eq. (26.15), and its inverse \mathcal{G}^{-1} is defined by Eq. (26.17) with Eq. (26.12), and is such that, for all \mathbf{x} in Ω ,

$$[\mathbf{K}(\mathbf{x})] = \mathcal{G}([\mathbf{G}(\mathbf{x})]) := \frac{1}{1 + \varepsilon} [\underline{L}(\mathbf{x})]^T \{ \varepsilon [I_n] + [\mathcal{L}([\mathbf{G}(\mathbf{x})])]^T [\mathcal{L}([\mathbf{G}(\mathbf{x})])] \} [\underline{L}(\mathbf{x})], \quad (26.21)$$

$$[\mathbf{G}(\mathbf{x})] = \mathcal{G}^{-1}([\mathbf{K}(\mathbf{x})]) := \mathbb{L}^{-1}\{ (1 + \varepsilon)[\underline{L}(\mathbf{x})]^{-T} [\mathbf{K}(\mathbf{x})] [\underline{L}(\mathbf{x})]^{-1} - \varepsilon [I_n] \}. \quad (26.22)$$

Let $\mathbb{M}_n^{+b}(\mathbb{R})$ be the subset of $\mathbb{M}_n^+(\mathbb{R})$, constituted of all the positive-definite matrices $[K]$ such that, for all \mathbf{x} in Ω , the matrix $[K] - [K_\varepsilon(\mathbf{x})] > 0$. Transformation \mathcal{G} maps $\mathbb{M}_n^S(\mathbb{R})$ into $\mathbb{M}_n^{+b}(\mathbb{R}) \subset \mathbb{M}_n^+(\mathbb{R})$ and \mathcal{G}^{-1} maps $\mathbb{M}_n^{+b}(\mathbb{R})$ into $\mathbb{M}_n^S(\mathbb{R})$.

7.3 Truncated Reduced Representation of Second-Order Random Field $[\mathbf{G}]$ and Its Polynomial Chaos Expansion

Two versions of the nonlinear transformation \mathcal{G} from $\mathbb{M}_n^S(\mathbb{R})$ into $\mathbb{M}_n^+(\mathbb{R})$ are defined by Eqs. (26.19) and (26.21). For the statistical inverse problem, $[\mathbf{G}]$ is chosen in the class of the second-order random field indexed by Ω with values in $\mathbb{M}_n^S(\mathbb{R})$, which is reduced using its truncated Karhunen-Loève decomposition in which the random coordinates are represented using a truncated polynomial Gaussian chaos. Consequently, the approximation $[\mathbf{G}^{(m,N,N_g)}]$ of the non-Gaussian second-order random field $[\mathbf{G}]$ is introduced such that

$$[\mathbf{G}^{(m,N,N_g)}(\mathbf{x})] = [G_0(\mathbf{x})] + \sum_{i=1}^m \sqrt{\lambda_i} [G_i(\mathbf{x})] \eta_i, \quad (26.23)$$

$$\eta_i = \sum_{j=1}^N y_i^j \Psi_j(\Xi), \quad (26.24)$$

in which

- $\lambda_1 \geq \dots \geq \lambda_m > 0$ are the dominant eigenvalues and $[G_1], \dots, [G_m]$ are the corresponding orthonormal eigenfunctions of the covariance operator Cov_G of random field $[G]$. The kernel of this covariance operator is the tensor-valued cross covariance function $C_G(\mathbf{x}, \mathbf{x}')$ of $[G]$, which is assumed to be square integrable on $\Omega \times \Omega$,
- $\{\Psi_j\}_{j=1}^N$ only depends on a random vector $\boldsymbol{\Xi} = (\Xi_1, \dots, \Xi_{N_g})$ of $N_g \leq m$ independent normalized Gaussian random variables Ξ_1, \dots, Ξ_{N_g} defined on probability space $(\Theta, \mathcal{T}, \mathcal{P})$,
- $\{\Psi_j\}_{j=1}^N$ are the polynomial Gaussian chaos that are written as $\Psi_j(\boldsymbol{\Xi}) = \Phi_{\alpha_1}(\Xi_1) \times \dots \times \Phi_{\alpha_{N_g}}(\Xi_{N_g})$, in which j is the index associated with the multi-index $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_{N_g})$ in \mathbb{N}^{N_g} , the degree of $\Psi_j(\boldsymbol{\Xi})$ is $\alpha_1 + \dots + \alpha_{N_g} \leq N_d$ and where $\Phi_{\alpha_k}(\Xi_k)$ is the normalized univariate Hermite polynomial on \mathbb{R} . Consequently, $\{\Psi_j\}_{j=1}^N$ are composed of the normalized multivariate Hermite polynomials such that $E\{\Psi_j(\boldsymbol{\Xi}) \Psi_{j'}(\boldsymbol{\Xi})\} = \delta_{jj'}$,
- the constant Hermite polynomial $\Psi_0(\boldsymbol{\Xi}) = 1$ with index $j = 0$ (corresponding to the zero multi-index $(0, \dots, 0)$) is not included in Eq. (26.24). Consequently, the integer N is such that $N = (N_d + N_g)! / (N_d! N_g!) - 1$ where N_d is the maximum degree of the normalized multivariate Hermite polynomials,
- y_i^j are the coefficients that are supposed to verify $\sum_{j=1}^N y_i^j y_{i'}^j = \delta_{ii'}$, which ensures that the random variables, $\{\eta_i\}_{i=1}^m$, are uncorrelated centered random variables with unit variance, which means that $E\{\eta_i \eta_{i'}\} = \delta_{ii'}$. The relation between the coefficients can be rewritten as

$$[z]^T [z] = [I_m], \quad (26.25)$$

in which $[z] \in \mathbb{M}_{N,m}(\mathbb{R})$ is such that

$$[z]_{ji} = y_i^j, \quad 1 \leq i \leq m, \quad 1 \leq j \leq N. \quad (26.26)$$

Introducing the random vectors $\boldsymbol{\eta} = (\eta_1, \dots, \eta_m)$ and $\boldsymbol{\Psi}(\boldsymbol{\Xi}) = (\Psi_1(\boldsymbol{\Xi}), \dots, \Psi_N(\boldsymbol{\Xi}))$, Eq. (26.24) can be rewritten as

$$\boldsymbol{\eta} = [z]^T \boldsymbol{\Psi}(\boldsymbol{\Xi}). \quad (26.27)$$

Equation (26.25) means that $[z]$ belongs to the compact Stiefel manifold

$$\mathbb{V}_m(\mathbb{R}^N) = \{[z] \in \mathbb{M}_{N,m}(\mathbb{R}); [z]^T [z] = [I_m]\}. \quad (26.28)$$

7.4 Parameterization of Compact Stiefel Manifold $\mathbb{V}_m(\mathbb{R}^N)$

A parametrization of $\mathbb{V}_m(\mathbb{R}^N)$ defined by Eq. (26.28) is given hereinafter. For all $[z_0]$ fixed in $\mathbb{V}_m(\mathbb{R}^N)$, let $T_{[z_0]}$ be the tangent vector space to $\mathbb{V}_m(\mathbb{R}^N)$ at $[z_0]$. The objective is to construct a mapping $[w] \mapsto [z] = \mathcal{R}_{[z_0]}([w])$ from $T_{[z_0]}$ onto $\mathbb{V}_m(\mathbb{R}^N)$ such that $\mathcal{R}_{[z_0]}([0]) = [z_0]$ and such that, if $[w]$ belongs to a subset of $T_{[z_0]}$, this subset being centered in $[w] = [0]$ and having a sufficiently small diameter, then $[z] = \mathcal{R}_{[z_0]}([w])$ belongs to a subset of $\mathbb{V}_m(\mathbb{R}^N)$, approximatively centered in $[z] = [z_0]$. There are several possibilities for constructing such a parameterization (see, for instance, [1, 19]). For instance, a parameterization can be constructed as described in [48] using the geometry of algorithms with orthogonality constraints [19]. Hereinafter, we present the construction proposed in [1] for which the algorithm has a small complexity with respect to the other possible possibilities. Let us assume that $N > m$ that is generally the case. For $[z_0]$ fixed in $\mathbb{V}_m(\mathbb{R}^N)$, the mapping $\mathcal{R}_{[z_0]}$ is defined by

$$[z] = \mathcal{R}_{[z_0]}([w]) := \text{qr}([z_0] + \sigma [w]), \quad [w] \in T_{[z_0]}, \quad (26.29)$$

in which qr is the mapping that corresponds to the QR economy-size decomposition of matrix $[z_0] + \sigma [w]$, for which only the first m columns of matrix $[q]$ such that $[z_0] + \sigma [w] = [q] [r]$ are computed and such that $[z]^T [z] = [I_m]$. In Eq. (26.29), σ allows the diameter of the subset of $T_{[z_0]}$ centered in $[0]$ to be controlled.

7.5 Parameterized Representation for Non-Gaussian Random Field $[\mathbf{K}]$

Let $\{[\mathbf{G}^{(m,N,N_g)}(\mathbf{x})], \mathbf{x} \in \Omega\}$ be defined by Eqs. (26.23) and (26.24), and let \mathcal{G} be defined by Eq. (26.19) for the *exponential-type representation* and by Eq. (26.21) for the *square-type representation*. The corresponding parameterized representation for non-Gaussian positive-definite matrix-valued random field $\{[\mathbf{K}(\mathbf{x})], \mathbf{x} \in \Omega\}$ is denoted by $\{[\mathbf{K}^{(m,N,N_g)}(\mathbf{x})], \mathbf{x} \in \Omega\}$ and is rewritten, for all \mathbf{x} in Ω , as

$$[\mathbf{K}^{(m,N,N_g)}(\mathbf{x})] = \mathcal{K}^{(m,N,N_g)}(\mathbf{x}, \boldsymbol{\Xi}, [z]), \quad (26.30)$$

in which $(\mathbf{x}, \boldsymbol{\xi}, [z]) \mapsto \mathcal{K}^{(m,N,N_g)}(\mathbf{x}, \boldsymbol{\xi}, [z])$ is a deterministic mapping defined on $\Omega \times \mathbb{R}^{N_g} \times \mathbb{V}_m(\mathbb{R}^N)$ with values in $\mathbb{M}_n^+(\mathbb{R})$ such that

$$\mathcal{K}^{(m,N,N_g)}(\mathbf{x}, \boldsymbol{\xi}, [z]) = \mathcal{G}([G_0(\mathbf{x})] + \sum_{i=1}^m \sqrt{\lambda_i} [G_i(\mathbf{x})] \{[z]^T \Psi(\boldsymbol{\xi})\}_i). \quad (26.31)$$

7.6 Parametric Model-Based Representation of Random Observation Model \mathbf{U}

From Eqs. (26.9) and (26.30), the parametric model-based representation of random model observation \mathbf{U} with values in \mathbb{R}^{N_U} , corresponding to the representation $\{[\mathbf{K}^{(m,N,N_g)}(\mathbf{x})], \mathbf{x} \in \Omega\}$ of random field $\{[\mathbf{K}(\mathbf{x})], \mathbf{x} \in \Omega\}$, is denoted by $\mathbf{U}^{(m,N,N_g)}$ and is written as

$$\mathbf{U}^{(m,N,N_g)} = \mathcal{B}^{(m,N,N_g)}(\boldsymbol{\Xi}, [z]), \quad (26.32)$$

in which $(\xi, [z]) \mapsto \mathcal{B}^{(m,N,N_g)}(\xi, [z])$ is a deterministic mapping defined on $\mathbb{R}^{N_g} \times \mathbb{V}_m(\mathbb{R}^N)$ with values in \mathbb{R}^{N_U} such that

$$\mathcal{B}^{(m,N,N_g)}(\xi, [z]) = \mathbf{h}(\mathcal{K}^{(m,N,N_g)}(\mathbf{x}^1, \xi, [z]), \dots, \mathcal{K}^{(m,N,N_g)}(\mathbf{x}^{N_p}, \xi, [z])). \quad (26.33)$$

For N_p fixed, the sequence $\{\mathbf{U}^{(m,N,N_g)}\}_{m,N,N_g}$ of \mathbb{R}^{N_U} -valued random variables converge to \mathbf{U} in \mathcal{L}_{N_U} ².

8 Methodology for Solving the Statistical Inverse Problem in High Stochastic Dimension

A general methodology is presented for solving the statistical inverse problem defined in the previous section entitled Sect. 6. The steps of the identification procedure are defined hereinafter.

8.1 Step 1: Introduction of a Family $\{[\mathbf{K}^{\text{APSM}}(\mathbf{x}; \mathbf{s})]; \mathbf{x} \in \Omega\}$ of Algebraic Prior Stochastic Models (APSM) for Non-Gaussian Random Field $[\mathbf{K}]$

The first step consists in introducing a family $\{[\mathbf{K}^{\text{APSM}}(\mathbf{x}; \mathbf{s})], \mathbf{x} \in \Omega\}$ of algebraic prior stochastic models (APSM) for the non-Gaussian second-order random field $[\mathbf{K}]$, defined on $(\Theta, \mathcal{T}, \mathcal{P})$, indexed by Ω , with values in $\mathbb{M}_n^+(\mathbb{R})$, which has been introduced in the previous paragraph entitled Sect. 6.1. This family depends on an unknown hyperparameter \mathbf{s} belonging to an admissible set \mathcal{C}_s that is a subset of \mathbb{R}^{N_s} , for which the dimension, N_s , is assumed to be relatively small, while the stochastic dimension of $[\mathbf{K}^{\text{APSM}}]$ is high. For instance, \mathbf{s} can be made up of the mean function, a matrix-valued lower bound, some spatial-correlation lengths, some parameters controlling the statistical fluctuations and the shape of the tensor-valued correlation function. For \mathbf{s} fixed in \mathcal{C}_s , the probability distribution (i.e., the system of marginal probability distributions) of random field $[\mathbf{K}^{\text{APSM}}]$ and the corresponding generator of independent realizations are assumed to have been constructed and, consequently, are assumed to be known.

An example of such a construction is explicitly given in the next section entitled Sect. 9.

As it has been explained in the previous paragraph entitled Sect. 3.7 of Sect. 3, Step 1 is a fundamental step of the methodology. The real capability to correctly solve the statistical inverse problem in high stochastic dimension is directly related to the pertinence and to the quality of the constructed APSM that allows for enriching the information in order to overcome the lack of experimental data (only partial experimental data are assumed to be available). Such a construction must be carried out using the MaxEnt principle of Information Theory, under the constraints defined by the available information such as the symmetries, the positiveness, the invertibility in mean square, the boundedness, the capability of the APSM to exhibit simultaneously anisotropic statistical fluctuations and some statistical fluctuations in a given symmetry class such as isotropic, cubic, transversely isotropic, orthotropic, etc. In addition, the corresponding generators of realizations must be developed. For the MaxEnt principle and the construction of generators, we refer the reader to ► Chap. 8, “Random Matrix Models and Nonparametric Method for Uncertainty Quantification” section in part II of the present Handbook on Uncertainty Quantification.

8.2 Step 2: Identification of an Optimal Algebraic Prior Stochastic Model (OAPSM) for Non-Gaussian Random Field [K]

The second step consists in identifying an optimal value \mathbf{s}^{opt} in \mathcal{C}_s of hyperparameter \mathbf{s} using experimental data sets $\mathbf{u}^{\text{exp},1}, \dots, \mathbf{u}^{\text{exp},v_{\text{exp}}}$ relative to the random model observation \mathbf{U} of the stochastic computational model, which is written, taking into account Eq. (26.9), as

$$\mathbf{U} = \mathbf{h}([\mathbf{K}^{\text{APSM}}(\mathbf{x}^1; \mathbf{s})], \dots, [\mathbf{K}^{\text{APSM}}(\mathbf{x}^{N_p}; \mathbf{s})]), \quad (26.34)$$

The calculation of \mathbf{s}^{opt} in \mathcal{C}_s can be carried out by using the maximum likelihood method:

$$\mathbf{s}^{\text{opt}} = \arg \max_{\mathbf{s} \in \mathcal{C}_s} \sum_{\ell=1}^{v_{\text{exp}}} \log p_{\mathbf{U}}(\mathbf{u}^{\text{exp},\ell}; \mathbf{s}), \quad (26.35)$$

in which $p_{\mathbf{U}}(\mathbf{u}^{\text{exp},\ell}; \mathbf{s})$ is the value, in $\mathbf{u} = \mathbf{u}^{\text{exp},\ell}$, of the probability density function $p_{\mathbf{U}}(\mathbf{u}; \mathbf{s})$ of the random vector \mathbf{U} defined by Eq. (26.34) and depending on \mathbf{s} . The optimal algebraic prior model $\{[\mathbf{K}^{\text{OAPSM}}(\mathbf{x})], \mathbf{x} \in \Omega\} := \{[\mathbf{K}^{\text{APSM}}(\mathbf{x}; \mathbf{s}^{\text{opt}})], \mathbf{x} \in \Omega\}$ is then obtained. Using the generator of realizations of the optimal APSM, v_{KL} independent realizations $[K^{(1)}], \dots, [K^{(v_{\text{KL}})}]$ can be computed such that, for $\ell = 1, \dots, v_{\text{KL}}$ and $\theta_\ell \in \Theta$, the deterministic field $[K^{(\ell)}] := \{[K^{(\ell)}(\mathbf{x})], \mathbf{x} \in \Omega\}$ is such that

$$[K^{(\ell)}] = \{[\mathbf{K}^{\text{OAPSM}}(\mathbf{x}; \theta_\ell)], \mathbf{x} \in \Omega\}. \quad (26.36)$$

These realizations can be generated at points $\mathbf{x}^1, \dots, \mathbf{x}^{N_p}$ (or at any other points), with v_{KL} as large as it is desired without inducing a significant computational cost.

8.3 Step 3: Choice of an Adapted Representation for Non-Gaussian Random Field [K] and Optimal Algebraic Prior Stochastic Model for Non-Gaussian Random Field [G]

For a fixed choice of the type of representation for random field [K] given by Eq. (26.19) (exponential type) or Eq. (26.21) (square type), the corresponding optimal algebraic prior model $\{[G^{OAPSM}(\mathbf{x})], \mathbf{x} \in \Omega\}$ of random field $\{[G(\mathbf{x})], \mathbf{x} \in \Omega\}$ is written as

$$[G^{OAPSM}(\mathbf{x})] = \mathcal{G}^{-1}([K^{OAPSM}(\mathbf{x})]), \quad \forall \mathbf{x} \in \Omega, \quad (26.37)$$

in which \mathcal{G}^{-1} is defined by Eq. (26.20) (exponential type) or by Eq. (26.22) (square type). It is assumed that random field $[G^{OAPSM}]$ is a second-order random field. From the v_{KL} independent realizations $[K^{(1)}], \dots, [K^{(v_{KL})}]$ of random field $[K^{OAPSM}]$ (see Eq. (26.36)), it can be deduced the v_{KL} independent realizations $[G^{(1)}], \dots, [G^{(v_{KL})}]$ of random field $[G^{OAPSM}]$ such that,

$$[G^{(\ell)}(\mathbf{x})] = \mathcal{G}^{-1}([K^{(\ell)}(\mathbf{x})]), \quad \forall \mathbf{x} \in \Omega, \quad \ell = 1, \dots, v_{KL}. \quad (26.38)$$

8.4 Step 4: Construction of a Truncated Reduced Representation of Second-Order Random Field $[G^{OAPSM}]$

The v_{KL} independent realizations $[G^{(1)}], \dots, [G^{(v_{KL})}]$ of random field $[G^{OAPSM}]$ (computed with Eq. (26.38)) are used to calculate, for random field $[G^{OAPSM}]$, an estimation, $[G_0]$, of the mean function and an estimation, $\text{Cov}_{G^{OAPSM}}$, of the covariance operator whose kernel is the tensor-valued cross covariance function $C_{G^{OAPSM}}(\mathbf{x}, \mathbf{x}')$ that is assumed to be square integrable on $\Omega \times \Omega$. The first m eigenvalues $\lambda_1 \geq \dots \geq \lambda_m$ and the corresponding orthonormal eigenfunctions $[G_1], \dots, [G_m]$ of covariance operator $\text{Cov}_{G^{OAPSM}}$ are then computed. For a given convergence tolerance, the optimal value of m is calculated, and the truncated reduced representation $\{[G^{OAPSM(m)}(\mathbf{x})], \mathbf{x} \in \Omega\}$ of the second-order random field $\{[G^{OAPSM}(\mathbf{x})], \mathbf{x} \in \Omega\}$ is written (see Eq. (26.23)) as

$$[G^{OAPSM(m)}(\mathbf{x})] = [G_0(\mathbf{x})] + \sum_{i=1}^m \sqrt{\lambda_i} [G_i(\mathbf{x})] \eta_i^{OAPSM}, \quad \forall \mathbf{x} \in \Omega. \quad (26.39)$$

Using the v_{KL} independent realizations $[G^{(1)}], \dots, [G^{(v_{KL})}]$ of random field $[G^{OAPSM}]$ calculated with Eq. (26.38), v_{KL} independent realizations $\eta^{(1)}, \dots, \eta^{(v_{KL})}$ of the

random vector $\boldsymbol{\eta}^{\text{OAPSM}} = (\eta_1^{\text{OAPSM}}, \dots, \eta_m^{\text{OAPSM}})$ are calculated, for $i = 1, \dots, m$ and for $\ell = 1, \dots, v_{\text{KL}}$, by

$$\eta_i^{(\ell)} = \frac{1}{\sqrt{\lambda_i}} \int_{\Omega} \ll [G^{(\ell)}(\mathbf{x})] - [G_0(\mathbf{x})], [G_i(\mathbf{x})] \gg d\mathbf{x}. \quad (26.40)$$

8.5 Step 5: Construction of a Truncated Polynomial Chaos Expansion of $\boldsymbol{\eta}^{\text{OAPSM}}$ and Representation of Random Field $[\mathbf{K}^{\text{OAPSM}}]$

Using independent realizations $\boldsymbol{\eta}^{(1)}, \dots, \boldsymbol{\eta}^{(v_{\text{KL}})}$ of random vector $\boldsymbol{\eta}^{\text{OAPSM}}$ (see Eq. (26.40)), this step consists in constructing the approximation $\boldsymbol{\eta}^{\text{chaos}}(N_d, N_g) = (\eta_1^{\text{chaos}}(N_d, N_g), \dots, \eta_m^{\text{chaos}}(N_d, N_g))$ of $\boldsymbol{\eta}^{\text{OAPSM}}$ using Eq. (26.27), for which the matrix $[z]$ in $\mathbb{M}_{N,m}(\mathbb{R})$ of the coefficients verifies $[z]^T [z] = [I_m]$,

$$\boldsymbol{\eta}^{\text{OAPSM}} \simeq \boldsymbol{\eta}^{\text{chaos}}(N_d, N_g), \quad \boldsymbol{\eta}^{\text{chaos}}(N_d, N_g) = [z]^T \Psi(\boldsymbol{\Xi}), \quad (26.41)$$

in which the integer N is defined by

$$N = \mathbb{h}(N_d, N_g) := (N_d + N_g)! / (N_d! N_g!) - 1, \quad (26.42)$$

where the integer N_d is the maximum degree of the normalized multivariate Hermite polynomials and N_g the dimension of random vector $\boldsymbol{\Xi}$. In Eq. (26.41), the symbol “ \simeq ” means that the mean-square convergence is reached for N_d and N_g (with $N_g \leq m$) sufficiently large.

■ Identification of an optimal value $[z_0(N_d, N_g)]$ of $[z]$ for a fixed value of N_d and N_g .

For a fixed value of N_d and N_g such that $N_d \geq 1$ and $1 \leq N_g \leq m$, the identification of $[z]$ is performed using the maximum likelihood method. The log-likelihood function is written as

$$\mathcal{L}([z]) = \sum_{\ell=1}^{v_{\text{KL}}} \log p_{\boldsymbol{\eta}^{\text{chaos}}(N_d, N_g)}(\boldsymbol{\eta}^{(\ell)}; [z]), \quad (26.43)$$

and the optimal value $[z_0(N_d, N_g)]$ of $[z]$ is given by

$$[z_0(N_d, N_g)] = \arg \max_{[z] \in \mathbb{V}_m(\mathbb{R}^N)} \mathcal{L}([z]), \quad (26.44)$$

in which $\mathbb{V}_m(\mathbb{R}^N)$ is defined by Eq. (26.28).

- (i) For $[z]$ fixed in $\mathbb{V}_m(\mathbb{R}^N)$, the probability density function $\mathbf{e} \mapsto p_{\boldsymbol{\eta}^{\text{chaos}}(N_d, N_g)}(\mathbf{e}; [z])$ of random variable $\boldsymbol{\eta}^{\text{chaos}}(N_d, N_g)$ is estimated by the multidimensional

kernel density estimation method using v_{chaos} independent realizations $\boldsymbol{\eta}^{\text{chaos}(1)}, \dots, \boldsymbol{\eta}^{\text{chaos}(v_{\text{chaos}})}$ of random vector $\boldsymbol{\eta}^{\text{chaos}}(N_d, N_g)$, which is such that $\boldsymbol{\eta}^{\text{chaos}(\ell)} = [z]^T \boldsymbol{\Psi}(\boldsymbol{\Xi}^{(\ell)})$ in which $\boldsymbol{\Xi}^{(1)}, \dots, \boldsymbol{\Xi}^{(v_{\text{chaos}})}$ are v_{chaos} independent realizations of $\boldsymbol{\Xi}$.

- (ii) For the high-dimension case, i.e., for $m \times N$ very large, the optimization problem defined by Eq. (26.44) must be solved with adapted and robust algorithms:

- The first one is required for generating the independent realizations $\boldsymbol{\Psi}_j(\boldsymbol{\Xi}^{(\ell)})$ of $\boldsymbol{\Psi}_j(\boldsymbol{\Xi})$ in preserving the orthogonality condition for any high values of N_g and N_d . An efficient algorithm is presented hereinafter.
- The second one requires an advanced algorithm to optimize the trials for solving the high-dimension optimization problem defined by Eq. (26.44), the constraint $[z]^T[z] = [I_m]$ being automatically and exactly satisfied as described in [61].

■ *Efficient algorithm for generating realizations of the multivariate polynomial chaos in high dimension and for an arbitrary probability measure.*

Let $\boldsymbol{\Psi}(\boldsymbol{\Xi}) = (\boldsymbol{\Psi}_1(\boldsymbol{\Xi}), \dots, \boldsymbol{\Psi}_N(\boldsymbol{\Xi}))$ be the \mathbb{R}^N -valued random vector in which $\{\boldsymbol{\Psi}_j(\boldsymbol{\Xi})\}_{j=1}^N$ are the normalized multivariate Hermite polynomials. The objective is to compute the $(N \times v_{\text{chaos}})$ real matrix $[\boldsymbol{\Psi}] = [\boldsymbol{\Psi}(\boldsymbol{\Xi}^{(1)}) \dots \boldsymbol{\Psi}(\boldsymbol{\Xi}^{(v_{\text{chaos}})})]$,

$$[\boldsymbol{\Psi}] = \begin{bmatrix} \boldsymbol{\Psi}_1(\boldsymbol{\Xi}^{(1)}) & \dots & \boldsymbol{\Psi}_1(\boldsymbol{\Xi}^{(v_{\text{chaos}})}) \\ \vdots & \ddots & \vdots \\ \boldsymbol{\Psi}_N(\boldsymbol{\Xi}^{(1)}) & \dots & \boldsymbol{\Psi}_N(\boldsymbol{\Xi}^{(v_{\text{chaos}})}) \end{bmatrix}, \quad (26.45)$$

of the v_{chaos} independent realizations $\boldsymbol{\Psi}(\boldsymbol{\Xi}^{(1)}), \dots, \boldsymbol{\Psi}(\boldsymbol{\Xi}^{(v_{\text{chaos}})})$, in preserving the orthogonality properties

$$\lim_{v_{\text{chaos}} \rightarrow +\infty} \frac{1}{v_{\text{chaos}}} [\boldsymbol{\Psi}] [\boldsymbol{\Psi}]^T = [I_N]. \quad (26.46)$$

It should be noted that the algorithm, which is used for the Gaussian chaos $\boldsymbol{\Psi}_j(\boldsymbol{\Xi}) = \Phi_{\alpha_1}(\boldsymbol{\Xi}_1) \times \dots \times \Phi_{\alpha_{N_g}}(\boldsymbol{\Xi}_{N_g})$ for $j = 1, \dots, N$, can also be used for an arbitrary non-separable probability distribution $p_{\boldsymbol{\Xi}}(\boldsymbol{\xi}) d\boldsymbol{\xi}$ on \mathbb{R}^{N_g} without any modification, but in such a case, the multivariate polynomials $\{\boldsymbol{\Psi}_j(\boldsymbol{\Xi})\}_{j=1}^N$, which verify the orthogonality property, $E\{\boldsymbol{\Psi}_j(\boldsymbol{\Xi}) \boldsymbol{\Psi}_{j'}(\boldsymbol{\Xi})\} = \int_{\mathbb{R}^{N_g}} \boldsymbol{\Psi}_j(\boldsymbol{\xi}) \boldsymbol{\Psi}_{j'}(\boldsymbol{\xi}) p_{\boldsymbol{\Xi}}(\boldsymbol{\xi}) d\boldsymbol{\xi} = \delta_{jj'}$, are not written as a tensorial product of univariate polynomials (we have not $\boldsymbol{\Psi}_j(\boldsymbol{\Xi}) = \Phi_{\alpha_1}(\boldsymbol{\Xi}_1) \times \dots \times \Phi_{\alpha_{N_g}}(\boldsymbol{\Xi}_{N_g})$). It has been proved in [65] that, for the usual probability measure, the use of the explicit algebraic formula (constructed with a symbolic Toolbox) or the use of the computational recurrence relation with respect to the degree, induces important numerical noise, and the orthogonality property is lost. In addition, if a global orthogonalization was done to correct this loss of orthogonality, then the independence of the realizations would be lost. A robust computational method has been proposed in [49, 65] to preserve the orthogonality

properties and the independence of the realizations. The two main steps are the following.

- (i) Using a generator of independent realizations of Ξ whose probability distribution is $p_{\Xi}(\xi) d\xi$, the realizations $\mathcal{M}_j(\Xi^{(1)}), \dots, \mathcal{M}_j(\Xi^{(v_{\text{chaos}})})$ of the multivariate monomials $\mathcal{M}_j(\Xi) = \Xi_1^{j_1} \times \dots \times \Xi_{N_g}^{j_{N_g}}$ are computed, in which $j = 1, \dots, N$ is the index associated with the multi-index (j_1, \dots, j_{N_g}) . Let $\mathcal{M}(\Xi) = (\mathcal{M}_1(\Xi), \dots, \mathcal{M}_N(\Xi))$ be the \mathbb{R}^N -valued random variable and let $[M]$ be the $(N \times v_{\text{chaos}})$ real matrix such that

$$[M] = [\mathcal{M}(\Xi^{(1)}) \dots \mathcal{M}(\Xi^{(v_{\text{chaos}})})] = \begin{bmatrix} \mathcal{M}_1(\Xi^{(1)}) & \dots & \mathcal{M}_1(\Xi^{(v_{\text{chaos}})}) \\ \vdots & \ddots & \vdots \\ \mathcal{M}_N(\Xi^{(1)}) & \dots & \mathcal{M}_N(\Xi^{(v_{\text{chaos}})}) \end{bmatrix}. \quad (26.47)$$

- (ii) An orthogonalization of the realizations of the multivariate monomials is carried out using an algorithm (that is different from the Gram-Schmidt orthogonalization algorithm, which is not stable in high dimension) based on the fact that:
(a) the matrix $[\Psi]$, defined by Eq. (26.45), can be written as $[\Psi] = [A][M]$ in which $[A]$ is an invertible $(N \times N)$ real matrix and where $[M]$ is defined by Eq. (26.47), and (b) the matrix $[R] = E\{\mathcal{M}(\Xi)\mathcal{M}(\Xi)^T\}$ is written as $[R] = \lim_{v_{\text{chaos}} \rightarrow +\infty} \frac{1}{v_{\text{chaos}}} [M][M]^T = [A]^{-1}[A]^{-T}$. The algorithm is summarized as follows:

- Computing matrix $[M]$ and then $[R] \simeq \frac{1}{v_{\text{chaos}}} [M][M]^T$ for v_{chaos} sufficiently high.
- Computing $[A]^{-T}$ that corresponds to the Cholesky decomposition of $[R]$.
- Computing the lower triangular matrix $[A]$.
- Computing $[\Psi] = [A][M]$.

■ *Identification of truncation parameters N_d and N_g .*

The quantification of the mean-square convergence of $\eta^{\text{chaos}}(N_d, N_g) = [z_0(N_d, N_g)]^T \Psi(\Xi)$ toward η^{OAPSM} with respect to N_d and N_g , in which $[z_0(N_d, N_g)]$ is given by Eq. (26.44), is carried out using the L^1 -log error function introduced in [61], which allows for measuring the errors of the small values of the probability density function (the tails of the pdf).

- (i) For a fixed value of $N_d \leq m$ and N_g , and for $i = 1, \dots, m$:
- Let $e \mapsto p_{\eta_i^{\text{OAPSM}}}(e)$ be the pdf of random variable η_i^{OAPSM} , which is estimated with the one-dimensional kernel density estimation method using the independent realizations $\eta^{(1)}, \dots, \eta^{(v_{\text{KL}})}$ of the random vector η^{OAPSM} .
 - Let $e \mapsto p_{\eta_i^{\text{chaos}}(N_d, N_g)}(e; [z_0(N_d, N_g)])$ be the pdf of random variable $\eta_i^{\text{chaos}}(N_d, N_g)$, which is estimated with the one-dimensional kernel density estimation method using v_{chaos} independent realizations,

$\eta^{\text{chaos}^{(1)}}(N_d, N_g), \dots, \eta^{\text{chaos}^{(v_{\text{chaos}})}}(N_d, N_g)$, of random vector $\eta^{\text{chaos}}(N_d, N_g)$, which are such that $\eta^{\text{chaos}^{(\ell)}}(N_d, N_g) = [z_0(N_d, N_g)]^T \Psi(\Xi^{(\ell)})$ in which $\Xi^{(1)}, \dots, \Xi^{(v_{\text{chaos}})}$ are v_{chaos} independent realizations of Ξ .

- The L^1 -log error is introduced as described in [61]:

$$\text{err}_i(N_d, N_g) = \int_{\text{BI}_i} |\log_{10} p_{\eta_i^{\text{OAPSM}}}(e) - \log_{10} p_{\eta_i^{\text{chaos}}(N_d, N_g)}(e; [z_0(N_d, N_g)])| de, \quad (26.48)$$

in which BI_i is a bounded interval of the real line, which is defined as the support of the one-dimensional kernel density estimator of random variable η_i^{OAPSM} and which is then adapted to independent realizations $\eta^{(1)}, \dots, \eta^{(v_{\text{KL}})}$ of η^{OAPSM} .

- (ii) For random vector $\eta^{\text{chaos}}(N_d, N_g)$, the L^1 -log error function is denoted by $\text{err}(N_d, N_g)$ and is defined by

$$\text{err}(N_g, N_d) = \frac{1}{m} \sum_{i=1}^m \text{err}_i(N_d, N_g). \quad (26.49)$$

- (iii) The optimal values N_d^{opt} and N_g^{opt} of the truncation parameters N_d and N_g are determined for minimizing the error function $\text{err}(N_d, N_g)$ in taking into account the admissible set for the values of N_d and N_g as described in [49]. Let \mathcal{C}_{N_d, N_g} be the admissible set for the values of N_d and N_g , which is defined by

$$\mathcal{C}_{N_d, N_g} = \{(N_d, N_g) \in \mathbb{N}^2 \mid N_g \leq m, (N_d + N_g)! / (N_d! N_g!) - 1 \geq m\}.$$

It should be noted the more the values of N_d and N_g are high, the bigger is the matrix $[z_0(N_d, N_g)]$, and thus, the more difficult it is to perform the numerical identification. Rather than directly minimizing error function $\text{err}(N_d, N_g)$, it is more accurate to search for the optimal values of N_d and N_g that minimize the dimension of the projection basis, $(N_d + N_g)! / (N_d! N_g!)$. For a given error threshold ε , we then introduce the admissible set \mathcal{C}_ε such that

$$\mathcal{C}_\varepsilon = \{(N_d, N_g) \in \mathcal{C}_{N_d, N_g} \mid \text{err}(N_g, N_d) \leq \varepsilon\},$$

and the optimal values N_d^{opt} and N_g^{opt} are given as the solution of the optimization problem,

$$(N_d^{\text{opt}}, N_g^{\text{opt}}) = \arg \min_{(N_d, N_g) \in \mathcal{C}_\varepsilon} (N_d + N_g)! / (N_d! N_g!), \quad N^{\text{opt}} = h(N_d^{\text{opt}}, N_g^{\text{opt}}).$$

■ *Changing the notation.*

Until the end of Step 5 and in Steps 6 and 7, in order to simplify the notations, N_d^{opt} , N_g^{opt} , N^{opt} , and $[z_0(N_d^{\text{opt}}, N_g^{\text{opt}})]$ are simply rewritten as N_d , N_g , N , and $[z_0]$.

■ *Representation of random field $[\mathbf{K}^{\text{OAPSM}}]$.*

It can then be deduced that the optimal representation $\{[\mathbf{K}^{\text{OAPSM}}(m, N, N_g)(\mathbf{x})], \mathbf{x} \in \Omega\}$ of random field $\{[\mathbf{K}^{\text{OAPSM}}(\mathbf{x})], \mathbf{x} \in \Omega\}$ is written as

$$[\mathbf{K}^{\text{OAPSM}}(m, N, N_g)(\mathbf{x})] = \mathcal{K}^{(m, N, N_g)}(\mathbf{x}, \boldsymbol{\Xi}, [z_0]), \quad \forall \mathbf{x} \in \Omega, \quad (26.50)$$

in which $\mathcal{K}^{(m, N, N_g)}(\mathbf{x}, \boldsymbol{\Xi}, [z_0])$ is defined by Eq. (26.30) with $N_d = N_d^{\text{opt}}$, $N_g = N_g^{\text{opt}}$, and $[z] = [z_0(N_d^{\text{opt}}, N_g^{\text{opt}})]$.

8.6 Step 6: Identification of the Prior Stochastic Model $[\mathbf{K}^{\text{prior}}]$ of $[\mathbf{K}]$ in the General Class of the Non-Gaussian Random Fields

This step consists in identifying the prior stochastic model $\{[\mathbf{K}^{\text{prior}}(\mathbf{x})], \mathbf{x} \in \Omega\}$ of $\{[\mathbf{K}(\mathbf{x})], \mathbf{x} \in \Omega\}$, using the maximum likelihood method and the experimental data sets $\mathbf{u}^{\text{exp},1}, \dots, \mathbf{u}^{\text{exp},v_{\text{exp}}}$ relative to the random model observation \mathbf{U} of the stochastic computational model (see Eq. (26.9)) and using the parametric model-based representation of random observation model \mathbf{U} (see Eq. (26.32)). We thus have to identify the value $[z^{\text{prior}}]$ in $\mathbb{V}_m(\mathbb{R}^{N^{\text{opt}}})$ of $[z]$ such that

$$[z^{\text{prior}}] = \arg \max_{[z] \in \mathbb{V}_m(\mathbb{R}^N)} \sum_{\ell=1}^{v_{\text{exp}}} \log p_{\mathbf{U}^{(m, N, N_g)}}(\mathbf{u}^{\text{exp},\ell}; [z]), \quad (26.51)$$

in which $p_{\mathbf{U}^{(m, N, N_g)}}(\mathbf{u}^{\text{exp},\ell}; [z])$ is the value, in $\mathbf{u} = \mathbf{u}^{\text{exp},\ell}$, of the pdf $p_{\mathbf{U}^{(m, N, N_g)}}(\mathbf{u}; [z])$ of the random vector $\mathbf{U}^{(m, N, N_g)}$ given (see Eq. (26.32)) by

$$\mathbf{U}^{(m, N, N_g)} = \mathcal{B}^{(m, N, N_g)}(\boldsymbol{\Xi}, [z]), \quad (26.52)$$

where $(\boldsymbol{\xi}, [z]) \mapsto \mathcal{B}^{(m, N, N_g)}(\boldsymbol{\xi}, [z])$ is the deterministic mapping from $\mathbb{R}^{N_g} \times \mathbb{V}_m(\mathbb{R}^N)$ into \mathbb{R}^{N_U} defined by Eq. (26.33) with Eq. (26.31) in which $[G_0(\mathbf{x})]$, λ_i , and $[G_i(\mathbf{x})]$, for $i = 1, \dots, m$, are the quantities computed in Step 4.

- (i) For $[z]$ fixed in $\mathbb{V}_m(\mathbb{R}^N)$, pdf $\mathbf{u} \mapsto p_{\mathbf{U}^{(m, N, N_g)}}(\mathbf{u}; [z])$ of random variable $\mathbf{U}^{(m, N, N_g)}$ is estimated by the multidimensional kernel density estimation method using v_{chaos} independent realizations $\boldsymbol{\Xi}^{(1)}, \dots, \boldsymbol{\Xi}^{(v_{\text{chaos}})}$ of $\boldsymbol{\Xi}$.
- (ii) Let us assume that $N > m$ is generally the case. The parameterization $[z] = \mathcal{R}_{[z_0]}([w])$ defined by Eq. (26.29) is used for exploring, with a random search algorithm, the subset of $\mathbb{V}_m(\mathbb{R}^N)$, centered in $[z_0] := [z_0(N_d, N_g)] \in \mathbb{V}_m(\mathbb{R}^N)$ computed in Step 5. The optimization problem defined by Eq. (26.51) is replaced by $[z^{\text{prior}}] = \mathcal{R}_{[z_0]}([w^{\text{prior}}])$ with

$$[w^{\text{prior}}] = \arg \max_{[w] \in T_{[z_0]}} \sum_{\ell=1}^{v_{\text{exp}}} \log p_{\mathbf{U}^{(m,N,N_g)}}(\mathbf{u}^{\text{exp},\ell}; \mathcal{R}_{[z_0]}([w])). \quad (26.53)$$

For solving the high-dimension optimization problem defined by Eq. (26.53), a random search algorithm is used for which $[w]$ is modeled by a random matrix $[\mathbf{W}] = \text{Proj}_{T_{[z_0]}}([\Lambda])$ with values in $T_{[z_0]}$, which is the projection on $T_{[z_0]}$ of a random matrix $[\Lambda]$ with values in $\mathbb{M}_{N,m}(\mathbb{R})$ whose entries are independent normalized Gaussian real-valued random variables, i.e., $E\{[\Lambda]_{ji}\} = 0$ and $E\{[\Lambda]_{ji}^2\} = 1$. The positive parameter σ introduced in Eq. (26.29) allows for controlling the “diameter” of the subset (centered in $[z_0]$) that is explored by the random search algorithm.

- (iii) The representation of the prior stochastic model $\{[\mathbf{K}^{\text{prior}}(m,N,N_g)(\mathbf{x})], \mathbf{x} \in \Omega\}$ of random field $\{[\mathbf{K}(\mathbf{x})], \mathbf{x} \in \Omega\}$ is given by Eqs. (26.30) and (26.31) that are rewritten as

$$[\mathbf{K}^{\text{prior}}(m,N,N_g)(\mathbf{x})] = \mathcal{K}^{(m,N,N_g)}(\mathbf{x}, \boldsymbol{\Xi}, [z^{\text{prior}}]), \quad \forall \mathbf{x} \in \Omega, \quad (26.54)$$

in which $[z^{\text{prior}}]$ is given by Eq. (26.51) and where $\mathcal{K}^{(m,N,N_g)}(\mathbf{x}, \boldsymbol{\xi}, [z^{\text{prior}}])$ is defined by Eq. (26.31) with $[z] = [z^{\text{prior}}]$.

8.7 Step 7: Identification of a Posterior Stochastic Model $[\mathbf{K}^{\text{post}}]$ of $[\mathbf{K}]$

- (i) A posterior stochastic model $\{[\mathbf{K}^{\text{post}}(\mathbf{x})], \mathbf{x} \in \Omega\}$ of random field $\{[\mathbf{K}(\mathbf{x})], \mathbf{x} \in \Omega\}$ can be constructed using the Bayesian method. In such a framework, the coefficients $[z]$ of the polynomial chaos expansion $\eta^{\text{chaos}}(N_d, N_g) = [z]^T \boldsymbol{\Psi}(\boldsymbol{\Xi})$ (see Eq. (26.41)) are modeled by a random matrix $[\mathbf{Z}]$ (see [66]) as proposed in [62] and consequently, $[z]$ is modeled by a $\mathbb{V}_m(\mathbb{R}^N)$ -valued random variable $[\mathbf{Z}]$. The prior model $[\mathbf{Z}^{\text{prior}}]$ of $[\mathbf{Z}]$ is chosen as

$$[\mathbf{Z}^{\text{prior}}] = \mathcal{R}_{[z^{\text{prior}}]}([\mathbf{W}^{\text{prior}}]), \quad (26.55)$$

in which $\mathcal{R}_{[z^{\text{prior}}]}$ is the mapping defined by Eq. (26.29), where $[z^{\text{prior}}]$ has been calculated in Step 6 and where $[\mathbf{W}^{\text{prior}}] = \text{Proj}_{T_{[z^{\text{prior}}]}}([\Lambda^{\text{prior}}])$ is a random matrix with values in $T_{[z^{\text{prior}}]}$, which is the projection on $T_{[z^{\text{prior}}]}$ of a random matrix $[\Lambda^{\text{prior}}]$ with values in $\mathbb{M}_{N,m}(\mathbb{R})$ whose entries are independent normalized Gaussian real-valued random variables, i.e. $E\{[\Lambda]_{ji}\} = 0$ and $E\{[\Lambda]_{ji}^2\} = 1$. For a sufficiently small value of σ , the statistical fluctuations of the $\mathbb{V}_m(\mathbb{R}^{N^{\text{opt}}})$ -valued random matrix $[\mathbf{Z}^{\text{prior}}]$ are approximatively centered around $[z^{\text{prior}}]$. The Bayesian update allows the posterior distribution of the random matrix $[\mathbf{W}^{\text{post}}]$ with values in $T_{[z^{\text{prior}}]}$ to be estimated using the stochastic

solution $\mathbf{U}^{(m,N,N_g)} = \mathcal{B}^{(m,N,N_g)}(\boldsymbol{\Xi}, \mathcal{R}_{[\varepsilon^{\text{prior}}]}([\mathbf{W}^{\text{prior}}]))$ and the experimental data set $\mathbf{u}^{\text{exp},1}, \dots, \mathbf{u}^{\text{exp},N_{\text{exp}}}$.

- (ii) The representation of the posterior stochastic model $\{[\mathbf{K}^{\text{post}(m,N,N_g)}(\mathbf{x})], \mathbf{x} \in \Omega\}$ of random field $\{[\mathbf{K}(\mathbf{x})], \mathbf{x} \in \Omega\}$ is given by Eqs. (26.30) and (26.31) that are rewritten as

$$[\mathbf{K}^{\text{post}(m,N,N_g)}(\mathbf{x})] = \mathcal{K}^{(m,N,N_g)}(\mathbf{x}, \boldsymbol{\Xi}, \mathcal{R}_{[\varepsilon^{\text{prior}}]}([\mathbf{W}^{\text{post}}])), \quad \forall \mathbf{x} \in \Omega, \quad (26.56)$$

in which $\mathcal{K}^{(m,N^{\text{opt}},N_g^{\text{opt}})}$ is defined by Eq. (26.31).

- (iii) Once the probability distribution of $[\mathbf{W}^{\text{post}}]$ has been estimated by Step 7, ν_{KL} independent realizations can be calculated for the random field $[\mathbf{G}^{\text{post}}(\mathbf{x})] = [G_0(\mathbf{x})] + \sum_{i=1}^m \sqrt{\sigma_i} [G_i(\mathbf{x})] \eta_i^{\text{post}}$ in which $\eta^{\text{post}} = [\mathbf{Z}^{\text{post}}]^T \boldsymbol{\Psi}(\boldsymbol{\Xi})$ and where $[\mathbf{Z}^{\text{post}}] = \mathcal{R}_{[\varepsilon^{\text{prior}}]}([\mathbf{W}^{\text{post}}])$. The identification procedure can then be restarted from Step 4 replacing $[\mathbf{G}^{\text{OAPSM}}]$ by $[\mathbf{G}^{\text{post}}]$.

9 Construction of a Family of Algebraic Prior Stochastic Models

We present an explicit construction of a family $\{[\mathbf{K}^{\text{APS}}(\mathbf{x}; \mathbf{s})], \mathbf{x} \in \Omega\}$ of algebraic prior stochastic models for the non-Gaussian second-order random field $[\mathbf{K}]$ indexed by Ω , with values in $\mathbb{M}_n^+(\mathbb{R})$, which has been introduced in Step 1 of Sect. 8. This family depends on a hyperparameter \mathbf{s} belonging to the admissible set \mathcal{C}_s that is a subset of \mathbb{R}^{N_s} , for which the dimension, N_s , is assumed to be relatively small, while the stochastic dimension of $[\mathbf{K}^{\text{APS}}]$ is high. For \mathbf{s} fixed in \mathcal{C}_s , we give a construction of the random field $[\mathbf{K}^{\text{APS}}]$ and the corresponding generator of its realizations. In order to simplify the notations, \mathbf{s} will be omitted as long as no confusion is possible. The formalism and the results, presented in Sect. 12 of ▶ Chap. 8, “Random Matrix Models and Nonparametric Method for Uncertainty Quantification” in part II of the present Handbook on Uncertainty Quantification, are reused. Two prior algebraic stochastic models $[\mathbf{K}^{\text{APS}}]$ are presented hereinafter.

- The first one is the algebraic prior stochastic model $[\mathbf{K}^{\text{APS}}]$ for the non-Gaussian positive-definite matrix-valued random field $[\mathbf{K}]$ that exhibits anisotropic statistical fluctuations (initially introduced in [56, 58]) and for which there is a parameterization with a maximum of $d \times n(n+1)/2$ spatial-correlation lengths and for which a positive-definite lower bound is given [60, 63]. An extension of this model can be found in [32] for the case for which some positive-definite lower and upper bounds are introduced as constraints.
- The second one is the algebraic prior stochastic model $[\mathbf{K}^{\text{APS}}]$ described in [28, 29] for the non-Gaussian positive-definite matrix-valued random field $[\mathbf{K}]$ that exhibits (i) dominant statistical fluctuations in a symmetry class $\mathbb{M}_n^{\text{sym}}(\mathbb{R}) \subset \mathbb{M}_n^+(\mathbb{R})$ of dimension N (isotropic, cubic, transversal isotropic, tetragonal,

trigonal, orthotropic, monoclinic) for which there is a parameterization with $d N$ spatial-correlation lengths, (ii) anisotropic statistical fluctuations for which there is a parameterization with a maximum of $d \times n(n+1)/2$ spatial-correlation lengths, and (iii) a positive-definite lower bound.

9.1 General Properties of the Non-Gaussian Random Field $[K]$ with a Lower Bound

Let $\{[K(x)], x \in \Omega\}$ be a non-Gaussian random defined on the probability space $(\Theta, \mathcal{T}, \mathcal{P})$, indexed by $\Omega \subset \mathbb{R}^d$ with $1 \leq d \leq 3$, with values in $\mathbb{M}_n^+(\mathbb{R})$ with $n = 6$, homogeneous on \mathbb{R}^d , and of second-order, $E\{\|[K(x)]\|_F^2\} < +\infty$ for all x in Ω . Let $[K] \in \mathbb{M}_n^+(\mathbb{R})$ be its mean value that is independent of x (homogeneous random field) and let $[C_\ell] \in \mathbb{M}_n^+(\mathbb{R})$ be its positive-definite lower bound that is also assumed to be independent of x . For all x in Ω ,

$$[K] = E\{[K(x)]\}, \quad [K(x)] - [C_\ell] > 0 \quad a.s. \quad (26.57)$$

9.2 Algebraic Prior Stochastic Model for the Case of Anisotropic Statistical Fluctuations

We consider the case for which the random field exhibits anisotropic statistical fluctuations.

9.2.1 Introduction of an Adapted Representation

The prior stochastic model $\{[K^{APSM}(x)], x \in \Omega\}$ of the random field $\{[K(x)], x \in \Omega\}$ is defined on $(\Theta, \mathcal{T}, \mathcal{P})$, is indexed by $\Omega \subset \mathbb{R}^d$, is with values in $\mathbb{M}_n^+(\mathbb{R})$, is homogeneous on \mathbb{R}^d , and is a second-order random field that is written as

$$[K^{APSM}(x)] = [C_\ell] + [\underline{C}]^{1/2} [G_0(x)] [\underline{C}]^{1/2}, \quad \forall x \in \Omega, \quad (26.58)$$

where $[\underline{C}]^{1/2}$ is the square root of the matrix $[\underline{C}]$ in $\mathbb{M}_n^+(\mathbb{R})$, independent of x , defined by

$$[\underline{C}] = [K] - [C_\ell] \in \mathbb{M}_n^+(\mathbb{R}). \quad (26.59)$$

In Eq. (26.58), $\{[G_0(x)], x \in \mathbb{R}^d\}$ is a random field defined on $(\Theta, \mathcal{T}, \mathcal{P})$, indexed by \mathbb{R}^d , with values in $\mathbb{M}_n^+(\mathbb{R})$, homogeneous on \mathbb{R}^d , second order such that, for all x in \mathbb{R}^d ,

$$E\{[G_0(x)]\} = [I_n], \quad [G_0(x)] > 0 \quad a.s. \quad (26.60)$$

It can then be deduced that, for all x in Ω ,

$$E\{[K^{APSM}(x)]\} = [K], \quad [K^{APSM}(x)] - [C_\ell] > 0 \quad a.s. \quad (26.61)$$

9.2.2 Construction of Random Field $[\mathbf{G}_0]$ and Its Generator of Realizations

■ *Random fields \mathcal{U}_{jk} as the stochastic germs of the random field $[\mathbf{G}_0]$.*

Random field $\{[\mathbf{G}_0(\mathbf{x})], \mathbf{x} \in \mathbb{R}^d\}$ is constructed as a nonlinear transformation of $n(n+1)/2$ independent second-order, centered, homogeneous, Gaussian, and normalized random fields $\{\mathcal{U}_{jk}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}_{1 \leq j \leq k \leq n}$, defined on probability space $(\Theta, \mathcal{T}, \mathcal{P})$, indexed by \mathbb{R}^d , with values in \mathbb{R} , and named the *stochastic germs* of the non-Gaussian random field $[\mathbf{G}_0]$. We then have

$$E\{\mathcal{U}_{jk}(\mathbf{x})\} = 0, \quad E\{\mathcal{U}_{jk}(\mathbf{x})^2\} = 1. \quad (26.62)$$

Consequently, the random fields $\{\mathcal{U}_{jk}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}_{1 \leq j \leq k \leq n}$ are completely and uniquely defined by the $n(n+1)/2$ autocorrelation functions $\boldsymbol{\zeta} = (\zeta_1, \dots, \zeta_d) \mapsto R_{\mathcal{U}_{jk}}(\boldsymbol{\zeta}) = E\{\mathcal{U}_{jk}(\mathbf{x} + \boldsymbol{\zeta})\mathcal{U}_{jk}(\mathbf{x})\}$ from \mathbb{R}^d into \mathbb{R} , such that $R_{\mathcal{U}_{jk}}(0) = 1$. The spatial-correlation lengths $L_1^{jk}, \dots, L_d^{jk}$ of random field $\{\mathcal{U}_{jk}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$ are defined by

$$L_\alpha^{jk} = \int_0^{+\infty} |R_{\mathcal{U}_{jk}}(0, \dots, \zeta_\alpha, \dots, 0)| d\zeta_\alpha, \quad \alpha = 1, \dots, d, \quad (26.63)$$

and are generally chosen as parameters for the parameterization.

Example of parameterization for autocorrelation function $R_{\mathcal{U}_{jk}}$. The autocorrelation function (corresponding to a minimal parameterization) is written as

$$R_{\mathcal{U}_{jk}}(\boldsymbol{\zeta}) = \rho_1^{jk}(\zeta_1) \times \dots \times \rho_d^{jk}(\zeta_d), \quad (26.64)$$

in which, for all $\alpha = 1, \dots, d$, $\rho_\alpha^{jk}(0) = 1$, and for all $\zeta_\alpha \neq 0$,

$$\rho_\alpha^{jk}(\zeta_\alpha) = 4(L_\alpha^{jk})^2 / (\pi^2 \zeta_\alpha^2) \sin^2(\pi \zeta_\alpha / (2L_\alpha^{jk})), \quad (26.65)$$

where $L_1^{jk}, \dots, L_d^{jk}$ are positive real numbers. Each random field \mathcal{U}_{jk} is mean-square continuous on \mathbb{R}^d and its power spectral density function defined on \mathbb{R}^d has a compact support, $[-\pi/L_1^{jk}, \pi/L_1^{jk}] \times \dots \times [-\pi/L_d^{jk}, \pi/L_d^{jk}]$. Such a model has $d n(n+1)/2$ real parameters $\{L_1^{jk}, \dots, L_d^{jk}\}_{1 \leq j \leq k \leq n}$ that represent the spatial-correlation lengths of the stochastic germs $\{\mathcal{U}_{jk}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}_{1 \leq j \leq k \leq n}$, because

$$\int_0^{+\infty} |R_{\mathcal{U}_{jk}}(0, \dots, \zeta_\alpha, \dots, 0)| d\zeta_\alpha = L_\alpha^{jk}. \quad (26.66)$$

■ *Defining an adapted family of functions for the nonlinear transformation.*

Let $\{u \mapsto h(u; a)\}_{a > 0}$ be the adapted family of functions from \mathbb{R} into $]0, +\infty[$, in which a is a positive real number, such that $\Gamma_a = h(\mathcal{U}; a)$ is a gamma random

variable with parameter a , while \mathcal{U} is a normalized Gaussian random variable ($E\{\mathcal{U}\} = 0$ and $E\{\mathcal{U}^2\} = 1$). Consequently, for all u in \mathbb{R} , we have

$$h(u; a) = F_{\Gamma_a}^{-1}(F_{\mathcal{U}}(u)), \quad (26.67)$$

in which $u \mapsto F_{\mathcal{U}}(u) = \int_{-\infty}^u \frac{1}{\sqrt{2\pi}} e^{-v^2/2} dv$ is the cumulative distribution function of the normalized Gaussian random variable \mathcal{U} . The function $p \mapsto F_{\Gamma_a}^{-1}(p)$, from $]0, 1[$ into $]0, +\infty[$, is the reciprocal function of the cumulative distribution function $\gamma \mapsto F_{\Gamma_a}(\gamma) = \int_0^\gamma \frac{1}{\Gamma(a)} t^{a-1} e^{-t} dt$ of the gamma random variable Γ_a with parameter a , in which $\Gamma(a)$ is the gamma function defined by $\Gamma(a) = \int_0^{+\infty} t^{a-1} e^{-t} dt$.

■ Defining the random field $\{[\mathbf{G}_0(\mathbf{x})], \mathbf{x} \in \mathbb{R}^d\}$ and its generator of realizations.

For all \mathbf{x} fixed in \mathbb{R}^d , the available information is defined by Eq. (26.60) and by the constraint $|E\{\log(\det[\mathbf{G}_0(\mathbf{x})])\}| < +\infty$, which is introduced in order that the zero matrix be a repulsive value for the random matrix $[\mathbf{G}_0(\mathbf{x})]$. The use of the maximum entropy principle under the constraints defined by this available information leads to taking the random matrix $[\mathbf{G}_0(\mathbf{x})]$ in ensemble SG_0^+ defined in Sect. 8.1 of ►Chap. 8, “Random Matrix Models and Nonparametric Method for Uncertainty Quantification” in part II of the present Handbook on Uncertainty Quantification. Taking into account the algebraic representation of any random matrix belonging to ensemble SG_0^+ , the spatial-correlation structure of random field $[\mathbf{G}_0]$ is then introduced in replacing the Gaussian random variables U_{jk} by the Gaussian real-valued random fields $\{\mathcal{U}_{jk}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$ defined above, for which the spatial-correlation structure is defined by the spatial-correlation lengths $\{L_\alpha^{jk}\}_{\alpha=1,\dots,d}$. Consequently, the random field $\{[\mathbf{G}_0(\mathbf{x})], \mathbf{x} \in \mathbb{R}^d\}$, defined on probability space $(\Theta, \mathcal{T}, \mathcal{P})$, indexed by \mathbb{R}^d , with values in $\mathbb{M}_n^+(\mathbb{R})$, is constructed as follows:

- (i) Let $\{\mathcal{U}_{jk}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}_{1 \leq j \leq k \leq n}$ be the $n(n+1)/2$ independent random fields introduced above. Consequently, for all \mathbf{x} in \mathbb{R}^d ,

$$E\{\mathcal{U}_{jk}(\mathbf{x})\} = 0, \quad E\{\mathcal{U}_{jk}(\mathbf{x})^2\} = 1, \quad 1 \leq j \leq k \leq n. \quad (26.68)$$

- (ii) Let δ be the real number, independent of \mathbf{x} , such that

$$0 < \delta < \sqrt{(n+1)/(n+5)} < 1. \quad (26.69)$$

The parameter δ allows for controlling the statistical fluctuations (dispersion) of the random field $[\mathbf{G}_0]$.

- (iii) For all \mathbf{x} fixed in \mathbb{R}^d , the random matrix $[\mathbf{G}_0(\mathbf{x})]$ is written as

$$[\mathbf{G}_0(\mathbf{x})] = [\mathbf{L}(\mathbf{x})]^T [\mathbf{L}(\mathbf{x})], \quad (26.70)$$

in which $[\mathbf{L}(\mathbf{x})]$ is the upper $(n \times n)$ real triangular random matrix defined as follows:

- For $1 \leq j \leq k \leq n$, the $n(n+1)/2$ random fields $\{[\mathbf{L}(\mathbf{x})]_{jk}, \mathbf{x} \in \Omega\}$ are independent.
 - For $j < k$, the real-valued random field $\{[\mathbf{L}(\mathbf{x})]_{jk}, \mathbf{x} \in \Omega\}$ is defined by $[\mathbf{L}(\mathbf{x})]_{jk} = \sigma_n \mathcal{U}_{jk}(\mathbf{x})$ in which σ_n is such that $\sigma_n = \delta/\sqrt{n+1}$.
 - For $j = k$, the positive-valued random field $\{[\mathbf{L}(\mathbf{x})]_{jj}, \mathbf{x} \in \Omega\}$ is defined by $[\mathbf{L}(\mathbf{x})]_{jj} = \sigma_n \sqrt{2 h(\mathcal{U}_{jj}(\mathbf{x}), a_j)}$ in which $a_j = (n+1)/(2\delta^2) + (1-j)/2$.
- (iv) The representation of random field $[\mathbf{G}_0]$ defined by Eq.(26.70) allows for computing realizations of the family of dependent random matrices $\{[\mathbf{G}_0(\mathbf{x}^1)], \dots, [\mathbf{G}_0(\mathbf{x}^{N_p})]\}$ in which $\mathbf{x}^1, \dots, \mathbf{x}^{N_p}$ are N_p given points in Ω , which are expressed using the realizations of $\{\mathcal{U}_{jk}(\mathbf{x}^1), \dots, \mathcal{U}_{jk}(\mathbf{x}^{N_p})\}_{1 \leq j \leq k \leq n}$ that are simulated using either the representation adapted to a large value of N_p , or another one adapted to a small or moderate value of N_p (see [58]).

■ *A few basic properties of random field $[\mathbf{G}_0]$.*

The random field $\{[\mathbf{G}_0(\mathbf{x})], \mathbf{x} \in \Omega\}$, defined on $(\Theta, \mathcal{T}, \mathcal{P})$, indexed by \mathbb{R}^d , with values in $\mathbb{M}_n^+(\mathbb{R})$, is a homogeneous, second-order, and mean-square continuous random field. For all \mathbf{x} in \mathbb{R}^d ,

$$E\{\|\mathbf{G}_0(\mathbf{x})\|_F^2\} < +\infty, \quad E\{[\mathbf{G}_0(\mathbf{x})]\} = [I_n]. \quad (26.71)$$

It can be proved that the introduced dispersion parameter corresponds to the following definition

$$\delta = \left\{ \frac{1}{n} E\{\|\mathbf{G}_0(\mathbf{x}) - [I_n]\|_F^2\} \right\}^{1/2}, \quad (26.72)$$

which shows that

$$E\{\|\mathbf{G}_0(\mathbf{x})\|_F^2\} = n(\delta^2 + 1), \quad (26.73)$$

in which δ is independent of \mathbf{x} . For all \mathbf{x} fixed in \mathbb{R}^d , the probability density function with respect to the measure $d^S G = 2^{n(n-1)/4} \prod_{1 \leq j \leq k \leq n} dG_{jk}$ of random matrix $[\mathbf{G}_0(\mathbf{x})]$ is independent of \mathbf{x} and is written as

$$P_{[\mathbf{G}_0(\mathbf{x})]}([G]) = \mathbb{1}_{\mathbb{M}_n^+(\mathbb{R})}([G]) \times C_{\mathbf{G}_0} \times (\det[G])^{\frac{(n+1)(1-\delta^2)}{2\delta^2}} \times \exp\left\{-\frac{(n+1)}{2\delta^2} \text{tr}[G]\right\}, \quad (26.74)$$

where $C_{\mathbf{G}_0}$ is the positive constant of normalization. For all \mathbf{x} fixed in \mathbb{R}^d , the random variables $\{[\mathbf{G}_0(\mathbf{x})]_{jk}, 1 \leq j \leq k \leq 6\}$ are mutually dependent. In addition, the system of the marginal probability distributions of random field $\{[\mathbf{G}_0(\mathbf{x})], \mathbf{x} \in \Omega\}$

is completely defined and is not Gaussian. There exists a positive constant b_G independent of \mathbf{x} , but depending on δ , such that for all $\mathbf{x} \in \mathbb{R}^d$,

$$E\{\|[\mathbf{G}_0(\mathbf{x})]^{-1}\|^2\} \leq b_G < +\infty. \quad (26.75)$$

Since $[\mathbf{G}_0(\mathbf{x})]$ is a random matrix with values in $\mathbb{M}_n^+(\mathbb{R})$, then $[\mathbf{G}_0(\mathbf{x})]^{-1}$ exists (almost surely). However, since almost sure convergence does not imply mean-square convergence, Eq. (26.75) cannot simply be deduced. Let $\overline{\Omega} = \Omega \cup \partial\Omega$ be the closure of the bounded set Ω . We then have

$$E\left\{\left(\sup_{\mathbf{x} \in \overline{\Omega}} \|[\mathbf{G}_0(\mathbf{x})]^{-1}\|\right)^2\right\} = c_G^2 < +\infty, \quad (26.76)$$

in which sup is the supremum and where $0 < c_G < +\infty$ is a finite positive constant.

9.2.3 Definition of the Hyperparameter s

The hyperparameter $\mathbf{s} \in \mathcal{C}_s \subset \mathbb{R}^{N_s}$ of the algebraic prior stochastic model $\{[\mathbf{K}^{\text{APSM}}(\mathbf{x}; \mathbf{s})], \mathbf{x} \in \Omega\}$ that has been constructed for the anisotropic statistical fluctuations is constituted of:

- the reshaping of $[C_\ell] \in \mathbb{M}_n^+(\mathbb{R})$ (the lower bound) and $[\underline{K}] \in \mathbb{M}_n^+(\mathbb{R})$ (the mean value),
- the $d n(n+1)/2$ positive real numbers, $\{L_1^{jk}, \dots, L_d^{jk}\}_{1 \leq j \leq k \leq n}$ (the spatial-correlation lengths, for the parameterization given in the example) and δ (the dispersion) such that $0 < \delta < \sqrt{(n+1)/(n+5)}$.

9.3 Algebraic Prior Stochastic Model for the Case of Dominant Statistical Fluctuations in a Symmetry Class with Some Anisotropic Statistical Fluctuations

We now consider the case for which the random field exhibits dominant statistical fluctuations in a symmetry class and some anisotropic statistical fluctuations.

9.3.1 Positive-Definite Matrices Belonging to a Symmetry Class

A given symmetry class is defined by a subset $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ of $\mathbb{M}_n^+(\mathbb{R})$ such that any matrix $[M]$ belonging to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ is written as

$$[M] = \sum_{j=1}^N m_j [E_j^{\text{sym}}], \quad \mathbf{m} = (m_1, \dots, m_N) \in \mathcal{C}_{\mathbf{m}} \subset \mathbb{R}^N, \quad [E_j^{\text{sym}}] \in \mathbb{M}_n^S(\mathbb{R}), \quad (26.77)$$

in which $\{[E_j^{\text{sym}}], j = 1, \dots, N\}$ is the matrix basis of $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ (Walpole's tensor basis [75] in the framework of the elasticity theory) and where the admissible subset $\mathcal{C}_{\mathbf{m}}$ of \mathbb{R}^N is defined by

$$\mathcal{C}_{\mathbf{m}} = \{\mathbf{m} \in \mathbb{R}^N \mid \sum_{j=1}^N m_j [E_j^{\text{sym}}] \in \mathbb{M}_n^+(\mathbb{R})\}. \quad (26.78)$$

It should be noted that matrices $[E_1^{\text{sym}}], \dots, [E_N^{\text{sym}}]$ are symmetric but are not positive definite. For the usual material symmetry classes, the possible values of N are the following: 2 for isotropic, 3 for cubic, 5 for transversely isotropic, 6 or 7 for tetragonal, 6 or 7 for trigonal, 9 for orthotropic, 13 for monoclinic, and 21 for anisotropic. The following properties are proved (see [34, 75]):

- (i) If $[M]$ and $[M']$ belong to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$, then for all a and b in \mathbb{R} , $a[M] + b[M'] \in \mathbb{M}_n^{\text{sym}}(\mathbb{R})$, and

$$[M][M'] \in \mathbb{M}_n^{\text{sym}}(\mathbb{R}), \quad [M]^{-1} \in \mathbb{M}_n^{\text{sym}}(\mathbb{R}), \quad [M]^{1/2} \in \mathbb{M}_n^{\text{sym}}(\mathbb{R}). \quad (26.79)$$

- (ii) Any matrix $[N]$ belonging to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ can be written as

$$[N] = \exp_{\mathbb{M}}([\mathcal{N}]), \quad [\mathcal{N}] = \sum_{j=1}^N y_j [E_j^{\text{sym}}], \quad \mathbf{y} = (y_1, \dots, y_N) \in \mathbb{R}^N, \quad (26.80)$$

in which $\exp_{\mathbb{M}}$ is the exponential of symmetric real matrices. It should be noted that matrix $[\mathcal{N}]$ is a symmetric real matrix but does not belong to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ (because \mathbf{y} is in \mathbb{R}^N and not in $\mathcal{C}_{\mathbf{m}}$ and therefore, $[\mathcal{N}]$ is not positive definite).

- (iii) From Eqs. (26.77) and (26.80), it can be deduced that

$$\exp_{\mathbb{M}}\left(\sum_{j=1}^N y_j [E_j^{\text{sym}}]\right) = \sum_{j=1}^N m_j(\mathbf{y}) [E_j^{\text{sym}}], \quad \forall \mathbf{y} \in \mathbb{R}^N, \quad (26.81)$$

in which $\mathbf{m}(\mathbf{y}) = (m_1(\mathbf{y}), \dots, m_N(\mathbf{y}))$ belongs to $\mathcal{C}_{\mathbf{m}(\mathbf{y})}$ that is defined by Eq. (26.78). Let $[\mathcal{E}]$ be the matrix in $\mathbb{M}_N^S(\mathbb{R})$ such that $[\mathcal{E}]_{kj} = \ll [E_j^{\text{sym}}], [E_k^{\text{sym}}] \gg$ and let $\mathcal{F}(\mathbf{y}) = (\mathcal{F}_1(\mathbf{y}), \dots, \mathcal{F}_N(\mathbf{y}))$ be the vector in \mathbb{R}^N such that $\mathcal{F}_k(\mathbf{y}) = \ll \exp_{\mathbb{M}}(\sum_{j=1}^N y_j [E_j^{\text{sym}}]), [E_k^{\text{sym}}] \gg$. For all \mathbf{y} fixed in \mathbb{R}^N , $\mathbf{m}(\mathbf{y})$ is the unique solution in $\mathcal{C}_{\mathbf{m}(\mathbf{y})}$ of the linear system,

$$[\mathcal{E}] \mathbf{m}(\mathbf{y}) = \mathcal{F}(\mathbf{y}). \quad (26.82)$$

It should be noted that, in the purely computational framework that is proposed in the previous Sect. 8, an explicit calculation of $\mathcal{F}(\mathbf{y})$ is not required. For each numerical value of vector \mathbf{y} , vector $\mathbf{m}(\mathbf{y})$ is computed by solving the linear equation defined by Eq. (26.82) in which $\mathcal{F}(\mathbf{y})$ is numerically calculated.

9.3.2 Introduction of the Matrices $[\underline{C}]$, $[\underline{S}]$, and $[\underline{A}]$ Related to the Mean Value of the Matrix-Valued Random Field

Let $[\underline{C}]$ be the matrix in $\mathbb{M}_n^+(\mathbb{R})$, independent of \mathbf{x} , representing the mean value of the random matrix $[\mathbf{C}(\mathbf{x})] = [\mathbf{K}(\mathbf{x})] - [C_\ell]$. From Eq. (26.57), it can then be deduced that

$$[\underline{C}] = [\underline{K}] - [C_\ell] \in \mathbb{M}_n^+(\mathbb{R}). \quad (26.83)$$

Let $[\underline{A}]$ be the deterministic matrix in $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$, independent of \mathbf{x} , representing the projection of the mean matrix $[\underline{C}]$ on the symmetry class $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$,

$$[\underline{A}] = P^{\text{sym}}([\underline{C}]) \in \mathbb{M}_n^{\text{sym}}(\mathbb{R}), \quad (26.84)$$

in which $[\underline{C}]$ is defined by Eq. (26.83) and where P^{sym} is the projection operator from $\mathbb{M}_n^+(\mathbb{R})$ onto $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$.

- (i) For a random field with values in a given symmetry class with $N < 21$ (there are no anisotropic statistical fluctuations), the matrices $[\underline{K}]$ and $[C_\ell]$ belong to the symmetry class and consequently, $[\underline{C}]$ must belong to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$, and thus, $[\underline{A}]$ is equal to $[\underline{C}]$.
- (ii) If the class of symmetry is anisotropic (thus, $N = 21$), then $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ coincides with $\mathbb{M}_n^+(\mathbb{R})$ and again, $[\underline{A}]$ is equal to the mean matrix $[\underline{C}]$ that belongs to $\mathbb{M}_n^+(\mathbb{R})$.
- (iii) In general, for a given symmetry class with $N < 21$, and due to the presence of anisotropic statistical fluctuations, the mean value $[\underline{C}]$ of the random matrix $[\mathbf{C}(\mathbf{x})] = [\mathbf{K}(\mathbf{x})] - [C_\ell]$ belongs to $\mathbb{M}_n^+(\mathbb{R})$ but does not belong to $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$. For this case, an invertible deterministic $(n \times n)$ real matrix $[\underline{S}]$ is introduced such that

$$[\underline{C}] = [\underline{S}]^T [\underline{A}] [\underline{S}]. \quad (26.85)$$

The construction of $[\underline{S}]$ is performed as follows. Let $[\underline{L}_{\underline{C}}]$ and $[\underline{L}_{\underline{A}}]$ be the upper triangular real matrices with positive diagonal entries resulting from the Cholesky factorization of matrices $[\underline{C}]$ and $[\underline{A}]$,

$$[\underline{C}] = [\underline{L}_{\underline{C}}]^T [\underline{L}_{\underline{C}}], \quad [\underline{A}] = [\underline{L}_{\underline{A}}]^T [\underline{L}_{\underline{A}}]. \quad (26.86)$$

Therefore, the matrix $[\underline{S}]$ is defined by

$$[\underline{S}] = [\underline{L}_{\underline{A}}]^{-1} [\underline{L}_{\underline{C}}]. \quad (26.87)$$

It should be noted that for cases (i) and (ii) above, Eq. (26.85) shows that $[\underline{S}] = [I_n]$.

9.3.3 Introduction of an Adapted Representation for the Random Field

The prior stochastic model $\{[\mathbf{K}^{\text{APSM}}(\mathbf{x})], \mathbf{x} \in \Omega\}$ of the second-order random field $\{[\mathbf{K}(\mathbf{x})], \mathbf{x} \in \Omega\}$, indexed by $\Omega \subset \mathbb{R}^d$, with values in $\mathbb{M}_n^+(\mathbb{R})$, is written as

$$[\mathbf{K}^{\text{APSM}}(\mathbf{x})] = [C_t] + [\underline{S}]^T [\mathbf{A}(\mathbf{x})]^{1/2} [\mathbf{G}_0(\mathbf{x})] [\mathbf{A}(\mathbf{x})]^{1/2} [\underline{S}], \quad \forall \mathbf{x} \in \Omega. \quad (26.88)$$

in which the deterministic $(n \times n)$ real matrix $[\underline{S}]$ is defined by Eq. (26.85) and where $\{[\mathbf{G}_0(\mathbf{x})], \mathbf{x} \in \Omega\}$ and $\{[\mathbf{A}(\mathbf{x})], \mathbf{x} \in \Omega\}$ are random fields indexed by \mathbb{R}^d and homogeneous on \mathbb{R}^d . Consequently, the random field $\{[\mathbf{K}^{\text{APSM}}(\mathbf{x})], \mathbf{x} \in \Omega\}$ that is indexed by Ω is the restriction to $\Omega \subset \mathbb{R}^d$ of a homogeneous random field.

- *Anisotropic statistical fluctuations described by $\{[\mathbf{G}_0(\mathbf{x})], \mathbf{x} \in \mathbb{R}^d\}$.*

The random field $\{[\mathbf{G}_0(\mathbf{x})], \mathbf{x} \in \mathbb{R}^d\}$ models the anisotropic statistical fluctuations. This random field and its generator of realizations are constructed in the previous paragraph *Construction of random field $[\mathbf{G}_0]$ and its generator of realizations of Algebraic prior stochastic model for the case of anisotropic statistical fluctuations* section (see Eq. (26.70)). The random field $\{[\mathbf{G}_0(\mathbf{x})], \mathbf{x} \in \Omega\}$ is defined on the probability space $(\Theta, \mathcal{T}, \mathcal{P})$; is indexed by \mathbb{R}^d , with values in $\mathbb{M}_n^+(\mathbb{R})$; and is non-Gaussian, homogeneous, second-order, and mean-square continuous on \mathbb{R}^d .

- For all \mathbf{x} in \mathbb{R}^d , the mean value of random matrix $[\mathbf{G}_0(\mathbf{x})]$ is matrix $[I_n]$ (see Eq. (26.71)).
- The level of the anisotropic statistical fluctuations is controlled by the dispersion parameter δ (independent of \mathbf{x}) such that $0 < \delta < \sqrt{(n+1)/(n+5)}$ (see Eq. (26.72)).
- The hyperparameter s_{G_0} of random field $[\mathbf{G}_0]$ is constituted of the dispersion parameter δ and of the spatial-correlation lengths $\{L_1^{jk}, \dots, L_d^{jk}\}_{1 \leq j \leq k \leq n}$ that are positive real numbers (see Eq. (26.63)).

- *Statistical fluctuations in the given symmetry class described by $\{[\mathbf{A}(\mathbf{x})], \mathbf{x} \in \mathbb{R}^d\}$.*

The random field $\{[\mathbf{A}(\mathbf{x})], \mathbf{x} \in \mathbb{R}^d\}$ models the statistical fluctuations belonging to the given symmetry class $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$. This random field, defined on the probability space $(\Theta', \mathcal{T}', \mathcal{P}')$, is statistically independent of random field $\{[\mathbf{G}_0(\mathbf{x})], \mathbf{x} \in \mathbb{R}^d\}$; is indexed by \mathbb{R}^d , with values in $\mathbb{M}_n^{\text{sym}}(\mathbb{R}) \subset \mathbb{M}_n^+(\mathbb{R})$; and is non-Gaussian, homogeneous, second-order, and mean-square continuous on \mathbb{R}^d . In Eq. (26.88), for all \mathbf{x} fixed in \mathbb{R}^d , the random matrix $[\mathbf{A}(\mathbf{x})]^{1/2}$ is the square root of random matrix $[\mathbf{A}(\mathbf{x})]$ and, due to Eq. (26.79), is with values in $\mathbb{M}_n^{\text{sym}}(\mathbb{R}) \subset \mathbb{M}_n^+(\mathbb{R})$.

- For all \mathbf{x} in \mathbb{R}^d , the mean value of random matrix $[\mathbf{A}(\mathbf{x})]$ is the matrix $[\underline{A}]$ (independent of \mathbf{x} and defined by Eq. (26.84)) such that

$$E\{[\mathbf{A}(\mathbf{x})]\} = [\underline{A}] \in \mathbb{M}_n^{\text{sym}}(\mathbb{R}) \subset \mathbb{M}_n^+(\mathbb{R}). \quad (26.89)$$

- In order that, for all \mathbf{x} in \mathbb{R}^d , the zero matrix be a repulsive value for random matrix $[\mathbf{A}(\mathbf{x})]$, the following constraint is introduced,

$$E\{\log(\det[\mathbf{A}(\mathbf{x})])\} = c_A, \quad |c_A| < +\infty, \quad (26.90)$$

in which real constant c_A is independent of \mathbf{x} .

- The level of the statistical fluctuations belonging to the given symmetry class is controlled by the dispersion parameter δ_A (independent of \mathbf{x}) defined by

$$\delta_A = \sqrt{\frac{E\{\|\mathbf{A}(\mathbf{x}) - \underline{A}\|_F^2\}}{\|\underline{A}\|_F^2}} = \sqrt{\frac{E\{\|\mathbf{A}(\mathbf{x})\|_F^2\}}{\|\underline{A}\|_F^2} - 1}. \quad (26.91)$$

- Due to the statistical independence of $[\mathbf{A}(\mathbf{x})]$ and $[\mathbf{G}_0(\mathbf{x})]$, taking the mathematical expectation of the two members of Eq. (26.88), and from Eqs. (26.83) and (26.85), it can be deduced that, for all \mathbf{x} in Ω ,

$$E\{[\mathbf{K}^{\text{APSM}}(\mathbf{x})]\} = [\underline{K}], \quad [\mathbf{K}^{\text{APSM}}(\mathbf{x})] - [C_\ell] > 0 \quad a.s. \quad (26.92)$$

9.3.4 Remarks Concerning the Control of the Statistical Fluctuations and the Limit Cases

- Anisotropic statistical fluctuations going to zero ($\delta \rightarrow 0$).

For a given symmetry class with $N < 21$, if the level of anisotropic statistical fluctuations goes to zero, i.e., if $\delta \rightarrow 0$, which implies that, for all \mathbf{x} in \mathbb{R}^d , random matrix $[\mathbf{G}_0(\mathbf{x})]$ goes to $[I_n]$ (in probability distribution) and implies that $[\underline{A}]$ goes to $[\underline{C}]$ and thus $[\underline{S}]$ goes to $[I_n]$, then Eq. (26.86) shows that $[\mathbf{K}^{\text{APSM}}(\mathbf{x})] - [C_\ell]$ goes to $[\mathbf{A}(\mathbf{x})]$ (in probability distribution), which is a random matrix with values in $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$. Consequently, if there are no anisotropic statistical fluctuations ($\delta = 0$), then Eq. (26.88) becomes

$$[\mathbf{K}^{\text{APSM}}(\mathbf{x})] = [C_\ell] + [\mathbf{A}(\mathbf{x})], \quad \forall \mathbf{x} \in \Omega, \quad (26.93)$$

and $\{[\mathbf{K}^{\text{APSM}}(\mathbf{x})], \mathbf{x} \in \Omega\}$ is a random field indexed by Ω with values in $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$.

- Statistical fluctuations in the symmetry class going to zero ($\delta_A \rightarrow 0$).

If the given symmetry class is anisotropic ($N = 21$) and if $\delta_A \rightarrow 0$, then $[\underline{A}]$ goes to the mean matrix $[\underline{C}]$ and $[\underline{S}]$ goes to $[I_n]$, and Eq. (26.88) shows that $[\mathbf{K}^{\text{APSM}}(\mathbf{x})] - [C_\ell]$ goes to $[\underline{C}]^{1/2} [\mathbf{G}_0(\mathbf{x})] [\underline{C}]^{1/2}$ (in probability distribution), which is a random matrix with values in $\mathbb{M}_n^+(\mathbb{R})$. Consequently, if there are no statistical fluctuations in the symmetry class ($\delta_A = 0$), then Eq. (26.86) becomes

$$[\mathbf{K}^{\text{APSM}}(\mathbf{x})] = [C_\ell] + [\underline{C}]^{1/2} [\mathbf{G}_0(\mathbf{x})] [\underline{C}]^{1/2}, \quad \forall \mathbf{x} \in \Omega, \quad (26.94)$$

which is Eq. (26.58).

9.3.5 Parameterization of Random Field $\{[\mathbf{A}(\mathbf{x})], \mathbf{x} \in \mathbb{R}^d\}$

Random field $\{[\mathbf{A}(\mathbf{x})], \mathbf{x} \in \mathbb{R}^d\}$, with values in $\mathbb{M}_n^{\text{sym}}(\mathbb{R}) \subset \mathbb{M}_n^+(\mathbb{R})$, is written as

$$[\mathbf{A}(\mathbf{x})] = [\underline{A}]^{1/2} [\mathbf{N}(\mathbf{x})] [\underline{A}]^{1/2}, \quad \forall \mathbf{x} \in \mathbb{R}^d, \quad (26.95)$$

in which $\{[\mathbf{N}(\mathbf{x})], \mathbf{x} \in \mathbb{R}^d\}$ is the random field indexed by \mathbb{R}^d with values in $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$,

$$[\mathbf{N}(\mathbf{x})] = \exp_{\mathbb{M}} \left(\sum_{j=1}^N Y_j(\mathbf{x}) [E_j^{\text{sym}}] \right), \quad \forall \mathbf{x} \in \mathbb{R}^d, \quad (26.96)$$

in which $\exp_{\mathbb{M}}$ denotes the exponential of the symmetric real matrices, where $\mathbf{Y}(\mathbf{x}) = (Y_1(\mathbf{x}), \dots, Y_N(\mathbf{x}))$ and where $\{\mathbf{Y}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$ is a non-Gaussian random field defined on $(\Theta', \mathcal{T}', \mathcal{P}')$, indexed by \mathbb{R}^d with values in \mathbb{R}^N , homogeneous, second-order, mean-square continuous on \mathbb{R}^d . Using the change of representation defined by Eqs. (26.81) and (26.82), random matrix $[\mathbf{N}(\mathbf{x})]$ defined by Eq. (26.96) can be rewritten as

$$[\mathbf{N}(\mathbf{x})] = \sum_{j=1}^N m_j(\mathbf{Y}(\mathbf{x})) [E_j^{\text{sym}}]. \quad (26.97)$$

- *Remark concerning the set of the values of random matrix $[\mathbf{A}(\mathbf{x})]$.*

For all \mathbf{x} fixed in \mathbb{R}^d , $[\mathbf{N}(\mathbf{x})]$ is a random matrix with values in $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ (see Eq. (26.96)) and $[\underline{A}]$ is in $\mathbb{M}_n^{\text{sym}}(\mathbb{R})$ (see Eq. (26.89)). From Eqs. (26.79) and (26.95), it can be deduced that random matrix $[\mathbf{A}(\mathbf{x})]$ is in $\mathbb{M}_n^{\text{sym}}(\mathbb{R}) \subset \mathbb{M}_n^+(\mathbb{R})$.

- *Available information for random matrix $[\mathbf{N}(\mathbf{x})]$.*

For all \mathbf{x} fixed in \mathbb{R}^d , substituting the representation of $[\mathbf{A}(\mathbf{x})]$ defined by Eq. (26.95) into Eqs. (26.89) and (26.90) yields the following available information for random matrix $[\mathbf{N}(\mathbf{x})]$,

$$E\{[\mathbf{N}(\mathbf{x})]\} = [I_n], \quad (26.98)$$

$$E\{\log(\det[\mathbf{N}(\mathbf{x})])\} = c_N, \quad |c_N| < +\infty, \quad (26.99)$$

in which real constant c_N is independent of \mathbf{x} .

- *Available information for random matrix $\mathbf{Y}(\mathbf{x})$.*

Substituting the representation of $[\mathbf{N}(\mathbf{x})]$ defined by Eq. (26.96) into the constraint defined by Eq. (26.99) yields the following constraint for $\mathbf{Y}(\mathbf{x})$,

$$E \left\{ \sum_{j=1}^N Y_j(\mathbf{x}) \text{tr}[E_j^{\text{sym}}] \right\} = c_N, \quad |c_N| < +\infty, \quad \forall \mathbf{x} \in \mathbb{R}^d. \quad (26.100)$$

Substituting the representation of $[N(\mathbf{x})]$ defined by Eq. (26.97) into the constraint defined by Eq. (26.98) yields $E\{\sum_{j=1}^N m_j(\mathbf{Y}(\mathbf{x})) [E_j^{\text{sym}}]\} = [I_n]$. Performing the projection of this equation on the basis $\{[E_k^{\text{sym}}], k = 1, \dots, N\}$ yields (similarly to Eq. (26.82)), $[\mathcal{E}] E\{\mathbf{m}(\mathbf{Y}(\mathbf{x}))\} = \mathcal{I}$ in which $\mathcal{I} = (\mathcal{I}_1, \dots, \mathcal{I}_N)$ is the vector in \mathbb{R}^N such that $\mathcal{I}_k = \ll [I_n, [E_k^{\text{sym}}]] \gg$. The constraint on $[N(\mathbf{x})]$ defined by Eq. (26.98) is transferred in the following constraint on $\mathbf{Y}(\mathbf{x})$,

$$E\{\mathbf{m}(\mathbf{Y}(\mathbf{x}))\} = [\mathcal{E}]^{-1} \mathcal{I} \quad \text{on } \mathbb{R}^N, \quad (26.101)$$

The constraints defined by Eqs. (26.100) and (26.101) are globally rewritten as

$$E\{\mathbf{g}(\mathbf{Y}(\mathbf{x}))\} = \mathbf{f} \quad \text{on } \mathbb{R}^{1+N}, \quad (26.102)$$

in which

- $\mathbf{y} \mapsto \mathbf{g}(\mathbf{y}) = (g_1(\mathbf{y}), \dots, g_{1+N}(\mathbf{y}))$ is the mapping from \mathbb{R}^N into \mathbb{R}^{1+N} such that $g_1(\mathbf{y}) = \sum_{j=1}^N y_j \text{tr}[E_j^{\text{sym}}]$ and $g_{1+j}(\mathbf{y}) = m_j(\mathbf{y})$ for $j = 1, \dots, N$.
- $\mathbf{f} = (f_1, \dots, f_{1+N})$ is the vector in \mathbb{R}^{1+N} such that $f_1 = c_N$ and $f_{1+j} = \{[\mathcal{E}]^{-1} \mathcal{I}\}_j$ for $j = 1, \dots, N$.

9.3.6 Construction of the pdf for Random Vector $\mathbf{Y}(\mathbf{x})$ Using the MaxEnt Principle

For all \mathbf{x} fixed in \mathbb{R}^d , the probability density function $\mathbf{y} \mapsto p_{\mathbf{Y}(\mathbf{x})}(\mathbf{y})$ from \mathbb{R}^N into \mathbb{R}^+ of the \mathbb{R}^N -valued random vector $\mathbf{Y}(\mathbf{x})$ is independent of \mathbf{x} (\mathbf{Y} is homogeneous). This pdf is constructed using the maximum entropy principle presented in Sect. 11 of ▶ Chap. 8, “Random Matrix Models and Nonparametric Method for Uncertainty Quantification” in part II of the present Handbook on Uncertainty Quantification, under the constraints defined by the normalization condition $\int_{\mathbb{R}^N} p_{\mathbf{Y}(\mathbf{x})}(\mathbf{y}) d\mathbf{y} = 1$ and by Eq. (26.102). For all \mathbf{y} in \mathbb{R}^N , the pdf is written as

$$p_{\mathbf{Y}(\mathbf{x})}(\mathbf{y}) = c_0(\boldsymbol{\lambda}^{\text{sol}}) \exp(- < \boldsymbol{\lambda}^{\text{sol}}, \mathbf{g}(\mathbf{y}) >), \quad \forall \mathbf{y} \in \mathbb{R}^N, \quad (26.103)$$

in which $c_0(\boldsymbol{\lambda})$ is defined by

$$c_0(\boldsymbol{\lambda}) = \left\{ \int_{\mathbb{R}^N} \exp(- < \boldsymbol{\lambda}, \mathbf{g}(\mathbf{y}) >) d\mathbf{y} \right\}^{-1}, \quad \boldsymbol{\lambda} \in \mathbb{R}^{1+N}, \quad (26.104)$$

where the Lagrange multiplier $\boldsymbol{\lambda}^{\text{sol}} = (\lambda_1^{\text{sol}}, \dots, \lambda_{1+N}^{\text{sol}})$ belongs to an admissible set $\mathcal{C}_{\boldsymbol{\lambda}} \subset \mathbb{R}^{1+N}$ and is calculated for satisfying Eq. (26.102) by using the efficient numerical method presented in Sect. 11.2 with the MCMC generator presented

in Sect. 11.3 of ▶ Chap. 8 “Random Matrix Models and Nonparametric Method for Uncertainty Quantification” in part II of the present Handbook on Uncertainty Quantification.

Remark. In pdf $p_{\mathbf{Y}(\mathbf{x})}(\mathbf{y})$ constructed with Eq. (26.103), the Lagrange multiplier λ^{sol} depends only on one real parameter that is c_N . Such a parameter has no physical meaning and must be expressed as a function, κ , of the coefficient of variation δ_A defined by Eq. (26.91), such that $c_N = \kappa(\delta_A)$. This means that the family of the pdf constructed with Eq. (26.103) is reparameterized as a function of the dispersion parameter δ_A using $c_N = \kappa(\delta_A)$. An explicit expression of function κ cannot be obtained and is constructed numerically in using Eq. (26.91) in which $E\{\|\mathbf{A}(\mathbf{x})\|_F^2\} = \sum_{j=1}^N \sum_{k=1}^N \ll [E_j^{\text{sym}}][A], [A][E_k^{\text{sym}}] \gg \gg \int_{\mathbb{R}^N} m_j(\mathbf{y}) m_k(\mathbf{y}) p_{\mathbf{Y}(\mathbf{x})}(\mathbf{y}) d\mathbf{y}$.

9.3.7 Constructing a Spatial-Correlation Structure for Random Field $\{\mathbf{Y}(\mathbf{x}); \mathbf{x} \in \mathbb{R}^d\}$ and Its Generator

A spatial-correlation structure is introduced as proposed in [28] for the non-Gaussian second-order homogeneous random field $\{\mathbf{Y}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$ with values in \mathbb{R}^N , for which its first-order marginal probability density function $\mathbf{y} \mapsto p_{\mathbf{Y}(\mathbf{x})}(\mathbf{y})$ (see Eq. (26.103)) is imposed. This pdf is independent of \mathbf{x} and depends on dispersion parameter δ_A . Such a spatial-correlation structure for random field $\{\mathbf{Y}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$ is transferred to random field $\{\mathbf{A}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$, thanks to the transformation defined by Eqs. (26.95) and (26.96), which is written, for all \mathbf{x} in \mathbb{R}^d , as $[\mathbf{A}(\mathbf{x})] = [A]^{1/2} \exp_{\mathbb{M}}(\sum_{j=1}^N Y_j(\mathbf{x}) [E_j^{\text{sym}}]) [A]^{1/2}$.

■ *Introduction of a Gaussian random field $\{\mathbf{B}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$ that defines the spatial-correlation structure.*

- (i) Let $\mathbf{B} = (B_1, \dots, B_N)$ be a random field defined on the probability space $(\Theta', \mathcal{T}', \mathcal{P}')$, indexed by \mathbb{R}^d , with values in \mathbb{R}^N , such that the components B_1, \dots, B_N are N independent real-valued second-order random fields that are Gaussian, homogeneous, centered, normalized, and mean-square continuous. The continuous autocorrelation function $\xi \mapsto [R_{\mathbf{B}}(\xi)] = E\{\mathbf{B}(\mathbf{x} + \xi) \mathbf{B}(\mathbf{x})^T\}$ from \mathbb{R}^d into $\mathbb{M}_N(\mathbb{R})$ is thus diagonal,

$$[R_{\mathbf{B}}(\xi)]_{jk} = \delta_{jk} R_j(\xi), \quad [R_{\mathbf{B}}(\mathbf{0})] = [I_N], \quad (26.105)$$

in which $\xi \mapsto R_j(\xi) = E\{B_j(\mathbf{x} + \xi) B_j(\mathbf{x})\}$, from \mathbb{R}^d into \mathbb{R} , is the autocorrelation function of the centered random field $\{B_j(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$. For all fixed j , since the second-order random field $\{B_j(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$ is Gaussian and centered, this random field is completely and uniquely defined by its autocorrelation function $R_j(\xi) = E\{B_j(\mathbf{x} + \xi) B_j(\mathbf{x})\}$ defined for all $\xi = (\xi_1, \dots, \xi_d)$ in \mathbb{R}^d and such that $R_j(0) = 1$. The spatial-correlation lengths $\mathbb{L}_1^j, \dots, \mathbb{L}_d^j$ of random field $\{B_j(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$ are defined by

$$\mathbb{L}_\alpha^j = \int_0^{+\infty} |R_j(0, \dots, \zeta_\alpha, \dots, 0)| d\zeta_\alpha.$$

In the parameterization of each autocorrelation function R_j , the parameters $\mathbb{L}_1^j, \dots, \mathbb{L}_d^j$ are generally chosen as hyperparameters.

Example of parameterization for autocorrelation function R_j . A minimal parameterization can be defined as $R_j(\xi) = \rho_1^j(\xi_1) \times \dots \times \rho_d^j(\xi_d)$ in which, for all $\alpha = 1, \dots, d$, $\rho_\alpha^j(0) = 1$ and where, for $\xi_\alpha \neq 0$, $\rho_\alpha^j(\xi_\alpha) = 4(\mathbb{L}_\alpha^j)^2 / (\pi^2 \xi_\alpha^2) \sin^2(\pi \xi_\alpha / (2\mathbb{L}_\alpha^j))$, in which $\mathbb{L}_1^j, \dots, \mathbb{L}_d^j$ are positive real numbers. Each random field B_j is mean-square continuous on \mathbb{R}^d and its power spectral density function defined on \mathbb{R}^d has a compact support, $[-\pi/\mathbb{L}_1^j, \pi/\mathbb{L}_1^j] \times \dots \times [-\pi/\mathbb{L}_d^j, \pi/\mathbb{L}_d^j]$. The parameters, $\mathbb{L}_1^j, \dots, \mathbb{L}_d^j$, represent the spatial-correlation lengths of the stochastic germ $\{B_j(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$.

- (ii) For all countable ordered subsets $0 \leq r_1 < \dots < r_k < r_{k+1} < \dots$ of \mathbb{R}^+ , the sequence of random fields $\{\mathbf{B}^{r_k r_{k+1}}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}_{k \in \mathbb{N}}$
 - is mutually independent random fields,
 - is such that, $\forall k \in \mathbb{N}$, $\{\mathbf{B}^{r_k r_{k+1}}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$ is an independent copy of $\{\mathbf{B}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$, which implies that $E\{\mathbf{B}^{r_k r_{k+1}}(\mathbf{x})\} = E\{\mathbf{B}(\mathbf{x})\} = \mathbf{0}$ and that

$$E\{\mathbf{B}^{r_k r_{k+1}}(\mathbf{x}) (\mathbf{B}^{r_k r_{k+1}}(\mathbf{x}))^T\} = E\{\mathbf{B}(\mathbf{x}) \mathbf{B}(\mathbf{x})^T\} = [R_{\mathbf{B}}(\mathbf{0})] = [I_N]. \quad (26.106)$$

■ Defining an \mathbf{x} -dependent family of normalized Wiener stochastic processes $\{\mathbf{W}_{\mathbf{x}}(r), r \geq 0\}$ containing the spatial-correlation structure.

Let $\{\mathbf{W}_{\mathbf{x}}(r), r \geq 0\}$ be the \mathbf{x} -dependent family of stochastic processes defined on probability space $(\mathcal{O}', \mathcal{T}', \mathcal{P}')$, indexed by $r \geq 0$, with values in \mathbb{R}^N , such that $\mathbf{W}_{\mathbf{x}}(0) = \mathbf{0}$ almost surely and, for all \mathbf{x} fixed \mathbb{R}^d and for all $0 \leq s < r < +\infty$, the increment $\Delta \mathbf{W}_{\mathbf{x}}^{sr} := \mathbf{W}_{\mathbf{x}}(r) - \mathbf{W}_{\mathbf{x}}(s)$ is written as

$$\Delta \mathbf{W}_{\mathbf{x}}^{sr} = \sqrt{r-s} \mathbf{B}^{sr}(\mathbf{x}). \quad (26.107)$$

From the properties of random field $\{\mathbf{B}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$ and of the family of random fields $\{\mathbf{B}^{r_k r_{k+1}}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}_{k \in \mathbb{N}}$ for all countable ordered subsets $0 \leq r_1 < \dots < r_k < r_{k+1} < \dots$, it is deduced that, for all \mathbf{x} fixed in \mathbb{R}^d ,

- (i) the components $W_{\mathbf{x}}^{(1)}, \dots, W_{\mathbf{x}}^{(N)}$ of $\mathbf{W}_{\mathbf{x}}$ are mutually independent real-valued stochastic processes,
- (ii) $\{\mathbf{W}_{\mathbf{x}}(r), r \geq 0\}$ is a stochastic process with independent increments,
- (iii) For all $0 \leq s < r < +\infty$, the increment $\Delta \mathbf{W}_{\mathbf{x}}^{sr} = \mathbf{W}_{\mathbf{x}}(r) - \mathbf{W}_{\mathbf{x}}(s)$ is a \mathbb{R}^N -valued second-order random variable which is Gaussian, centered, and with a covariance matrix that is written as $[C_{\Delta \mathbf{W}_{\mathbf{x}}^{sr}}] = E\{\Delta \mathbf{W}_{\mathbf{x}}^{sr} (\Delta \mathbf{W}_{\mathbf{x}}^{sr})^T\} = (r-s) [I_N]$.
- (iv) Since $\mathbf{W}_{\mathbf{x}}(0) = \mathbf{0}$, and from (i), (ii), and (iii), it can be deduced that $\{\mathbf{W}_{\mathbf{x}}(r), r \geq 0\}$ is a \mathbb{R}^N -valued normalized Wiener process.

■ *Constructing random field $\{\mathbf{Y}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$ and its generator.*

The construction of random field $\{\mathbf{Y}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$ is carried out by introducing a family (indexed by \mathbf{x} in \mathbb{R}^d) of Itô stochastic differential equations (ISDE),

- for which the Wiener process is the family $\{\mathbf{W}_x(r), r \geq 0\}$ that contains the imposed spatial-correlation structure defined by Eq. (26.105),
- that admits the same unique invariant measure (independent of \mathbf{x}), which is defined by the pdf $p_{\mathbf{Y}(\mathbf{x})}$ given by Eqs. (26.103) and (26.104).

Taking into account Eq. (26.103), the potential $\mathbf{u} \mapsto \Phi(\mathbf{u})$, from \mathbb{R}^N into \mathbb{R} , is defined by

$$\Phi(\mathbf{u}) = <\lambda^{\text{sol}}, \mathbf{g}(\mathbf{u})>. \quad (26.108)$$

For all \mathbf{x} fixed in \mathbb{R}^d , let $\{(\mathbf{U}_x(r), \mathbf{V}_x(r)), r \geq 0\}$ be the Markov stochastic process defined on the probability space $(\Theta', \mathcal{T}', \mathcal{P}')$, indexed by $r \geq 0$, with values in $\mathbb{R}^N \times \mathbb{R}^N$, satisfying, for all $r > 0$, the following ISDE,

$$d\mathbf{U}_x(r) = \mathbf{V}_x(r) dr, \quad (26.109)$$

$$d\mathbf{V}_x(r) = -\nabla_{\mathbf{u}}\Phi(\mathbf{U}_x(r)) dr - \frac{1}{2}f_0\mathbf{V}_x(r) dr + \sqrt{f_0} d\mathbf{W}_x(r), \quad (26.110)$$

with the initial conditions,

$$\mathbf{U}_x(0) = \mathbf{u}_0, \quad \mathbf{V}_x(0) = \mathbf{v}_0 \quad a.s., \quad (26.111)$$

in which \mathbf{u}_0 and \mathbf{v}_0 are given vectors in \mathbb{R}^N (that are generally taken as zero in the applications) and $f_0 > 0$ is a free parameter whose usefulness is explained below. From Eqs. (26.82) and (26.102), it can be deduced that function $\mathbf{u} \mapsto \Phi(\mathbf{u})$: (i) is continuous on \mathbb{R}^N and (ii) is such that $\mathbf{u} \mapsto \|\nabla_{\mathbf{u}}\Phi(\mathbf{u})\|$ is a locally bounded function on \mathbb{R}^N (i.e., is bounded on all compact sets in \mathbb{R}^N). In addition the Lagrange multiplier λ^{sol} , which belongs to $\mathcal{C}_{\lambda} \subset \mathbb{R}^{1+N}$, is such that

$$\inf_{\|\mathbf{u}\| > R} \Phi(\mathbf{u}) \rightarrow +\infty \quad \text{if} \quad R \rightarrow +\infty, \quad (26.112)$$

$$\inf_{\mathbf{u} \in \mathbb{R}^n} \Phi(\mathbf{u}) = \Phi_{\min} \quad \text{with} \quad \Phi_{\min} \in \mathbb{R}, \quad (26.113)$$

$$\int_{\mathbb{R}^n} \|\nabla_{\mathbf{u}}\Phi(\mathbf{u})\| e^{-\Phi(\mathbf{u})} d\mathbf{u} < +\infty. \quad (26.114)$$

Taking into account (i), (ii), and Eqs. (26.112), (26.113), and (26.114), using Theorems 4–7 in pages 211–216 of Ref. [55] for which the Hamiltonian is taken as $\mathbb{H}(\mathbf{u}, \mathbf{v}) = \|\mathbf{v}\|^2/2 + \Phi(\mathbf{u})$, and using [17, 39] for the ergodic property, it can be deduced that the problem defined by Eqs. (26.109), (26.110), and (26.111) admits a unique solution. For all \mathbf{x} fixed in \mathbb{R}^d , this solution is a second-order diffusion

stochastic process $\{(\mathbf{U}_x(r), \mathbf{V}_x(r)), r \geq 0\}$, which converges to a stationary and ergodic diffusion stochastic process $\{(\mathbf{U}_x^{\text{st}}(r_{\text{st}}), \mathbf{V}_x^{\text{st}}(r_{\text{st}})), r_{\text{st}} \geq 0\}$, when r goes to infinity, associated with the invariant probability measure $P_{\text{st}}(d\mathbf{u}, d\mathbf{v}) = \rho_{\text{st}}(\mathbf{u}, \mathbf{v}) d\mathbf{u} d\mathbf{v}$ (that is independent of x). The probability density function $(\mathbf{u}, \mathbf{v}) \mapsto \rho_{\text{st}}(\mathbf{u}, \mathbf{v})$ on $\mathbb{R}^N \times \mathbb{R}^N$ is the unique solution of the steady-state Fokker-Planck equation associated with Eqs. (26.109) and (26.110) and is written (see pp. 120–123 in [55]) as

$$\rho_{\text{st}}(\mathbf{u}, \mathbf{v}) = c_N \exp\left\{-\frac{1}{2}\|\mathbf{v}\|^2 - \Phi(\mathbf{u})\right\}, \quad (26.115)$$

in which c_N is the constant of normalization. Equations (26.103), (26.108), and (26.115) yield

$$p_{Y(x)}(\mathbf{y}) = \int_{\mathbb{R}^N} \rho_{\text{st}}(\mathbf{y}, \mathbf{v}) d\mathbf{v}, \quad \forall \mathbf{y} \in \mathbb{R}^N. \quad (26.116)$$

Random variable $Y(x)$ (for which the pdf $p_{Y(x)}$ is defined by Eq. (26.103)) can then be written, for all fixed positive value of r_{st} , as

$$Y(x) = \mathbf{U}_x^{\text{st}}(r_{\text{st}}) = \lim_{r \rightarrow +\infty} \mathbf{U}_x(r) \quad \text{in probability distribution.} \quad (26.117)$$

The free parameter $f_0 > 0$ introduced in Eq. (26.110) allows a dissipation term to be introduced in the nonlinear second-order dynamical system (formulated in the Hamiltonian form with an additional dissipative term) for obtaining more rapidly the asymptotic behavior corresponding to the stationary and ergodic solution associated with the invariant measure. Using Eq. (26.117) and the ergodic property of stationary stochastic process \mathbf{U}_x^{st} , it should be noted that, if w is any mapping from \mathbb{R}^N into an Euclidean space such that $E\{w(Y(x))\} = \int_{\mathbb{R}^N} w(\mathbf{y}) p_{Y(x)} d\mathbf{y}$ is finite, then

$$E\{w(Y(x))\} = \lim_{R \rightarrow +\infty} \frac{1}{R} \int_0^R w(\mathbf{U}_x(r, \theta')) dr, \quad (26.118)$$

in which, for $\theta' \in \Theta'$, $\mathbf{U}_x(\cdot, \theta')$ is any realization of \mathbf{U}_x .

9.3.8 Discretization Scheme of the Family of ISDE

A discretization scheme must be used for numerically solving Eqs. (26.109), (26.110), and (26.111). For general surveys on discretization schemes for ISDE, we refer the reader to [40, 70] (among others). The present case, related to a Hamiltonian dynamical system, has also been analyzed using an implicit Euler scheme in [71]. Hereinafter, we present the Störmer-Verlet scheme (see [28, 29]), which is an efficient scheme that preserves energy for nondissipative Hamiltonian dynamical systems (see [35] for reviews about this scheme in the deterministic case, and see [6] and the therein for the stochastic case).

Let $\mu \geq 1$ be an integer. For all \mathbf{x} in \mathbb{R}^d , the ISDE defined by Eqs. (26.109), (26.110), and (26.111) is solved on the finite interval $[0, (\mu - 1) \Delta r]$, in which Δr is the sampling step of the continuous index parameter r . The integration scheme is based on the use of the μ sampling points $r_k = (k - 1) \Delta r$ for $k = 1, \dots, \mu$, and the following notations are used: $\mathbf{U}_\mathbf{x}^k = \mathbf{U}_\mathbf{x}(r_k)$, $\mathbf{V}_\mathbf{x}^k = \mathbf{V}_\mathbf{x}(r_k)$, and $\mathbf{W}_\mathbf{x}^k = \mathbf{W}_\mathbf{x}(r_k)$, with $\mathbf{U}_\mathbf{x}^1 = \mathbf{u}_0$, $\mathbf{V}_\mathbf{x}^1 = \mathbf{v}_0$, and $\mathbf{W}_\mathbf{x}^1 = \mathbf{W}_\mathbf{x}(0) = \mathbf{0}$. From Eq. (26.107) and for $k = 1, \dots, \mu - 1$, the increment $\Delta \mathbf{W}_\mathbf{x}^{k+1} = \mathbf{W}_\mathbf{x}^{k+1} - \mathbf{W}_\mathbf{x}^k$ is written as

$$\Delta \mathbf{W}_\mathbf{x}^{k+1} = \sqrt{\Delta r} \mathbf{B}^{k+1}(\mathbf{x}), \quad \forall \mathbf{x} \in \mathbb{R}^d, \quad (26.119)$$

in which the $\mu - 1$ random fields $\{\mathbf{B}^{k+1}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}_{k=1,\dots,\mu-1}$ are independent copies of random field $\{\mathbf{B}(\mathbf{x}), \mathbf{x} \in \mathbb{R}^d\}$. For $k = 1, \dots, \mu - 1$, the Störmer-Verlet scheme is written as

$$\mathbf{U}_\mathbf{x}^{k+\frac{1}{2}} = \mathbf{U}_\mathbf{x}^k + \frac{\Delta r}{2} \mathbf{V}_\mathbf{x}^k, \quad (26.120)$$

$$\mathbf{V}_\mathbf{x}^{k+1} = \frac{1-b}{1+b} \mathbf{V}_\mathbf{x}^k + \frac{\Delta r}{1+b} \mathbf{L}_\mathbf{x}^{k+\frac{1}{2}} + \frac{\sqrt{f_0}}{1+b} \Delta \mathbf{W}_\mathbf{x}^{k+1}, \quad (26.121)$$

$$\mathbf{U}_\mathbf{x}^{k+1} = \mathbf{U}_\mathbf{x}^{k+\frac{1}{2}} + \frac{\Delta r}{2} \mathbf{V}_\mathbf{x}^{k+1}, \quad (26.122)$$

where $b = f_0 \Delta r / 4$, and where $\mathbf{L}_\mathbf{x}^{k+\frac{1}{2}}$ is the \mathbb{R}^N -valued random variable such that $\mathbf{L}_\mathbf{x}^{k+\frac{1}{2}} = -\{\nabla_{\mathbf{u}} \Phi(\mathbf{u})\}_{\mathbf{u}=\mathbf{U}_\mathbf{x}^{k+\frac{1}{2}}}$. For a given realization θ' in Θ' , the sequence $\{\mathbf{U}_\mathbf{x}^k(\theta'), k = 1, \dots, \mu\}$ is constructed using Eqs. (26.120), (26.121), and (26.122). The discretization of Eq. (26.118) yields the following estimation of the mathematical expectation,

$$E\{w(\mathbf{Y}(\mathbf{x}))\} = \lim_{\mu \rightarrow +\infty} \hat{w}_\mu(\mathbf{x}), \quad \hat{w}_\mu(\mathbf{x}) = \frac{1}{\mu - \mu_0 + 1} \sum_{k=\mu_0}^{\mu} w(\mathbf{U}_\mathbf{x}^k(\theta')), \quad (26.123)$$

in which, for f_0 fixed, the integer $\mu_0 > 1$ is chosen to remove the transient part of the response induced by the initial condition. For details concerning the optimal choice of the numerical parameters, such as μ_0 , μ , f_0 , Δr , \mathbf{u}_0 , and \mathbf{v}_0 , we refer the reader to [29, 34, 59].

9.3.9 Definition of the Hyperparameter \mathbf{s}

The hyperparameter parameter $\mathbf{s} \in \mathcal{C}_s \subset \mathbb{R}^{N_s}$ of the algebraic prior stochastic model $\{\mathbf{K}^{\text{APSM}}(\mathbf{x}; \mathbf{s}), \mathbf{x} \in \Omega\}$, which has been constructed for the dominant statistical fluctuations belonging to a given symmetry class of dimension n , with some anisotropic statistical fluctuations, are constituted of the quantities summarized hereinafter:

- the reshaping of $[C_\ell] \in \mathbb{M}_n^+(\mathbb{R})$ (the lower bound) and $[K] \in \mathbb{M}_n^+(\mathbb{R})$ (the mean value),

- for the control of the anisotropic statistical fluctuations (modeled by random field $[\mathbf{G}_0]$), the $d n(n+1)/2$ positive real numbers, $\{L_1^{jk}, \dots, L_d^{jk}\}_{1 \leq j \leq k \leq n}$ (the spatial-correlation lengths, for the parameterization given in the example), and δ (the dispersion) such that $0 < \delta < \sqrt{(n+1)/(n+5)}$,
- for the control of the statistical fluctuations belonging to a symmetry class (modeled by random field $[\mathbf{A}]$), the $d N$ positive real numbers, $\{\mathbb{L}_1^j, \dots, \mathbb{L}_d^j\}_{1 \leq j \leq N}$ (the spatial-correlation lengths, for the parameterization given in the example), and δ_A (the dispersion) such that $0 < \delta_A$.

10 Key Research Findings and Applications

10.1 Additional Ingredients for Statistical Reduced Models, Symmetry Properties, and Generators for High Stochastic Dimension

- Karhunen-Loëve's expansion revisited for vector-valued random fields and identification from a set of realizations: scaling [50], a posteriori error, and optimal reduced basis [51].
- Construction of a basis adaptation in homogeneous chaos spaces [73].
- ISDE-based generator for a class of non-Gaussian vector-valued random fields in uncertainty quantification [28, 29].
- Random elasticity tensors of materials exhibiting symmetry properties [26–28] and stochastic boundedness constraints [10, 27, 32].
- Random field representations and robust algorithms for the identification of polynomial chaos representations in high dimension from a set of realizations [3, 48, 49, 51, 61, 62, 64].

10.2 Tensor-Valued Random Fields and Continuum Mechanics of Heterogenous Materials

- Composites reinforced with fibers with experimental identification [30, 31].
- Polycrystalline microstructures [32].
- Porous materials with anisotropic permeability tensor random field [33] and with interphases [34].
- Human cortical bone with mechanical alterations in ultrasonic range [16].

11 Conclusions

A complete advanced methodology and the associated tools have been presented for solving the challenging statistical inverse problem related to the experimental identification of a non-Gaussian matrix-valued random field that is the model

parameter of a boundary value problem, using some partial and limited experimental data related to a model observation. Many applications and validation of this methodology can be found in the given references.

Abstract

This work surveys formulation and algorithms for model order reduction (MOR for short) techniques in accelerating computational forward and inverse UQ. Operator equations (comprising elliptic and parabolic partial differential equations (PDEs for short) and boundary integral equations (BIEs for short)) with distributed uncertain input, being an element of an infinite-dimensional, separable Banach space X , are admitted. Using an unconditional basis of X , computational UQ for these equations is reduced to numerical solution of countably parametric operator equations with smooth parameter dependence.

In computational forward UQ, efficiency of MOR is based on recent sparsity results for countably parametric solutions which imply upper bounds on Kolmogorov N -widths of the manifold of (countably) parametric solutions and quantities of interest (QoI for short) with dimension-independent convergence rates. Subspace sequences which realize the N -width convergence rates are obtained by greedy search algorithms in the solution manifold. Heuristic search strategies in parameter space based on finite searches over anisotropic sparse grids render greedy searches in reduced basis construction feasible. Instances of the parametric forward problems which arise in the greedy searches are assumed to be discretized by abstract classes of Petrov–Galerkin (PG for short) discretizations of the parametric operator equation, covering most conforming primal, dual, and mixed finite element methods (FEMs), as well as certain space-time Galerkin schemes for the application problem of interest. Based on the PG discretization, MOR for both linear and nonlinear and affine and nonaffine parametric problems are presented.

Computational inverse UQ for the mentioned operator equations is considered in the Bayesian setting of [M. Dashti and A.M. Stuart: Inverse problems a Bayesian perspective, arXiv:1302.6989v3, this Handbook]. The (countably) parametric Bayesian posterior density inherits, in the absence of concentration effects for small observation noise covariance, the sparsity and N -width bounds of the (countably) parametric manifolds of solution and QoI. This allows, in turn, for the deployment of MOR techniques for the parsimonious approximation of the parametric Bayesian posterior density, with convergence rates which are only limited by the sparsity of the uncertain inputs in the forward model.

1 Introduction

A core task in computational forward and inverse UQ in computational science is the numerical solution of parametric numerical models for the system of interest. Uncertainty in numerical solutions obtained from the computational model can be crudely classified as follows:

(i) *Modeling error*: the mathematical model under consideration does not correctly describe the physical phenomena of interest: its exact solution does not predict the QoI properly. (ii) *Discretization error*: the discretization of the mathematical model (the substitution of the continuous mathematical model by a discrete, finite-dimensional approximation which, in principle, is solvable to any prescribed numerical accuracy on computers in float point arithmetic), whose computational realization is used in forward UQ, introduces a mismatch between the “true response” (understood as exact solution of the mathematical model) and the “computed response” obtained from the computational model, *for a given (set of) input data*, and for a *prescribed quantity of interest (QoI)*. Discretization errors comprise replacing mathematical continuum models by finite difference, finite volume, or finite element models and inexact solution of the finite-dimensional problems which result from discretization, continuous time models by discrete timestepping, random variables by Monte Carlo samples, and their realization by random number generators. The classical paradigm of numerical analysis requires discretizations to be *stable* and *consistent*. Particular issues for discretizations in the context of UQ are *uniform stability and consistency*, with respect to all instances of the uncertain input u . (iii) *Computational error*: the discretized model for the numerical computation of the QoI which is obtained from a mathematical model and its subsequent discretization is not numerically solvable *for the given input data* with the computer resources at hand. This could be, for example, due to CPU limitations and imprecise float point arithmetic (rounding) but also due to runtime failures of hardware components, partial loss of data at runtime, etc.

Under the (strong) assumptions that modeling error (i) and computational error (iii) are negligible, which is to say that epistemic uncertainty is absent, i.e., the mathematical model under consideration is well posed and accounts in principle for all phenomena of interest, and the assumption that float point computations are reliable, a *first key task in computational forward UQ is the efficient computational prediction of the QoI of a mathematical model for any given instance of uncertain input u from a space of admissible input data X* . Computational challenges arise when the space X of uncertain inputs is infinite-dimensional. For example, for *distributed uncertain input* (such as material properties in inhomogeneous solids or fluids, shapes obtained from noisy imaging, random forcing, etc.), X is a (subset of a) function space. Computational UQ then involves *uncertainty parametrization* via a basis of X (such as, for example, a Fourier basis in $X = L^2$), resulting in a *parametric forward problem depending on sequences $y = (y_j)_{j \geq 1}$ of uncertain input parameters*. Probability measures on X which encode information on aleatoric uncertainty can be introduced via countable products of probability measures on sequence space. Computational UQ procedures access the parametric response or forward solutions *nonintrusively*, i.e., by numerical solution of the forward model for instances of the parameter sequence y . Due to the possibly infinite dimension of space of uncertain inputs y and due to the possibly high cost of each forward solve, two *key issues in computational UQ* are (a) efficient computational sampling of uncertain inputs from high (possibly infinite) dimensional parameter spaces and (b) efficient numerical solution of parametric forward models.

Two key methodologies are reviewed, which address issue (a) and issue (b): *sparsity* of the parametric response map and *model order reduction (MOR)*. Sparsity refers to the possibility to represent responses of the parametric forward model with user-specified accuracy $0 < \varepsilon \ll 1$ with responses at $O(\varepsilon^{-1/s})$ parameter instances where the sparsity parameter $s > 0$ and $O()$ are independent of the dimension of the parameter space. MOR refers to replacing the parametric response from the mathematical model for all admissible parameters by one parsimonious, the so-called reduced order model, respectively, *surrogate model* which allows fast response evaluation with certified accuracy ε for any parameter instance y . The accuracy which can be achieved by MOR with n basis functions, for a given set of solutions, is determined by the so-called *n -width of the solution set in the space of all possible solutions*.

Recent results on sparsity of parametric forward models are reviewed, covering in particular uncertain coefficients, loadings and domains of definition in partial differential equation models which arise in engineering and in the sciences. *Sparsity adapted interpolation schemes in parameter space* allow to build *polynomial chaos surrogates of the parametric forward response maps*. The corresponding point sets in parameter space are (*generalized*) *sparse grids*; they are based on dimension- and order-adaptive interpolation processes described here. As Monte Carlo sampling, the performance of collocation in these deterministic point sets is independent of the dimension of the parameter space, and their convergence rates can exceed $1/2$, provided the parametric response exhibits sufficient sparsity.

Sampling of high-dimensional parameter spaces on generalized sparse grids can be used in so-called stochastic collocation for building polynomial surrogates of the parametric forward maps, in the “training” phase of MOR and for deterministic Smolyak quadrature over all uncertainties to evaluate response statistics in forward UQ and Bayesian estimates in inverse UQ, for example.

The chapter’s focus is therefore on model order reduction and sparse, adaptive collocation methods in high-dimensional parameter spaces in computational forward and inverse UQ. All concepts are developed on abstract classes of forward problems with parametric *distributed* uncertain input data, which is to say that the uncertain data may take values in an infinite-dimensional function space. Mathematical forward models which are considered here are specified in terms of (linear or nonlinear) PDEs, of elliptic or parabolic type, with smooth nonlinearities. Key steps in the approach are:

- Uncertainty parametrization: upon choosing a basis Ψ of the space X of uncertain input data, the forward problem turns into a parametric problem. The choice of basis Ψ is, in general, highly nonunique. To ensure stability in float point realizations of the parametric forward problem, care must be taken to choose *well-conditioned* bases Ψ of X . For example, in Hilbert spaces X , ideally orthonormal bases Ψ should be chosen or at least so-called Riesz bases with good Riesz constants.
- Upon choosing a (well-conditioned) basis of X , a (countably) parametric family of parametric, deterministic problems are obtained; these are referred to in the

literature typically as “ y -PDE”. For distributed uncertain inputs u , these are, usually, *infinite-dimensional parameter sequences* y .

- The (minimal, for computational UQ) requirements of well-posedness of the forward problem for all admissible instances of the uncertain input u and for continuous dependence of the solution on the input imply that *the set of all parametric solutions* $\mathcal{M} := \{q(y) : y \in U\} \subset \mathcal{X}$ form a submanifold of the solution space \mathcal{X} . For smooth (linear or nonlinear) elliptic and parabolic problems, the manifold \mathcal{M} is in fact an analytic manifold; see [28] and the references therein.
- “Smooth” (analytic) dependence of PDE on uncertain inputs, resp. parameters implies algebraic (exponential) smallness of the n -width $\mathcal{M} \subset \mathcal{X}$. This enables, in principle, *accelerated forward solves with work which scales algebraic (logarithmic) in accuracy* ε .
- Determining (near-)optimal subspaces which realize Kolmogorov n -width approximation bounds is feasible using so-called reduced basis methods. Section 3 provides key elements of the corresponding algorithms and the related theoretical results, with particular attention to the countably parametric problems resulting from forward problems with distributed, uncertain input data. Detailed references to the literature on these techniques are provided.
- The availability of suitably compressed approximations of forward models with uncertain inputs implies, in particular, dramatic accelerations of any algorithm which involves numerous, repeated approximate evaluations of these forward models, for instance, optimization problems under uncertainty [14, 19], PDE-constrained optimization algorithms, and the corresponding inverse problems. An application to *inverse uncertainty quantification by Bayesian inversion* is presented in Sect. 4. Bayes’ theorem provides an expression for the “most likely” expected output in a quantity of interest (QoI), conditional on a set of given, noisy observations of (functionals of) the forward response. The numerical realization becomes, with the mentioned uncertainty parametrization, an *infinite-dimensional integration problem* against a probability measure which is only known up to a normalization constant. Current computational approaches to deal with this problem are various variants of Monte Carlo methods, such as Markov chain Monte Carlo (MCMC), sequential Monte Carlo, etc. Due to their generally slow convergence, numerous evaluations of the forward models are necessary, for a large number of proposals (generated by the corresponding samplers) of the uncertain input data. In this setting, running the Markov chains on a reduced basis surrogate of the forward model can afford dramatic reductions in CPU time; as shown in Sect. 4, the resulting computational Bayesian estimates of the expected QoI will inherit an error which is of the order of the error incurred in the MOR.

The propagation of MOR error bounds translates one-to-one to other recently developed computational methods for Bayesian inversion which circumvent the use of MC sampling. These methods rather tackle the infinite-dimensional, parametric integrals obtained by inserting the uncertainty parametrization into Bayes’ formula, for example, by adaptive Smolyak or higher-order quasi-Monte Carlo integration.

2 Forward UQ

By forward uncertainty quantification (“forward UQ” for short), we denote the efficient computational realization of the uncertainty-to-solution map. The present section specifies an abstract class of smooth, possibly nonlinear, operator equations with distributed, uncertain input data which allow for efficient computational forward UQ. The common feature of this class of problems is based on *holomorphic extension* of the parametric uncertainty-to-solution maps, as described in [28] and the references there.

2.1 A Class of Forward Problems with Uncertain Input Data

By \mathcal{X} and \mathcal{Y} , we denote separable Hilbert spaces with duals \mathcal{X}' and \mathcal{Y}' , respectively.

They are used for the formulation of the mathematical model of the forward problem: system responses q (such as temperature, concentration, displacements, electric fields, etc.) take values in \mathcal{X} , whereas loads and source terms are understood as objects in \mathcal{Y}' , i.e., they are assumed to act on “test functions” $v \in \mathcal{Y}$.

Admissible mathematical models take form of a *residual map* \mathcal{R} which associates, for a given uncertain input $u \in X$, to each state $q \in \mathcal{X}$ a response $\mathcal{R} : q \mapsto \mathcal{R}(u; q) \in \mathcal{Y}'$. With the space X of uncertain parameters $u \in X$ being infinite-dimensional, we speak about $u \in X$ as *distributed, uncertain parameters*. Three prototypical examples are presented: diffusion with uncertain diffusion coefficient, smooth nonlinear elliptic problem in a parametric domain, and a parabolic problem.

Example 1 (Linear diffusion problem with uncertain diffusion coefficient). The mathematical model is set in a bounded domain $D \subset \mathbb{R}^d$ (assumed certain), with diffusion coefficient $u(x) \in L^\infty(D)$ (assumed uncertain) and a source term $f(x) \in L^2(D)$ (assumed certain), find a concentration $q(x) \in H_0^1(D)$ such that

$$\mathcal{R}(q; u) := \operatorname{div}(u(x)\operatorname{grad}q(x)) + f(x) = 0 \quad \text{in } H^{-1}(D). \quad (27.1)$$

Here the spaces for the system response q are $\mathcal{X} = \mathcal{Y} = H_0^1(D)$, the space for the uncertain input is $X = L^\infty(D)$, and $\mathcal{Y}' = (H_0^1(D))^* = H^{-1}(D)$. Note that (27.1) is to hold in the weak or variational sense of $\mathcal{Y}' = H^{-1}(D)$; this gives rise to the *variational form of the residual equation*: find $q \in \mathcal{X}$ such that

$$0 = {}_{\mathcal{Y}}\langle v, \mathcal{R}(q; u) \rangle_{\mathcal{Y}'} = \int_D \operatorname{grad}v \cdot u(x)\operatorname{grad}q(x)dx - \int_D v(x)f(x)dx \quad (27.2)$$

for all $v \in \mathcal{Y} = H_0^1(D)$.

Here, and in what follows, ${}_{\mathcal{Y}}\langle \cdot, \cdot \rangle_{\mathcal{Y}'}$ denotes the $\mathcal{Y} \times \mathcal{Y}'$ -duality.

Analogous formulations arise for any second-order, linear elliptic PDE in divergence form, such as Helmholtz equations for time-harmonic wave propagation

in random media or in (displacement formulations) of boundary value problems in computational mechanics in solids with uncertain material properties.

Example 2. In a bounded domain $D \subset \mathbb{R}^n$, and in the time interval $I = (0, T)$ for a time-horizon $0 < T < \infty$, and for the affine-parametric, elliptic operator $A(\mathbf{y})q = \operatorname{div}(u(x)\operatorname{grad}q(x))$ as in (27.1), for given $f(x, t)$ and for given $u_0 \in L_2(D)$, the parametric, linear parabolic evolution problem is considered

$$B(\mathbf{y})q := \partial_t q - A(\mathbf{y})q = f, \quad q(\cdot, t)|_{\partial D} = 0 \quad \text{in } (0, T) \times D, \quad q(\cdot, 0) = q_0. \quad (27.3)$$

The parabolic, parametric evolution operator $B(\mathbf{y})$ in (27.3) allows for a weak residual formulation analogous to (27.1) with the Bochner spaces $\mathcal{X} = L_2(I; V) \cap H^1(I; V')$, $\mathcal{Y} = L_2(I; V) \times H$, $V = H_0^1(D)$ and $H = L_2(D)$. Here, the parametric bilinear form $B(\mathbf{y}; w, v)$ is defined, for $v = (v_1, v_2) \in L_2(I; V) \times H$, by

$$B(\mathbf{y}; w, v) := \int_I \langle \frac{dw}{dt}(t), v_1(t) \rangle_H + \int_D u(x, \mathbf{y}) \nabla w \cdot \nabla v_1 dx dt + \langle w(0), v_2 \rangle_H,$$

where $u(x, \mathbf{y})$ denotes the linear-parametric, isotropic diffusion coefficient as in (27.13).

An abstract setting is considered which accommodates both examples (and more general models) in a unified fashion. For a distributed, uncertain parameter $u \in X$, one considers a “forward” operator $\mathcal{R}(q; u)$ depending on u and acting on $q \in \mathcal{X}$. Assuming at our disposal, a “nominal parameter instance” $\langle u \rangle \in X$ (such as, for example, the expectation of an X -valued random field u) and for $u \in B_X(\langle u \rangle; R)$, an open ball of sufficiently small radius $R > 0$ in X centered at a nominal input instance $\langle u \rangle \in X$, the nonlinear operator equation is considered

$$\text{given } u \in B_X(\langle u \rangle; R), \text{ find } q \in \mathcal{X} \quad \text{s.t.} \quad {}_{\mathcal{Y}'} \langle \mathcal{R}(q; u), v \rangle_{\mathcal{Y}} = 0 \quad \forall v \in \mathcal{Y}. \quad (27.4)$$

Given $u \in B_X(\langle u \rangle; R)$, a solution q_0 of (27.4) is called *regular at u* if and only if $\mathcal{R}(\cdot; u)$ is differentiable with respect to q and if the differential $D_q \mathcal{R}(q_0; u) \in \mathcal{L}(\mathcal{X}; \mathcal{Y}')$ is an isomorphism. For the well-posedness of operator equations involving $\mathcal{R}(q; u)$, one assumes the map $\mathcal{R}(\cdot; u) : \mathcal{X} \mapsto \mathcal{Y}'$ admits a family of regular solutions *locally, in an open neighborhood of the nominal parameter instance $\langle u \rangle \in X$* .

Assumption 1. *The structural conditions*

$$\mathcal{R}(q; u) = A(q; u) - F(u) \quad \text{in } \mathcal{Y}', \quad (27.5)$$

hold, and for all u in a sufficiently small, closed neighborhood $\tilde{X} \subseteq X$ of $\langle u \rangle \in X$ the parametric forward problem: for every $u \in \tilde{X} \subseteq X$, given $F(u) \in \mathcal{Y}'$,

find $q(u) \in \mathcal{X}$ such that the residual Eq. (27.4) is well-posed. I.e., for every fixed $u \in \tilde{X} \subset X$, and for every $F(u) \in \mathcal{Y}'$, there exists a unique solution $q(u)$ of (27.4) which depends continuously on u .

The set $\{(q(u), u) : u \in \tilde{X}\} \subset \mathcal{X} \times X$ is called a *regular branch of solutions* of (27.5) if

$$\begin{aligned} \tilde{X} &\ni u \mapsto q(u) \text{ is continuous as mapping from } X \mapsto \mathcal{X}, \\ \mathcal{R}(q(u); u) &= 0 \quad \text{in } \mathcal{Y}'. \end{aligned} \tag{27.6}$$

The solutions is called in the regular branch (27.6) *nonsingular* if, in addition, the differential

$$(D_q \mathcal{R})(q(u); u) \in \mathcal{L}(\mathcal{X}, \mathcal{Y}') \text{ is an isomorphism from } \mathcal{X} \text{ onto } \mathcal{Y}', \text{ for all } u \in \tilde{X}. \tag{27.7}$$

The following proposition collects well-known sufficient conditions for well-posedness of (27.5). For regular branches of nonsingular solutions given by (27.5), (27.6), and (27.7), the mathematical model is well posed if the differential $D_q \mathcal{R}$ satisfies the so-called inf-sup conditions. In UQ, these classical (e.g., [5, 60]) conditions are to hold *uniformly with respect to the uncertain input data* $u \in \tilde{X} \subseteq X$.

Proposition 1. Assume that \mathcal{Y} is reflexive and that, for some nominal value $\langle u \rangle \in X$ of the uncertain input data, the operator equation (27.5) admits a regular branch of solutions (27.6). Then the differential $D_q \mathcal{R}$ at $(\langle u \rangle, q_0)$ given by the bilinear map

$$\mathcal{X} \times \mathcal{Y} \ni (\varphi, \psi) \mapsto {}_{\mathcal{Y}'} \langle D_q \mathcal{R}(q_0; \langle u \rangle) \varphi, \psi \rangle_{\mathcal{Y}}$$

is boundedly invertible, uniformly with respect to $u \in \tilde{X}$ where $\tilde{X} \subset X$ is an open neighborhood of the nominal instance $\langle u \rangle \in X$ of the uncertain parameter. In particular, there exists a constant $\beta > 0$ such that there holds

$$\forall u \in \tilde{X} : \begin{aligned} \inf_{0 \neq \varphi \in \mathcal{X}} \sup_{0 \neq \psi \in \mathcal{Y}} \frac{{}_{\mathcal{Y}'} \langle (D_q \mathcal{R})(q_0; u) \varphi, \psi \rangle_{\mathcal{Y}}}{\|\varphi\|_{\mathcal{X}} \|\psi\|_{\mathcal{Y}}} &\geq \beta > 0, \\ \inf_{0 \neq \psi \in \mathcal{Y}} \sup_{0 \neq \varphi \in \mathcal{X}} \frac{{}_{\mathcal{Y}'} \langle (D_q \mathcal{R})(q_0; u) \varphi, \psi \rangle_{\mathcal{Y}}}{\|\varphi\|_{\mathcal{X}} \|\psi\|_{\mathcal{Y}}} &\geq \beta > 0 \end{aligned} \tag{27.8}$$

and

$$\forall u \in \tilde{X} : \| (D_q \mathcal{R})(q_0, u) \|_{\mathcal{L}(\mathcal{X}, \mathcal{Y}')} = \sup_{0 \neq \varphi \in \mathcal{X}} \sup_{0 \neq \psi \in \mathcal{Y}} \frac{{}_{\mathcal{Y}'} \langle (D_q \mathcal{R})(q_0; u) \varphi, \psi \rangle_{\mathcal{Y}}}{\|\varphi\|_{\mathcal{X}} \|\psi\|_{\mathcal{Y}}} \leq \beta^{-1}. \tag{27.9}$$

The inf-sup conditions (27.8) and (27.9) are implied, for linear, self-adjoint PDEs such as the diffusion equation in Example 1, by the more familiar concept of *coercivity*.

Example 3. In the context of Example 1, one verifies with $\mathcal{Y} = \mathcal{X} = H_0^1(D)$ that

$$\gamma' \langle (D_q \mathcal{R})(q_0; u)\varphi, \psi \rangle_{\mathcal{Y}} = \int_D \nabla \psi \cdot u(x) \nabla \varphi(x) dx.$$

In particular, for linear operator equations, the residual $\mathcal{R}(q; u)$ is linear with respect to q and the differential $(D_q \mathcal{R})(q_0; u)$ in (27.8) does not depend on q_0 . Note that *uniform validity of (27.8) for all realizations of the uncertain input u* implies a constraint on the set $\tilde{X} \subseteq X$ of admissible data: one may choose, for example, $X = L^\infty(D)$ and require u to take values on

$$\tilde{X} = \{u \in X : \text{essinf}(u) \geq c_0 > 0\}.$$

Then (27.8) (and thus also (27.7)) are implied by the *coercivity of $(D_q \mathcal{R})(q_0; u)$ in $\mathcal{X} = H_0^1(D)$*

$$\begin{aligned} \gamma' \langle (D_q \mathcal{R})(q_0; u)\varphi, \varphi \rangle_{\mathcal{Y}} \int_D \nabla \varphi \cdot u(x) \nabla \varphi(x) dx &\geq c_0 \int_D |\nabla \varphi(x)|^2 dx \\ &\geq c_0 \frac{1}{2} (1 + C_P) \|\varphi\|_{\mathcal{X}}^2, \end{aligned}$$

where $C_P(D) > 0$ denotes the constant in the *Poincaré-inequality* $\|\nabla \varphi\|_{L^2(D)}^2 \geq C_P \|\varphi\|_{L^2(D)}^2$, valid in \mathcal{X} uniformly for all inputs $u \in \tilde{X}$. The saddle point stability conditions (27.8) and the possibility of different trial and test function spaces are not necessary here.

Remark 1. The saddle point stability conditions (27.8) are, however, indispensable for indefinite variational problems such as the space-time formulation of the parabolic evolution problem (27.3). For (27.3), the inf-sup conditions (27.8) have been verified in [70, Appendix]. Consider, for further illustration, the *Helmholtz Equations* for the propagation of time-harmonic pressure amplitude $\pi(x, t)$ in an uncertain, linearly elastic medium, in a bounded, certain domain $D \subset \mathbb{R}^d$, with homogeneous Dirichlet boundary conditions on ∂D .

Separation of variables $\pi(x, t) = \exp(i\omega t)q(x)$ implies the Helmholtz equation,

$$-\operatorname{div}(u(x) \nabla q(x)) - \omega^2 q(x) = f(x) \quad \text{in } D, \quad q|_{\partial D} = 0. \quad (27.10)$$

One chooses again $\mathcal{X} = \mathcal{Y} = H_0^1(D)$ and $u \in \tilde{X}$ as in Example 3. Then, for large frequency $\omega > 0$, the saddle point stability conditions (27.8) hold only if $\omega^2 \notin \bigcup_{u \in \tilde{X}} \Sigma(A(\cdot; u))$, where $\Sigma(A(\cdot; u)) \subset \mathbb{R}_{>0}$ denotes the (discrete and countable)

spectrum of the second order elliptic operator $A(q; u) := -\operatorname{div}(u(x)\nabla q(x)) \in \mathcal{L}(\mathcal{X}; \mathcal{X}')$ as is revealed by an straightforward eigenfunction argument. The stability constant β in (27.8) is $\beta = \inf_{\lambda \in \Sigma(A(\cdot; u)), u \in \tilde{X}} \{|\lambda - \omega^2|\}$.

Under conditions (27.8) and (27.9), for every $u \in \tilde{X} \subseteq X$, there exists a unique, regular solution $q(u)$ of (27.5) which is uniformly bounded with respect to $u \in \tilde{X}$ in the sense that there exists a constant $C(F, \tilde{X}) > 0$ such that

$$\sup_{u \in \tilde{X}} \|q(u)\|_{\mathcal{X}} \leq C(F, \tilde{X}). \quad (27.11)$$

For (27.8), (27.9), (27.10), and (27.11) being valid, we shall say that the set $\{(q(u), u) : u \in \tilde{X}\} \subset \mathcal{X} \times \tilde{X}$ forms a *regular branch of nonsingular solutions*.

If the data-to-solution map $\tilde{X} \ni u \mapsto q(u)$ is also Fréchet differentiable with respect to u at every point of the regular branch $\{(q(u); u) : u \in \tilde{X}\} \subset \mathcal{X} \times \tilde{X}$, the dependence of the “forward map,” i.e., the mapping relating u to $q(u)$ with the branch of nonsingular solutions, is locally Lipschitz on \tilde{X} : there exists a Lipschitz constant $L(F, \tilde{X})$ such that

$$\forall u, v \in \tilde{X} : \|q(u) - q(v)\|_{\mathcal{X}} \leq L(F, \tilde{X}) \|u - v\|_X. \quad (27.12)$$

This follows from the identity $(D_u q)(u) = -(D_q \mathcal{R})^{-1}(D_u \mathcal{R})$ and from the isomorphism property $(D_u \mathcal{R}_q)(q_0; \langle u \rangle) \in \mathcal{L}_{iso}(\mathcal{X}, \mathcal{Y}')$ which is implied by (27.8) and (27.9) and from the continuity of the differential $D_q \mathcal{R}$ on the regular branch.

In what follows, the abstract setting (27.4) is considered with uniformly continuously differentiable mapping $\mathcal{R}(q; u)$ in a product of neighborhoods $B_X(\langle u \rangle; R) \times B_{\mathcal{X}}(q(\langle u \rangle); R) \subset X \times \mathcal{X}$ of sufficiently small radius $R > 0$, satisfying the structural assumption (27.5). In Proposition 1 and throughout what follows, $q(\langle u \rangle) \in \mathcal{X}$ denotes the unique regular solution of (27.5) at the nominal input $\langle u \rangle \in X$.

2.2 Uncertainty Parametrization

As mentioned in the introduction, a key step in computational UQ is the *parametrization of the uncertain input data* $u \in X$ in terms of a (possibly infinite) sequence $\mathbf{y} = (y_j)_{j \geq 1}$ of parameters, taking values in a *parameter domain* U .

In the particular case where $u \in X$ is a random variable taking values in (a subset \tilde{X} of) the Banach space X , probabilistic UQ involves probability measures on the space X of uncertain input data.

In *uncertainty parametrization*, X is assumed to be separable. This is guaranteed in particular when X is finite-dimensional, i.e., when *the uncertain input data consists of a finite number of parameters*.

In the case of *distributed uncertain input* $u \in X$, the data space X is infinite-dimensional; to facilitate uncertainty parametrization, X is assumed to admit an

unconditional Schauder basis Ψ : $X = \text{span}\{\psi_j : j \geq 1\}$. This is in particular the case for separable Hilbert spaces X . Then, every $u \in \tilde{X} \subset X$ can be parametrized *linearly* in this basis, i.e., it admits a *parametric representation with linear dependence on the parameters y_j* :

$$u = u(\mathbf{y}) := \langle u \rangle + \sum_{j \geq 1} y_j \psi_j \quad \text{for some } \mathbf{y} = (y_j)_{j \geq 1} \in U. \quad (27.13)$$

Some examples of linear uncertainty parametrizations (27.13) are: (i) Karhunen–Loëve expansions which arise, in particular, from a numerical PCA of a random field model of uncertain input u (see, e.g., [32, 69, 72, 73]), (ii) unconditional Schauder bases (see, e.g., [27]), (iii) wavelet or trigonometric bases, and (iv) isogeometric geometry parametrizations from computer aided design (see, e.g., [3] and the references there).

The representation (27.13) is not unique: rescaling y_j and ψ_j will not change u . One assumes, therefore, throughout what follows that *the basis sequence $\{\psi_j\}_{j \geq 1}$ is normalized such that the parameter domain is $U = [-1, 1]^{\mathbb{N}}$* . However, for *Gaussian random field inputs*, the assumption of bounded parameter ranges is not satisfied: see [46, 69] for parametric formulations in this case.

Note that often, in applications, the dependence of u on the parameters y_j is not granted; one distinguishes:

- (a) *Linear parametrization* (27.13)
- (b) *Affine or separable parametrization*: the uncertain/parametric heat conductivity is given by [59]

$$u(x, \mathbf{y}) = \sum_{j \geq 1} \theta_j(\mathbf{y}) \psi_j(x), \quad \mathbf{y} \in U. \quad (27.14)$$

where we emphasize that for every $j \geq 1$, each coordinate function $\theta_j(\mathbf{y})$ may depend on *all* coordinates $y_j \in \mathbf{y}$. A typical example of a separable uncertainty parametrization is the so-called thermal fin problem (cp. [59])

$$u(x, \mathbf{y}) = \sum_{j=1}^J \chi_{D_j}(x) 10^{y_j}, \quad (27.15)$$

where $D := \bigcup_{j=1}^J D_j$ is decomposed into J nonoverlapping subdomains D_j , $j = 1, \dots, J$; χ_{D_j} is a characteristic function such that $\chi_{D_j}(x) = 1$ if $x \in D_j$ and 0 otherwise; $y_j \in [-1, 1]$, $j = 1, \dots, J$.

- (c) *Nonlinear transformation of an affine parametrization*. This case occurs, for example, in log Gaussian models with a positivity constraint, such as a linear diffusion equation with a log Gaussian permeability; for illustration, consider the Dirichlet problem:

$$-\nabla \cdot (u(x, \omega) \nabla q(x, \omega)) = f(x) \quad \text{in } D, \quad q|_{\partial D} = 0. \quad (27.16)$$

Here, the uncertain input is a log Gaussian random field, i.e.,

$$u(x, \omega) = \exp(g(x, \omega)), \quad \text{where} \quad g(x, \omega) = \sum_{j \geq 1} Y_j(\omega) \psi_j(x), \quad Y_j \sim N(0, 1). \quad (27.17)$$

Due to Y_j taking values in all of \mathbb{R} with positive probability, in (27.17), the normalization of the terms is effected by requiring that the standard deviation of Y_j be one.

- (d) *Nonseparable, nonlinear parametric operator equations.* Examples of this class typically arise in problems of *domain uncertainty*: upon diffeomorphic transformation of the problem to a fixed nominal domain, we obtain a parametric problem with uncertain operator whose coefficients are rational functions of the parameters. We refer the reader to Example 4 ahead for illustration.

Bases in the uncertain input space X are, in general, not unique, even when fixing the scaling of the coordinates y_j in (27.13). Being bases of X , they are mathematically equivalent. *In the context of computational UQ, the concrete choice of basis can have a significant impact on the numerical stability of UQ algorithms.* For illustration we mention the (textbook) example $X = L^2(-1, 1)$, for which two bases are given by $\Psi_1 = \{1, x, x^2, \dots\}$ and $\Psi_2 = \{P_j(x) : j = 0, 1, 2, \dots\}$ denoting P_j the classical Legendre polynomial of degree $j \geq 0$, with normalization $P_j(1) = 1$. Both bases, Ψ_1 and Ψ_2 , as well as the trigonometric functions constituting a Karhunen–Loëve basis of $X = L^2(-1, 1)$, are *global*, meaning that their elements are supported in the entire domain $[-1, 1]$. Alternative bases of $X = L^2(-1, 1)$ with local supports are spline wavelet bases, such as the Haar wavelet basis. Most localized bases have an intrinsic limit on the approximation order which can be reached for sufficiently smooth uncertain input data. Uncertainty parametrization with localized bases can, however, substantially increase sparsity in the parametric forward map.

Norm-convergence of the series (27.13) in X is implied by the *summability condition*

$$\sum_{j \geq 1} \|\psi_j\|_X < \infty, \quad (27.18)$$

“Uncertain input data” can also signify *domain uncertainty*, i.e., the shape of the physical domain D in which the boundary value problem is considered is uncertain. Upon suitable domain parametrization, such problems also are covered by the ensuing parametric, variational formulation; domain uncertainty in the physical domain can be reduced by domain mapping to a parametric problem in a fixed, nominal domain D_0 . This was considered for (27.2) with parametric coefficient u depending on the shape of the [28] for a particular example, and the following, smooth and nonlinear elliptic problem from [23]; see also [52] for applications to artery variability in Hemodynamics, to [45] for application of reduced basis techniques in electromagnetic scattering.

Example 4 (Domain uncertainty). A nonlinear operator equation in a random domain [28] is considered. The basic approach to dealing with domain uncertainty consists in *domain mapping* to a fixed reference domain, and in transforming the mathematical model from the physical domain to a fixed reference domain which is assumed known. Note that in certain classes of mathematical models, such as, for example, elastic deformation of a continuous medium, such reference domains arise naturally; in mathematical elasticity, the reference domain would be referred to as *reference configuration*. Note also that the reference domain may not necessarily be attained by concrete realizations of the uncertain input. Also, in stochastic domain modelling, the reference domain need not coincide with the nominal domain.

In transforming to a fixed reference domain, parametric domain uncertainty is transferred to the differential operator on the reference domain. Due to the smooth, but highly nonlinear nature of the domain transformations, the resulting parametric differential operators on the reference domain exhibit, as a rule, highly nonlinear, rational dependence w.r. to the parameter sequence \mathbf{y} , even if the mathematical model is linear.

Here we consider in addition a mathematical model which is nonlinear, also w.r. to the state variable q taking values in the function space \mathcal{X} .

The mathematical model in the physical domain reads: given $\mathbf{y} \in U$, find $q(\mathbf{y}) : D_{u(\mathbf{y})} \rightarrow \mathbb{R}$ such that

$$-\Delta q(\mathbf{y}) + q^3(\mathbf{y}) = f \quad \text{in } D_{u(\mathbf{y})}, \quad q(\mathbf{y}) = 0 \quad \text{on } \partial D_{u(\mathbf{y})}, \quad (27.19)$$

where the random domain $D_{u(\mathbf{y})}$ is homeomorphic to the unit disc, and explicitly given by

$$D_{u(\mathbf{y})} := \{x = (r \cos(\theta), r \sin(\theta)) : 0 \leq r < u(\mathbf{y}; \theta), 0 \leq \theta < 2\pi\}, \quad \mathbf{y} \in U. \quad (27.20)$$

Here, the random radius $u(\mathbf{y})$, as defined in (27.13), is given explicitly by

$$u(0) = \langle u \rangle = 1 \text{ and } \psi_j = \frac{0.5}{j^\alpha} \sin(j\theta) \quad j \geq 1, \text{ where } \alpha > 2. \quad (27.21)$$

By T_u we denote a transformation map from the nominal domain $D_{\langle u \rangle}$, the unit disk of \mathbb{R}^2 centered at the origin, to the parametric domain D_u , $T_u(r \cos(\theta), r \sin(\theta)) := (u(\mathbf{y})r \cos(\theta), u(\mathbf{y})r \sin(\theta))$. The nonlinear operator equation (27.19) in the parametric, uncertain physical domain becomes a parametric, nonlinear equation in the fixed nominal domain, which reads as: given a parameter sequence $\mathbf{y} \in U$, find a parametric response $q(\mathbf{y}) : D_{\langle u \rangle} \rightarrow \mathbb{R}$ such that

$$\begin{cases} -\operatorname{div}(M(\mathbf{y})\nabla q(\mathbf{y})) + q^3(\mathbf{y})d(\mathbf{y}) = f d(\mathbf{y}) & \text{in } D_{\langle u \rangle}, \\ q(\mathbf{y}) = 0 & \text{on } \partial D_{\langle u \rangle}, \end{cases} \quad (27.22)$$

where $d(\mathbf{y})$ denotes the determinant of the Jacobian dT_u of the map T_u , given as $d(\mathbf{y}) = (u(\mathbf{y}))^2$;

$$M(\mathbf{y}) := d(\mathbf{y})dT_u^{-1}dT_u^{-\top} = \begin{pmatrix} 1 + (b(\mathbf{y}))^2 & -b(\mathbf{y}) \\ -b(\mathbf{y}) & 1 \end{pmatrix} \quad \text{where } b(\mathbf{y}) := \frac{\partial_\theta u(\mathbf{y})}{u(\mathbf{y})}. \quad (27.23)$$

This example fits into the abstract setting of Sect. 2.1 as follows: the uncertain datum $\mathbf{u} = u(\mathbf{y}; \cdot) \in X_t = C_{\text{per}}^t([0, 2\pi))$ where the degree of smoothness $t = t(\alpha)$ depends on the exponent $\alpha > 2$ in (27.21). The spaces \mathcal{X} and \mathcal{Y} then are function spaces on the nominal domain, and chosen as $\mathcal{X} = \mathcal{Y} = H_0^1(D_{\langle u \rangle})$.

We note that uncertain inputs \mathbf{u} with “higher regularity” (when measured in a smoothness scale $\{X_t\}_{t \geq 0}$ with $X = X_0 \supset X_1 \supset X_2 \supset \dots$ on the admissible input data) correspond to stronger decay of ψ_j : for $\mathbf{u} \in X_t \subset X$, in (27.13) the $\{\psi_j\}_{j \geq 1}$ are assumed scaled such that

$$\mathbf{b} := \{\|\psi_j\|_X\}_{j \geq 1} \in \ell^p(\mathbb{N}) \quad \text{for some } 0 < p = p(t) < 1, \quad (27.24)$$

where the sequence $\mathbf{b} = (b_j)_{j \geq 1}$ is given by $b_j := \|\psi_j\|_X$. We also introduce the subset

$$U = \left\{ \mathbf{y} \in [-1, 1]^\mathbb{N} : u(\mathbf{y}) := \langle \mathbf{u} \rangle + \sum_{j \geq 1} y_j \psi_j \in \tilde{X} \right\}. \quad (27.25)$$

See (27.21) in Example 4, where the exponent $\alpha > 2$ determines the (Hölder) smoothness of the domain transformation, and where the spaces X_t correspond to Hölder spaces of 2π -periodic functions.

Once an unconditional basis $\{\psi_j\}_{j \geq 1}$ of X has been chosen, every realization $\mathbf{u} \in X$ can be identified in a one-to-one fashion with the pair $(\langle \mathbf{u} \rangle, \mathbf{y})$ where $\langle \mathbf{u} \rangle$ denotes the *nominal instance* of the uncertain datum \mathbf{u} and \mathbf{y} is the coordinate vector in representation (27.13). Inserting (27.13) into (27.4), we obtain under Assumption 1 the *equivalent, countably-parametric form*: given $F : U \rightarrow \mathcal{Y}'$,

$$\text{find } q(\mathbf{y}; F) \in \mathcal{X} : \forall \mathbf{y} \in U : \mathcal{R}(q; \mathbf{y}) := A(q; \mathbf{y}) - F(\mathbf{y}) = 0 \quad \text{in } \mathcal{Y}'. \quad (27.26)$$

Remark 2. In what follows, by a slight abuse of notation, one identifies the subset U in (27.25) with the countable set of parameters from the infinite-dimensional parameter domain $U \subseteq \mathbb{R}^\mathbb{N}$ without explicitly writing so. The operator $A(q; u)$ in (27.5) then becomes, via the parametric dependence $u = u(\mathbf{y})$, a parametric operator family $A(q; u(\mathbf{y}))$ which one denotes (with slight abuse of notation) by $\{A(q; \mathbf{y}) : \mathbf{y} \in U\}$, with the parameter set $U = [-1, 1]^\mathbb{N}$ (again, one uses in what follows this definition in place of the set U as defined in (27.25)). If $A(q; \mathbf{y})$ in (27.5) is linear, one has $A(q; \mathbf{y}) = A(\mathbf{y})q$ with $A(\mathbf{y}) \in \mathcal{L}(\mathcal{X}, \mathcal{Y}')$. One does not assume,

however, that the maps $q \mapsto A(q; \mathbf{y})$ are linear in what follows, unless explicitly stated.

With this understanding, and under the assumptions (27.11) and (27.12), the operator equation (27.5) will admit, for every $\mathbf{y} \in U$, a unique solution $q(\mathbf{y}; F)$ which is, due to (27.11) and (27.12), uniformly bounded and depends Lipschitz continuously on the parameter sequence $\mathbf{y} \in U$: there holds

$$\sup_{\mathbf{y} \in U} \|q(\mathbf{y}; F)\|_{\mathcal{X}} \leq C(F, U), \quad (27.27)$$

and, if the local Lipschitz condition (27.12) holds, there exists a Lipschitz constant $L > 0$ such that

$$\|q(\mathbf{y}; F) - q(\mathbf{y}'; F)\|_{\mathcal{X}} \leq L(F, U) \|u(\mathbf{y}) - u(\mathbf{y}')\|_{\mathcal{X}}. \quad (27.28)$$

The Lipschitz constant in (27.28) is not, in general, equal to $L(F, \tilde{X})$ in (27.12): it depends on the nominal instance $\langle u \rangle \in X$ and on the choice of basis $\{\psi_j\}_{j \geq 1}$.

Unless explicitly stated otherwise, throughout what follows, we identify $q_0 = q(\mathbf{0}; F) \in \mathcal{X}$ in Proposition 1 with the solution of (27.4) at the nominal input $\langle u \rangle \in X$.

2.3 Parameter Sparsity in Forward UQ

In forward UQ for problems with distributed, uncertain input data, upon uncertainty parametrizations such as (27.13), the solution of the forward problem becomes, as functions of the parameters y_j in the sequence \mathbf{y} , a countably parametric map from the parameter space U to the solutions' state space \mathcal{X} . Efficient computational UQ for such problems is crucially related to the approximation of such countably parametric maps with *convergence rates which are independent of the dimension*, i.e., independent of the number of coordinates which are active in the approximation. Mathematical results are reviewed which allow to establish such approximation results, with a key insight being that the attainable convergence rate is independent of the dimension of the space of active parameters, and depends only on the “sparsity” of the parametric map which is to be approximated. One technique to verify parametric sparsity for a broad class of parametric problems is to verify the existence of suitable *holomorphic extensions* of the parameter to solution map into the complex domain. The existence of such extensions is closely related to polynomial approximations of the parametric maps. The version presented here applies the holomorphic extension of countably parametric maps for which polynomial approximations take the form of so-called generalized polynomial chaos expansions which will be described in detail below. The results presented in this section are detailed in [28, 29] and the references there.

2.3.1 (b, p)-Holomorphy

For $s > 1$, introduce the Bernstein ellipse in the complex plane

$$\mathcal{E}_s := \left\{ \frac{w + w^{-1}}{2} : 1 \leq |w| \leq s \right\} \subset \mathbb{C}, \quad (27.29)$$

which has semi axes of length $\frac{s+s^{-1}}{2} > 1$ and $\frac{s-s^{-1}}{2} > 0$ and denote

$$\mathcal{E}_\rho := \bigotimes_{j \geq 1} \mathcal{E}_{\rho_j} \subset \mathbb{C}^{\mathbb{N}}, \quad (27.30)$$

the tensorized poly-ellipse when $\rho := (\rho_j)_{j \geq 1}$ is a sequence of semi-axis sums $\rho_j > 1$. With the convention $\mathcal{E}_1 = [-1, 1]$, one also admits $\rho_j = 1$ in (27.30), so that $U \subseteq \mathcal{E}_\rho$.

Sparsity analysis of parametric maps $q : U \mapsto \mathcal{X} : y \mapsto q(y)$ as in [28] and the references there relies on holomorphic extensions of parametric solutions q from U to \mathcal{E}_ρ .

Definition 1. For a positive sequence $\mathbf{b} = (b_j)_{j \geq 1} \in \ell^p(\mathbb{N})$ for some $0 < p < 1$, a parametric mapping $U \ni y \mapsto q(y) \in X$ satisfies the (\mathbf{b}, p) -holomorphy assumption in the Hilbert space \mathcal{X} if and only if

1. For each $y \in U$, there exists a unique $q(y) \in X$ and the map $y \mapsto q(y)$ from U to \mathcal{X} is uniformly bounded, i.e.,

$$\sup_{y \in U} \|q(y)\|_{\mathcal{X}} \leq C_0, \quad (27.31)$$

for some finite constant $C_0 > 0$.

2. For some $0 < \varepsilon < 1$ there exists a constant $C_\varepsilon \geq C_0 > 0$ such that for any sequence $\rho := (\rho_j)_{j \geq 1}$ of semiaxis sums ρ_j strictly larger than 1 that is $(\mathbf{b}, \varepsilon)$ -admissible, i.e.,

$$\sum_{j=1}^{\infty} (\rho_j - 1) b_j \leq \varepsilon, \quad (27.32)$$

the parametric map $y \mapsto q(y) \in X$ admits a complex extension $z \mapsto q(z)$ (taking values in the complexification of the space \mathcal{X}) that is a holomorphic mapping with respect to each variable z_j on a set of the form $\mathcal{O}_\rho := \bigotimes_{j \geq 1} \mathcal{O}_{\rho_j}$, $\mathcal{O}_{\rho_j} \subset \mathbb{C}$ is an open set containing \mathcal{E}_{ρ_j} , and the modulus $\|q(z)\|_{\mathcal{X}}$ of this extension is bounded on \mathcal{E}_ρ in (27.30) according to

$$\sup_{z \in \mathcal{E}_\rho} \|q(z)\|_{\mathcal{X}} \leq C_\varepsilon. \quad (27.33)$$

The significance of (\mathbf{b}, p) holomorphy lies in the following facts: (a) solution of well-posed, countably possibly nonlinear parametric operator equations with (\mathbf{b}, p) holomorphic, parametric operator families are (\mathbf{b}, p) holomorphic; (b) (\mathbf{b}, p) holomorphic parametric solution maps $\{q(\mathbf{y}) : \mathbf{y} \in U\} \subset \mathcal{X}$ allow for tensorized so-called “polynomial chaos” approximations with dimension-independent N -term approximation rates which depend only on the summability exponent p of the sequence \mathbf{b} ; (c) (\mathbf{b}, p) holomorphic parametric solution maps $\{q(\mathbf{y}) : \mathbf{y} \in U\} \subset \mathcal{X}$ can also be constructively approximated by sparse, Smolyak-type interpolation methods; see [25, 26]; and (d) (\mathbf{b}, p) holomorphy is preserved under composition with holomorphic maps, in particular, for example, in the context of *Bayesian inverse problems*; see [66, 68] for details. (e) (\mathbf{b}, p) holomorphic parametric solution maps $\{q(\mathbf{y}) : \mathbf{y} \in U\} \subset \mathcal{X}$ allow for *low-parametric, reduced basis surrogates*. Points (b) and (c) are explained next, detailing in particular computational approximation strategies for the efficient computation of sparse approximations of countably-parametric solution families.

2.3.2 Sparse Polynomial Approximation

(\mathbf{b}, p) -holomorphy ensures ℓ^p summability of gpc Legendre coefficients of (\mathbf{b}, p) holomorphic parametric solution maps $\{q(\mathbf{y}) : \mathbf{y} \in U\} \subset \mathcal{X}$. To state the result, from [26], for any coefficient bound sequence $\mathbf{c} := (c_\nu)_{\nu \in \mathcal{F}} \subset \mathbb{R}$, one associates its downward closed envelope $\mathbf{c}^* := (c_\nu^*)_{\nu \in \mathcal{F}}$ defined by

$$\mathbf{c}_\nu^* := \sup_{\mu \geq \nu} |c_\mu^*|, \quad \nu \in \mathcal{F}, \quad (27.34)$$

where $\mu \geq \nu$ means that $\mu_j \geq \nu_j$ for all j . An index set $\Lambda \subset \mathcal{F}$ is downward closed if and only if

$$\nu \in \Lambda \quad \text{and} \quad \mu \leq \nu \Rightarrow \mu \in \Lambda. \quad (27.35)$$

For a summability exponent $p > 0$, one introduces the space $\ell_m^p(\mathcal{F})$ of sequences that have their downward closed envelope in $\ell^p(\mathcal{F})$. One approximates the parametric responses by truncating the tensorized Legendre (“generalized polynomial chaos”) series

$$q(\mathbf{y}) = \sum_{\nu \in \mathcal{F}} q_\nu P_\nu(\mathbf{y}), \quad (27.36)$$

where the convergence is understood to be unconditional (in particular, the limit exists and is independent of the particular enumeration of \mathcal{F}) and where the tensorized Legendre polynomials $P_\nu(\mathbf{y})$ are given by $P_\nu(\mathbf{y}) := \prod_{j \geq 1} P_{\nu_j}(y_j)$, with P_n denoting the univariate Legendre polynomial of degree n for the interval $[-1, 1]$ with the classical normalization $\|P_n\|_{L^\infty([-1, 1])} = |P_n(1)| = 1$. The series (27.36) may be rewritten as

$$q(\mathbf{y}) = \sum_{\nu \in \mathcal{F}} v_\nu L_\nu(\mathbf{y}), \quad (27.37)$$

where $L_v(\mathbf{y}) := \prod_{j \geq 1} L_{v_j}(y_j)$, with L_n denoting the version of P_n normalized in $L^2([-1, 1], \frac{dt}{2})$, i.e.,

$$q_v = \left(\prod_{j \geq 1} (1 + 2v_j) \right)^{1/2} v_v. \quad (27.38)$$

Theorem 1 ([25]). *For a (\mathbf{b}, p) -holomorphic, parametric map $U \ni \mathbf{y} \rightarrow q(\mathbf{y}) \in \mathcal{X}$ in a Hilbert space \mathcal{X} , the sequences $(\|q_v\|_{\mathcal{X}})_{v \in \mathcal{F}}$ and $(\|v_v\|_{\mathcal{X}})_{v \in \mathcal{F}}$ of (norms of) the tensorized Legendre coefficients belong to $\ell_m^p(\mathcal{F})$, and*

$$q(\mathbf{y}) = \sum_{v \in \mathcal{F}} q_v P_v = \sum_{v \in \mathcal{F}} v_v L_v, \quad (27.39)$$

holds in the sense of unconditional convergence in $L^\infty(U, \mathcal{X})$.

There exists a sequence $(\Lambda_N)_{N \geq 1}$, with $\#(\Lambda_N) = N$ of nested downward closed sets such that

$$\inf_{w \in \mathcal{X}_{\Lambda_N}} \|q - w\|_{L^\infty(U, \mathcal{X})} \leq C(N+1)^{-s}, \quad s = \frac{1}{p} - 1, \quad (27.40)$$

where for any finite set $\Lambda \subset \mathcal{F}$ one defines

$$\mathcal{X}_\Lambda := \text{span} \left\{ \sum_{v \in \Lambda} w_v \mathbf{y}^v : w_v \in \mathcal{X} \right\}. \quad (27.41)$$

2.3.3 Sparse Grid Interpolation

Polynomial interpolation processes on the spaces \mathcal{X}_Λ for general downward closed sets Λ of multiindices have been introduced and studied in [26]. Given $z := (z_j)_{j \geq 1}$, a sequence of pairwise distinct points of $[-1, 1]$, one associates with any finite subset $\Lambda \subset \mathcal{F}$ the following *sparse interpolation grid* in U :

$$\Gamma_\Lambda := \{z_v : v \in \Lambda\} \quad \text{where} \quad z_v := (z_{v_j})_{j \geq 1}. \quad (27.42)$$

If $\Lambda \subset \mathcal{F}$ is downward closed, then the sparse grid Γ_Λ is unisolvant for \mathbb{P}_Λ : for any function g defined in Γ_Λ and taking values in \mathcal{X} , there exists a unique sparse grid interpolation polynomial $I_\Lambda g$ in \mathbb{P}_Λ that coincides with g on Γ_Λ . The interpolation polynomial $I_\Lambda g \in \mathbb{P}_\Lambda \otimes \mathcal{X}$ can be computed recursively: if $\Lambda := \{v^1, \dots, v^N\}$ such that for any $k = 1 \dots, N$, $\Lambda_k := \{v^1, \dots, v^k\}$ is downward closed, then

$$I_\Lambda g = \sum_{i=1}^N g_{v^i} H_{v^i}, \quad (27.43)$$

where the polynomials $(H_v)_{v \in \Lambda}$ are a hierarchical basis of \mathbb{P}_Λ given by

$$H_v(\mathbf{y}) := \prod_{j \geq 1} h_{v_j}(y_j) \quad \text{where } h_0(t) = 1 \text{ and } h_k(t) = \prod_{j=0}^{k-1} \frac{t - z_j}{z_k - z_j}, \quad k \geq 1, \quad (27.44)$$

and where the coefficients g_{v^k} are recursively defined by

$$g_{v^1} := g(z_0), \quad g_{v^k+1} := g(z_{v^k+1}) - I_{\Lambda_k} g(z_{v^k+1}) = g(z_{v^k+1}) - \sum_{i=1}^k g_{v^i} H_{v^i}(z_{v^k+1}). \quad (27.45)$$

The sparse grid $\Gamma_\Lambda \subset U$ is unisolvant for the space \mathcal{X}_Λ of multivariate polynomials with coefficients in \mathcal{X} . The interpolation operator that maps functions defined on U with values in \mathcal{X} into \mathcal{X}_Λ can be computed by the recursion (27.43) if one admits $g_v \in \mathcal{X}$. Naturally, in this case, the coefficients g_v being elements of a function space cannot be exactly represented and must be additionally approximated, e.g., by a finite element or a collocation approximation in a finite-dimensional subspace $\mathcal{X}_h \subset \mathcal{X}$.

The following result recovers the best N -term approximation rate $\mathcal{O}(N^{-s})$ in (27.40) for the interpolation in \mathbb{P}_Λ different choice of downward closed sets Λ . See [25] for a proof.

Theorem 2. *For any (b, p) -holomorphic, \mathcal{X} -valued parametric map $\mathbf{y} \mapsto q(\mathbf{y})$ there exists a constant $C > 0$ and a nested sequence of downward closed sets $(\Lambda_n)_{N \geq 1}$ with $\#(\Lambda_N) = N$ for which*

$$\|q - I_{\Lambda_N} q\|_{L^\infty(U, \mathcal{X})} \leq C(N + 1)^{-s}, \quad s = \frac{1}{p} - 1. \quad (27.46)$$

Remark 3. The above theorem guarantees the *existence of some sparse grid interpolant* with dimension-independent error convergence rate. However, practical construction of a sparse grid is not a trivial task, which depends on specific problems. A dimension-adaptive algorithm has been proposed in [42] and further developed in [15, 54, 66]. This algorithm has been found to perform well in a host of examples from forward and inverse UQ. Its convergence and (quasi)optimality are, however, not yet justified mathematically.

3 Model Order Reduction

Given any sample $\mathbf{y} \in U$, an accurate solution of the forward PDE model (27.26) relies on a stable and consistent numerical solver with high precision, which typically requires a high-fidelity discretization of the PDE model and a computationally expensive solving of the corresponding algebraic system. Such a large-scale

computation for a large number of samples is the most critical challenge in UQ problems. This section outlines *model order reduction* (MOR for short) methods in order to effectively alleviate the computational burden while facilitating certified accuracy of the parametric solution as well as its related quantities of interest. The material in this section is related to developments during the past decade. Our presentation is therefore synoptic, and the reader is referred to the surveys [44, 50, 51] and the references there for more detailed elaboration, and further references.

3.1 High-Fidelity Approximation

At first, a stable and consistent high-fidelity approximation of the solution of the parametric problem (27.26) following [23] is presented. To guarantee the stability of the HiFi approximation at any given $\mathbf{y} \in U$, one considers the Petrov–Galerkin (PG) discretization in the one-parameter family of pairs of subspaces $\mathcal{X}_h \subset \mathcal{X}$ and $\mathcal{Y}_h \subset \mathcal{Y}$ with equal dimensions, i.e., $N_h = \dim(\mathcal{X}_h) = \dim(\mathcal{Y}_h) < \infty$, where h represents a discretization parameter, for instance, the meshwidth of a PG finite element discretization. To ensure the convergence of the HiFi PG solution $q_h \in \mathcal{X}_h$ to the exact solution $q \in \mathcal{X}$ as $h \rightarrow 0$, one assumes the subspace families \mathcal{X}_h and \mathcal{Y}_h to be dense in \mathcal{X} and \mathcal{Y} as the discretization parameter (being, e.g., a meshwidth or an inverse spectral order) $h \rightarrow 0$, i.e.,

$$\forall w \in \mathcal{X} : \lim_{h \rightarrow 0} \inf_{w_h \in \mathcal{X}_h} \|w - w_h\|_{\mathcal{X}} = 0, \text{ and } \forall v \in \mathcal{Y} : \lim_{h \rightarrow 0} \inf_{v_h \in \mathcal{Y}_h} \|v - v_h\|_{\mathcal{Y}} = 0. \quad (27.47)$$

Moreover, to quantify the convergence rate of the discrete approximation, one introduces a *scale of smoothness spaces* $\mathcal{X}^s \subset \mathcal{X} = \mathcal{X}^0$ and $\mathcal{Y}^s \subset \mathcal{Y} = \mathcal{Y}^0$ indexed by the smoothness parameter $s > 0$. Here, one has in mind for example spaces of functions with s extra derivatives in Sobolev or Besov spaces. Then, for appropriate choices of the subspaces \mathcal{X}_h and \mathcal{Y}_h hold the approximation properties: there exist constants $C_s > 0$ such that for all $0 < h \leq 1$ holds

$$\begin{aligned} \forall w \in \mathcal{X}^s : \inf_{w_h \in \mathcal{X}_h} \|w - w_h\|_{\mathcal{X}} &\leq C_s h^s \|w\|_{\mathcal{X}^s} \\ \text{and } \forall v \in \mathcal{Y}^s : \inf_{v_h \in \mathcal{Y}_h} \|v - v_h\|_{\mathcal{Y}} &\leq C_s h^s \|v\|_{\mathcal{Y}^s}. \end{aligned} \quad (27.48)$$

Here, the constant C_s is assumed independent of the discretization parameter h but may depend on the smoothness parameter s . For small values of h and/or if s is large, the PG discretization produces high-fidelity (HiFi) approximations $q_h \in \mathcal{X}_h$ of the true solution $q \in \mathcal{X}$ by solving

$$\text{given } \mathbf{y} \in U, \text{ find } q_h(\mathbf{y}) \in \mathcal{X}_h : \quad \mathbf{y}' \langle \mathcal{R}(q_h(\mathbf{y}); \mathbf{y}), v_h \rangle_{\mathcal{Y}} = 0 \quad \forall v_h \in \mathcal{Y}_h. \quad (27.49)$$

A globally convergent Newton iteration method can be applied to solve the nonlinear, parametric HiFi-PG approximation problem (27.49) numerically; see [23, 33] for details.

To establish the well-posedness of the HiFi-PG approximation problem (27.49) as well as the a priori and a posteriori error estimates for the approximate solution q_h , the following assumptions are imposed.

Assumption 2. Let $a(\cdot, \cdot; y) : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$ denote the parametric bilinear form for each $y \in U$ associated with the Fréchet derivative of \mathcal{R} at q , i.e.

$$a(w, v; y) := {}_{\mathcal{Y}'} \langle D_q \mathcal{R}(q(y); y)(w), v \rangle_{\mathcal{Y}} \quad \forall w \in \mathcal{X}, \forall v \in \mathcal{Y}. \quad (27.50)$$

The following conditions are assumed to hold

A1 stability: the parametric bilinear form a satisfies the discrete HiFi-PG inf-sup condition

$$\forall y \in U : \inf_{0 \neq w_h \in \mathcal{X}_h} \sup_{0 \neq v_h \in \mathcal{Y}_h} \frac{a(w_h, v_h; y)}{\|w_h\|_{\mathcal{X}} \|v_h\|_{\mathcal{Y}}} =: \beta_h(y) \geq \beta_h > 0, \quad (27.51)$$

where the inf-sup constant $\beta_h(y)$ depends on h and on y and may vanish $\beta_h(y) \rightarrow 0$ as $h \rightarrow 0$.

A2 consistency: the best approximation satisfies the consistent approximation property

$$\forall y \in U : \lim_{h \rightarrow 0} \frac{1}{\beta_h^2(y)} \inf_{w_h \in \mathcal{X}_h} \|q(y) - w_h\|_{\mathcal{X}} = 0. \quad (27.52)$$

In view of the convergence rate in (27.48), (27.52) amounts to require $h^s/\beta_h^2(y) \rightarrow 0$ as $h \rightarrow 0$.

A3 local Lipschitz continuity: there exists ϵ_0 and $L > 0$ such that for all $w \in \mathcal{X}$ with $\|q(y) - w\|_{\mathcal{X}} \leq \epsilon_0$, there holds

$$\forall y \in U : \|D_q \mathcal{R}(q(y); y) - D_q \mathcal{R}(w; y)\|_{\mathcal{L}(\mathcal{X}, \mathcal{Y}')} \leq L \|q(y) - w\|_{\mathcal{X}}. \quad (27.53)$$

Assumption 2 is sufficient to guarantee the existence of a solution $q_h(y) \in \mathcal{X}_h$ of the HiFi-PG approximation problem (27.49) for any $y \in U$, which is locally unique and satisfies a priori error estimate. The results are presented in the following theorem, whose proof follows that in [60].

Theorem 3. Under Assumption 2, there exists $h_0 > 0$ and $\eta_0 > 0$ such that for $0 < h \leq h_0$, there exists a solution $q_h(y) \in \mathcal{X}_h$ of the HiFi-PG approximation

problem (27.49), which is unique in $\mathcal{B}_{\mathcal{X}}(q(\mathbf{y}); \eta_0 \beta_h(\mathbf{y}))$. Moreover, for $0 < h \leq h_0$, there holds the *a priori* error estimate

$$\|q(\mathbf{y}) - q_h(\mathbf{y})\|_{\mathcal{X}} \leq 2 \frac{\|a(\mathbf{y})\|}{\beta(\mathbf{y})} \left(1 + \frac{\|a(\mathbf{y})\|}{\beta_h(\mathbf{y})}\right) \inf_{w_h \in \mathcal{X}_h} \|q(\mathbf{y}) - w_h\|_{\mathcal{X}}, \quad (27.54)$$

where $\|a(\mathbf{y})\| := \|D_q \mathcal{R}(q(\mathbf{y}); \mathbf{y})\|_{\mathcal{L}(\mathcal{X}, \mathcal{Y})}$. Depending on the smoothness parameter $s > 0$ (see (27.48)) and the polynomial degree $r \geq 1$ of the Finite Element space, one has

$$\inf_{w_h \in \mathcal{X}_h} \|q(\mathbf{y}) - w_h\|_{\mathcal{X}} \leq Ch^k \|q(\mathbf{y})\|_{\mathcal{X}^s}, \quad k = \min\{s, r\}, \quad (27.55)$$

where C is independent of the mesh size h and uniformly bounded w.r.t. \mathbf{y} . Moreover, one has the *a posteriori* error estimate

$$\|q(\mathbf{y}) - q_h(\mathbf{y})\|_{\mathcal{X}} \leq \frac{4}{\beta(\mathbf{y})} \|\mathcal{R}(q_h(\mathbf{y}); \mathbf{y})\|_{\mathcal{Y}}. \quad (27.56)$$

In many (but not all) practical applications in UQ, the lower bound of the stability constants $\beta(\mathbf{y})$ and $\beta_h(\mathbf{y})$ in Assumption 2 are independent of \mathbf{y} and of h : consider specifically the parametric elliptic diffusion problem in Example 3. In this example, one has that for $\mathcal{X} = \mathcal{Y} = H_0^1(D)$ holds, for every $\mathbf{y} \in U$, that $\beta_h(\mathbf{y}) \geq \beta(\mathbf{y}) \geq c_0(1 + C_P)/2$.

3.2 Reduced Basis Compression

In order to avoid too many computationally expensive numerical forward solutions of the HiFi-PG problem (27.49) at a large number of required samples $\mathbf{y} \in U$, one computes surrogate solutions with certified accuracy at low cost by applying reduced basis (RB) compression techniques [4, 61, 63]. The rationale for this lies in that the intrinsic dimension of the solution manifold $\mathcal{M}_h := \{q_h(\mathbf{y}), \mathbf{y} \in U\}$ is often low, even if the dimension of parameter space is high or infinite, so that the parametric solution can be compressed into a low-dimensional subspace of the HiFi space.

One assumes available a pair of N -dimensional subspaces $\mathcal{X}_N \subset \mathcal{X}_h$ and $\mathcal{Y}_N \subset \mathcal{Y}_h$ with $N \ll N_h$, which are known as RB (trial and test) spaces, whose construction is detailed in the next section. The compressed RB-PG discretization of the HiFi-PG approximation (27.26) takes the following form.

$$\text{given } \mathbf{y} \in U, \text{ find } q_N(\mathbf{y}) \in \mathcal{X}_N : \quad \mathbf{y}' \langle \mathcal{R}(q_N(\mathbf{y}); \mathbf{y}), v_N \rangle_{\mathcal{Y}} = 0 \quad \forall v_N \in \mathcal{Y}_N, \quad (27.57)$$

which can be solved by a Newton iteration [23]. Note that the RB-PG problem (27.57) has a structure which is identical to that of the HiFi-PG problem (27.49),

except for the trial and test spaces, which indicate that the RB solution $q_N(\mathbf{y})$ is a PG compression/projection of the HiFi solution $q_h(\mathbf{y})$; specifically, a PG projection from the HiFi space into the RB space. To ensure the well-posedness of the RB solution, one makes the following assumptions.

Assumption 3. *Holding Assumption 2, with the same notation of the bilinear form $a(\cdot, \cdot; \mathbf{y}) : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$ defined as in (27.50), one makes the further assumptions that*

A1 stability: *the parametric bilinear form a satisfies the discrete RB-PG inf-sup condition: there holds*

$$\forall \mathbf{y} \in U : \inf_{0 \neq w_N \in \mathcal{X}_N} \sup_{0 \neq v_N \in \mathcal{Y}_N} \frac{a(w_N, v_N; \mathbf{y})}{\|w_N\|_{\mathcal{X}} \|v_N\|_{\mathcal{Y}}} =: \beta_N(\mathbf{y}) \geq \beta_N > 0, \quad (27.58)$$

where β_N is a lower bound of the inf-sup constant $\beta_N(\mathbf{y})$, which depends on N and on \mathbf{y} and may converge to the HiFi inf-sup constant $\beta_N(\mathbf{y}) \rightarrow \beta_h(\mathbf{y})$ as $N \rightarrow N_h$.

A2 consistency: *the best approximation satisfies the consistent approximation property*

$$\forall \mathbf{y} \in U : \lim_{N \rightarrow N_h} \frac{1}{\beta_N^2(\mathbf{y})} \inf_{w_N \in \mathcal{X}_N} \|q_h(\mathbf{y}) - w_N\|_{\mathcal{X}} = 0. \quad (27.59)$$

Proceeding as in [60], one can establish the following error estimates for the RB solution (see [23])

Theorem 4. *Under Assumption 3, there exist $N_0 > 0$ and $\eta'_0 > 0$ such that for $N \geq N_0$, there exists a solution $q_N(\mathbf{y}) \in \mathcal{X}_N$ of the RB-PG compression problem (27.57), which is unique in $\mathcal{B}_{\mathcal{X}}(q_h(\mathbf{y}); \eta'_0 \beta_N(\mathbf{y}))$. Moreover, for any $N \geq N_0$, there holds the a priori error estimate*

$$\|q_h(\mathbf{y}) - q_N(\mathbf{y})\|_{\mathcal{X}} \leq 2 \frac{\|a(\mathbf{y})\|}{\beta_h(\mathbf{y})} \left(1 + \frac{\|a(\mathbf{y})\|}{\beta_N(\mathbf{y})} \right) \inf_{w_N \in \mathcal{X}_N} \|q_h(\mathbf{y}) - w_N\|_{\mathcal{X}}. \quad (27.60)$$

Moreover, one has the a-posteriori error estimate

$$\|q_h(\mathbf{y}) - q_N(\mathbf{y})\|_{\mathcal{X}} \leq \frac{4}{\beta_h(\mathbf{y})} \|\mathcal{R}(q_N(\mathbf{y}); \mathbf{y})\|_{\mathcal{Y}}. \quad (27.61)$$

Remark 4. Note that both the a priori and the a posteriori error estimates of the RB solution turn out to be the same as those of the HiFi solution with different stability constants and different approximation spaces. These results are obtained as

a consequence of the fact that the RB-PG problem (27.57) is nothing different from the HiFi-PG problem (27.49) except in different approximation spaces.

3.3 Reduced Basis Construction

As the computational cost for the solution of the RB-PG problem (27.57) critically depends on the RB degrees of freedom (dof) N , one needs to construct the optimal RB space \mathcal{X}_N that is most “representative” for all the parametric solutions with required approximation accuracy, such that N is as small as possible. However, it is computationally unfeasible to obtain such a optimal subspace \mathcal{X}_N as it is an infinite dimensional optimization problem involving expensive HiFi solutions. In the following, two practical algorithms are presented that allow in practice quasi-optimal construction of RB trial spaces \mathcal{X}_N . Construction of the RB test space \mathcal{Y}_N is deferred to the next sections.

3.3.1 Proper Orthogonal Decomposition

Proper orthogonal decomposition (POD) [11], also known as principle component analysis (PCA for short) in statistics or Karhunen–Loëve (KL for short) decomposition in stochastic analysis, aims to extract the maximum information/energy/variance from a finite number of available solution “snapshots”. Such solution snapshots could be, e.g., solutions at a finite set of parameter values in our context. In practice, the POD is determined from a finite training set $\Xi_t = \{\mathbf{y}^n \in U, n = 1, \dots, N_t\}$ with N_t random samples, and the corresponding HiFi solutions $q_h(\mathbf{y})$, $\mathbf{y} \in \Xi_t$. The POD basis functions are defined as follows [62]: let \mathbb{C} denote the correlation matrix with rank $N_r \leq N_t$, which is given by

$$\mathbb{C}_{mn} = (q_h(\mathbf{y}^m), q_h(\mathbf{y}^n))_{\mathcal{X}}, \quad m, n = 1, \dots, N_t; \quad (27.62)$$

let $(\lambda_n, \boldsymbol{\psi}_n)_{n=1}^{N_r}$ denote the eigenpairs of the correlation matrix \mathbb{C} , i.e.

$$\mathbb{C}\boldsymbol{\psi}_n = \lambda_n \boldsymbol{\psi}_n, \quad n = 1, \dots, N_r. \quad (27.63)$$

Then the POD basis functions are given by

$$\xi_h^n = \sum_{m=1}^{N_t} \frac{1}{\sqrt{\lambda_n}} \boldsymbol{\psi}_n^{(m)} q_h(\mathbf{y}^m), \quad n = 1, \dots, N_r. \quad (27.64)$$

In common practice, instead of assembling the large correlation matrix \mathbb{C} and compute its eigenpairs, one may apply singular value decomposition (SVD) method or its reduced version such as thin SVD [10, 62] in order to speed up the computation of the POD basis functions.

The POD basis functions are optimal in the “average” sense [62].

Proposition 2. Let $W = \{w_h^1, \dots, w_h^N\}$ denote any N -dimensional ($N \leq N_r$) orthonormal functions in \mathcal{X}_h , i.e. $(w_h^m, w_h^n)_\mathcal{X} = \delta_{mn}$, $m, n = 1, \dots, N$; let P_N^W denote the \mathcal{X} -projection operator on W , i.e.

$$P_N^W w_h = \sum_{n=1}^N (w_h, w_h^n)_\mathcal{X} w_h^n \quad \forall w_h \in \mathcal{X}_h. \quad (27.65)$$

Then POD basis functions $W_{\text{pod}} = \{\xi_h^1, \dots, \xi_h^N\}$ given by (27.64) are orthonormal and satisfy

$$W_{\text{pod}} = \underset{W \subset \mathcal{X}_h}{\operatorname{argmin}} \sum_{n=1}^{N_t} \|q_h(\mathbf{y}^n) - P_N^W q_h(\mathbf{y}^n)\|_\mathcal{X}^2. \quad (27.66)$$

Moreover,

$$\sum_{n=1}^{N_t} \|q_h(\mathbf{y}^n) - P_N^{W_{\text{pod}}} q_h(\mathbf{y}^n)\|_\mathcal{X}^2 = \sum_{n=N+1}^{N_r} \lambda_n. \quad (27.67)$$

Remark 5. Proposition 2 implies that the POD basis functions achieve the optimal compression measured in the ensemble of square \mathcal{X} -norm of the orthogonal projection error. Moreover, the ensemble of the projection errors can be bounded explicitly according to (27.67), which can serve as an error indicator to choose the suitable number of POD basis functions given certain requirement of accuracy. Due to its optimality, POD has been widely used for reduced basis construction in Hilbert spaces [7, 10, 75].

Remark 6. However, to compute the POD basis functions, one needs to compute the HiFi solution at a sufficiently large number of properly chosen random samples. The possibly large training set could be prohibitive for the given computational budget, especially for high-dimensional problems that require numerous samples.

3.3.2 Greedy Algorithm

In order to avoid solving too many HiFi-PG problems for the construction of the RB spaces with a relatively much smaller number of basis functions, one turns to a greedy algorithm [4, 6, 58, 61, 63], which only requires the same number of HiFi solutions as that of the RB basis functions. An abstract formulation of the greedy search algorithm reads: choose the first sample \mathbf{y}^1 such that

$$\mathbf{y}^1 := \underset{\mathbf{y} \in U}{\operatorname{argsup}} \|q_h(\mathbf{y})\|_\mathcal{X}, \quad (27.68)$$

at which one constructs the first RB space $\mathcal{X}_1 = \text{span}\{q_h(\mathbf{y}^1)\}$. Then, for $N = 1, 2, \dots$, one seeks the next sample \mathbf{y}^{N+1} such that

$$\mathbf{y}^{N+1} := \underset{\mathbf{y} \in U}{\operatorname{argsup}} \|q_h(\mathbf{y}) - q_N(\mathbf{y})\|_\mathcal{X}, \quad (27.69)$$

where $q_N(\mathbf{y})$ is the RB solution, and construct the new RB space $\mathcal{X}_{N+1} = \mathcal{X}_N \oplus \text{span}\{q_h(\mathbf{y}^{N+1})\}$. However, both (27.68) and (27.69) are infinite dimensional optimization problems and necessitate many HiFi solutions for the evaluation of the RB errors. In order to tackle this challenge, the true error (27.69) is replaced ideally by a tight error bound $\Delta_N(\mathbf{y})$ [61, 63], i.e.

$$c \Delta_N(\mathbf{y}) \leq \|q_h(\mathbf{y}) - q_N(\mathbf{y})\|_{\mathcal{X}} \leq C \Delta_N(\mathbf{y}) \quad \forall \mathbf{y} \in U, \quad (27.70)$$

with constants $0 < c \leq C < \infty$ possibly depending on \mathbf{y} , and preferably $\gamma := c/C \approx 1$. Meanwhile, one can relax the first sample such that $\|q_h(\mathbf{y}^1)\|_{\mathcal{X}} \geq \gamma \sup_{\mathbf{y} \in U} \|q_h(\mathbf{y})\|_{\mathcal{X}}$. It is crucial that the cost for the evaluation of the error bound $\Delta_N(\mathbf{y})$ should be so small that its evaluation at a large number of training samples remains feasible, i.e., the cost at each sample is effectively independent of the HiFi dof. The relaxation of the true error to an effective error bound leads to the development of the so-called weak greedy algorithm for which an a priori error estimate of the error incurred by RB compression is established in the following theorem.

Theorem 5. Let $d_N(\mathcal{M}_h, \mathcal{X}_h)$ denote the Kolmogorov N -width, i.e., the worst-case scenario error of the \mathcal{X} -projection of the HiFi solution $q_h(\mathbf{y}) \in \mathcal{M}_h$ in the optimal among all possible N -dimensional subspaces $\mathcal{Z}_N \subset \mathcal{X}_h$. Specifically,

$$d_N(\mathcal{M}_h, \mathcal{X}_h) := \inf_{\mathcal{Z}_N \subset \mathcal{X}_h} \sup_{\mathbf{y} \in U} \inf_{w_N \in \mathcal{Z}_N} \|q_h(\mathbf{y}) - w_N\|_{\mathcal{X}}. \quad (27.71)$$

Let σ_N denote the worst-case scenario RB compression error, i.e.

$$\sigma_N := \sup_{\mathbf{y} \in U} \|q_h(\mathbf{y}) - q_N(\mathbf{y})\|_{\mathcal{X}}. \quad (27.72)$$

Then the following results hold for the convergence rates of the RB compression error [4, 34]:

- If $d_N \leq C_0 N^{-\alpha}$ for some $C_0 > 0$ and $\alpha > 0$, and any $N = 1, 2, \dots$, then $\sigma_N \leq C_1 N^{-\alpha}$ for all $N = 1, 2, \dots$, where $C_1 := 2^{5\alpha+1} \gamma^{-2} C_0$;
- If $d_N \leq C_0 e^{-c_0 N^\alpha}$ for some $C_0 > 0$, $c_0 > 0$, $\alpha > 0$, and any $N = 1, 2, \dots$, then $\sigma_N \leq C_1 e^{-c_1 N^\alpha}$ for all $N = 1, 2, \dots$, where $C_1 := \sqrt{2C_0} \gamma^{-1}$ and $c_1 := 2^{-1-2\alpha} c_0$.

Proof. The proof of the results in the finite dimensional approximation spaces \mathcal{X}_h and \mathcal{M}_h follows those in [34] where \mathcal{X} is a Hilbert space and the solution manifold \mathcal{M} is a compact set in \mathcal{X} .

Remark 7. The above results indicate that the RB compression by the (weak) greedy algorithm achieves optimal convergence rates in comparison with the Kolmogorov width, in the case of both algebraic rate and exponential rate. However,

the Kolmogorov width is typically not available for general parametric problems. In our setting, i.e., for smooth parameter dependence, it can be bounded from above by the sparse interpolation error estimate in (27.46), i.e., with algebraic convergence rate N^{-s} . Exponential convergence rates are shown in [16] for a one-dimensional parametric problem whose solution is analytic w.r.t. the parameter.

Remark 8. Construction of an N -dimensional RB space only requires N HiFi solutions by the greedy algorithm, which dramatically reduces the computational cost for the RB construction as long as evaluation of the error bound is inexpensive with operation independent of the HiFi dof N_h .

3.4 Linear and Affine-Parametric Problems

To illustrate the reduction in complexity which can be achieved by RB compression, linear and affine problems (e.g., Examples 1 and 3) with the uncertain parametrization given in Sect. 2.2 are first considered, for which one assumes the terms in (27.26) can be written more explicitly as

$$A(q; \mathbf{y}) = A(\mathbf{y})q = \sum_{j \geq 0} y_j A_j q \quad \text{and} \quad F(\mathbf{y}) = \sum_{j \geq 0} y_j F_j, \quad (27.73)$$

where one sets $y_0 = 1$ for notational simplicity and where $A_j \in \mathcal{L}(\mathcal{X}, \mathcal{Y}')$, and $F_j \in \mathcal{Y}'$, $j \geq 0$. The parametrization (27.73) is sometime also called *linear parametrization* uncertainty, whereas the term *affine parametrization* refers to separable expansions of the form (27.73) with y_j replaced by functions $\theta_j(\mathbf{y})$ where $\theta_0 = 1$ and where the θ_j , $j \geq 1$ depend on several or all parameters $y_j \in \mathbf{y}$, but are independent of the physical coordinates.

In computational practice, one truncates the affine expansion up to $J + 1$ terms with $J \in \mathbb{N}$, depending on the required accuracy of the truncation. For notational convenience, one defines $\mathbb{J} = \{0, 1, \dots, J\}$. The ensuing development applies verbatim in the affine-parametric case, when the parameters y_j are replaced by $\theta_j(\mathbf{y})$ for $j \in \mathbb{J}$, with functions that are independent of the physical variable and where each $\theta_j(\mathbf{y})$ possibly depends on all coordinates $y_j \in \mathbf{y}$.

3.4.1 High-Fidelity Approximation

Under the linear and affine assumptions, the parametric HiFi-PG approximation problem (27.49) becomes

given $\mathbf{y} \in U$, find $q_h(\mathbf{y}) \in \mathcal{X}_h$:

$$\sum_{j \in \mathbb{J}} y_j \langle A_j q_h(\mathbf{y}), v_h \rangle_{\mathcal{Y}} = \sum_{j \in \mathbb{J}} y_j \langle F_j, v_h \rangle_{\mathcal{Y}} \quad \forall v_h \in \mathcal{Y}_h. \quad (27.74)$$

By $(w_h^n)_{n=1}^{N_h}$ and $(v_h^n)_{n=1}^{N_h}$ one denotes the basis functions of the HiFi trial and test spaces \mathcal{X}_h and \mathcal{Y}_h . Then, the parametric solution $q_h(\mathbf{y})$ can be written as

$$q_h(\mathbf{y}) = \sum_{n=1}^{N_h} q_h^n(\mathbf{y}) w_h^n, \quad (27.75)$$

where $\mathbf{q}_h(\mathbf{y}) = (q_h^1(\mathbf{y}), \dots, q_h^{N_h}(\mathbf{y}))^\top$ denotes the (parametric) coefficient vector of the HiFi PG solution $q_h(\mathbf{y})$. The algebraic formulation of (27.74) reads:

$$\text{given } \mathbf{y} \in U, \text{ find } \mathbf{q}_h(\mathbf{y}) \in \mathbb{R}^{N_h} : \quad \sum_{j \in \mathbb{J}} y_j \mathbb{A}_j^h \mathbf{q}_h(\mathbf{y}) = \sum_{j \in \mathbb{J}} y_j \mathbf{f}_j^h. \quad (27.76)$$

The HiFi matrix $\mathbb{A}_j^h \in \mathbb{R}^{N_h \times N_h}$ and the HiFi vector $\mathbf{f}_j^h \in \mathbb{R}^{N_h}$ can be assembled as

$$(\mathbb{A}_j^h)_{mn} =_{\mathcal{Y}'} \langle A_j w_h^n, v_h^m \rangle_{\mathcal{Y}} \text{ and } (\mathbf{f}_j^h)_m =_{\mathcal{Y}'} \langle F_j, v_h^m \rangle_{\mathcal{Y}} \quad m, n = 1, \dots, N_h, j \in \mathbb{J}. \quad (27.77)$$

3.4.2 Reduced Basis Compression

Analogously, by $(w_N^n)_{n=1}^N$ and $(v_N^n)_{n=1}^N$ one denotes the basis functions of the RB trial and test spaces \mathcal{X}_N and \mathcal{Y}_N , so that the RB solution $q_N(\mathbf{y})$ can be written as

$$q_N(\mathbf{y}) = \sum_{n=1}^N q_N^n(\mathbf{y}) w_N^n, \quad (27.78)$$

with the coefficient vector $\mathbf{q}_N(\mathbf{y}) = (q_N^1(\mathbf{y}), \dots, q_N^N(\mathbf{y}))^\top$. Then, the parametric RB-PG compression problem can be written in the algebraic formulation as

$$\text{given } \mathbf{y} \in U, \text{ find } \mathbf{q}_N(\mathbf{y}) \in \mathbb{R}^N : \quad \sum_{j \in \mathbb{J}} y_j \mathbb{A}_j^N \mathbf{q}_N(\mathbf{y}) = \sum_{j \in \mathbb{J}} y_j \mathbf{f}_j^N. \quad (27.79)$$

where the RB matrix $\mathbb{A}_j^N \in \mathbb{R}^{N \times N}$ and the RB vector $\mathbf{f}_j^N \in \mathbb{R}^N$ are obtained as

$$\mathbb{A}_j^N = \mathbb{V}^\top \mathbb{A}_j^h \mathbb{W} \text{ and } \mathbf{f}_j^N = \mathbb{V}^\top \mathbf{f}_j^h, \quad j \in \mathbb{J}, \quad (27.80)$$

where \mathbb{W} and \mathbb{V} are the transformation matrices between the HiFi and RB basis functions, i.e.,

$$w_N^n = \sum_{m=1}^{N_h} \mathbb{W}_{mn} w_h^m \text{ and } v_N^n = \sum_{m=1}^{N_h} \mathbb{V}_{mn} v_h^m, \quad n = 1, \dots, N. \quad (27.81)$$

Thanks to the linear and affine structure of the parametric terms in (27.73), one can assemble the RB matrices \mathbb{A}_j^N and the RB vectors \mathbf{f}_j^N , $j \in \mathbb{J}$, once and for all. For each given \mathbf{y} , one only needs to assemble and solve the RB algebraic system (27.79) with computational cost depends only on N as $O(N^2)$ for assembling and $O(N^3)$ for solving (27.79), which leads to considerable computational reduction as long as $N \ll N_h$.

3.4.3 Tight A Posteriori Error Bound

A tight and inexpensive error bound that facilitates the weak greedy algorithm for RB construction is designed based on Assumption 2, in particular **A1 stability**, where the bilinear form is defined as

$$\text{given any } \mathbf{y} \in U : \quad a(w, v; \mathbf{y}) :=_{\mathcal{Y}'} \langle A(\mathbf{y})w, v \rangle_{\mathcal{Y}}, \quad \forall w \in \mathcal{X}, \forall v \in \mathcal{Y}, \quad (27.82)$$

which satisfies the stability condition in the HiFi spaces \mathcal{X}_h and \mathcal{Y}_h as in (27.51). Let the linear form be defined as

$$f(v; \mathbf{y}) =_{\mathcal{Y}'} \langle F(\mathbf{y}), v \rangle_{\mathcal{Y}}, \quad \forall v \in \mathcal{Y}, \quad (27.83)$$

then the RB residual in the HiFi space is defined as

$$r(v_h; \mathbf{y}) = f(v_h; \mathbf{y}) - a(q_N(\mathbf{y}), v_h; \mathbf{y}), \quad \forall v_h \in \mathcal{Y}_h. \quad (27.84)$$

Let $e_N(\mathbf{y}) = q_h(\mathbf{y}) - q_N(\mathbf{y})$ denote the RB error, then by the stability condition (27.51) one has

$$\|e_N(\mathbf{y})\|_{\mathcal{X}} \leq \frac{|a(e_N(\mathbf{y}), v_h; \mathbf{y})|}{\beta_h \|v_h\|_{\mathcal{Y}}} = \frac{|r(v_h; \mathbf{y})|}{\beta_h \|v_h\|_{\mathcal{Y}}} \leq \frac{\|r(\cdot; \mathbf{y})\|_{\mathcal{Y}'}}{\beta_h} =: \Delta_N(\mathbf{y}), \quad (27.85)$$

which indicates that $\Delta_N(\mathbf{y})$ is a rigorous upper error bound for the RB error $e_N(\mathbf{y})$. On the other hand, to see the lower bound one defines the Riesz representation of the residual as $\hat{e}_N(\mathbf{y}) \in \mathcal{Y}_h$, i.e.,

$$(\hat{e}_N(\mathbf{y}), v_h)_{\mathcal{Y}} = r(v_h; \mathbf{y}), \quad \forall v_h \in \mathcal{Y}_h, \quad (27.86)$$

so that $\|\hat{e}_N(\mathbf{y})\|_{\mathcal{Y}} = \|r(\cdot; \mathbf{y})\|_{\mathcal{Y}'}$. By setting $v_h = \hat{e}_N(\mathbf{y})$ in (27.86), one has

$$\|\hat{e}_N(\mathbf{y})\|_{\mathcal{Y}}^2 = r(\hat{e}_N(\mathbf{y}); \mathbf{y}) = a(e_N(\mathbf{y}), \hat{e}_N(\mathbf{y}); \mathbf{y}) \leq \alpha_h \|e_N(\mathbf{y})\|_{\mathcal{X}} \|\hat{e}_N(\mathbf{y})\|_{\mathcal{Y}}, \quad (27.87)$$

where α_h is the continuity constant of the bilinear form a in $\mathcal{X}_h \times \mathcal{Y}_h$, which implies that

$$\frac{\beta_h}{\alpha_h} \Delta_N(\mathbf{y}) \leq \|e_N(\mathbf{y})\|_{\mathcal{X}}. \quad (27.88)$$

Therefore, the error bound $\Delta_N(\mathbf{y})$ is tight with the constants in (27.69) as $c = \beta_h/\alpha_h$ and $C = 1$, and $\gamma = c/C = \beta_h/\alpha_h$.

For the evaluation of $\Delta_N(\mathbf{y})$, one makes use of the affine structure (27.73) by computing the Riesz representation \mathcal{A}_j^n of the linear functional $a_j(w_N^n; \cdot) = {}_{\mathcal{Y}'} \langle A_j w_N^n, \cdot \rangle_{\mathcal{Y}} : \mathcal{Y}_h \rightarrow \mathbb{R}$ as the solution of

$$(\mathcal{A}_j^n, v_h)_{\mathcal{Y}} = a_j(w_N^n; v_h), \quad \forall v_h \in \mathcal{Y}_h, \quad j \in \mathbb{J}, n = 1, \dots, N, \quad (27.89)$$

where w_N^n is the n th RB basis function. Analogously, one computes the Riesz representation \mathcal{F}_j of the linear functional $f_j(\cdot) = {}_{\mathcal{Y}'} \langle F_j, \cdot \rangle_{\mathcal{Y}} : \mathcal{Y}_h \rightarrow \mathbb{R}$ as the solution of

$$(\mathcal{F}_j, v_h) = f_j(v_h), \quad \forall v_h \in \mathcal{Y}_h, \quad j \in \mathbb{J}. \quad (27.90)$$

Finally, one can compute the dual norm of the residual in the error bound $\Delta_N(\mathbf{y})$ by

$$\begin{aligned} \|\hat{e}_N(\mathbf{y})\|_{\mathcal{Y}}^2 &= \sum_{j, j' \in \mathbb{J}} y_j y_{j'} \left((\mathcal{F}_j, \mathcal{F}_{j'})_{\mathcal{Y}} - 2 \sum_{n=1}^N q_N^n(\mathbf{y}) (\mathcal{F}_j, \mathcal{A}_{j'}^n)_{\mathcal{Y}} \right. \\ &\quad \left. + \sum_{n, n'=1}^N q_N^n(\mathbf{y}) q_N^{n'}(\mathbf{y}) (A_j^n, A_{j'}^{n'})_{\mathcal{Y}} \right), \end{aligned}$$

where $(\mathcal{F}_j, \mathcal{F}_{j'})_{\mathcal{Y}}$, $(\mathcal{F}_j, \mathcal{A}_{j'}^n)_{\mathcal{Y}}$, and $(A_j^n, A_{j'}^{n'})_{\mathcal{Y}}$, $j, j' \in \mathbb{J}$, $n, n' = 1, \dots, N$, can be computed once and for all. Given any \mathbf{y} , one only need to assemble (27.91) whose cost depends on N as $O(N^2)$, not on N_h , which results in effective computational reduction as long as $N \ll N_h$.

The lower bound of the stability constant β_h in $\Delta_N(\mathbf{y})$ can be computed for once based on the specific structure of the parametrization (e.g., at extreme points $\mathbf{y} = \{y_j = \pm 1 : j = 1, 2, \dots\}$, or by a successive constraint method (SCM for short) [48, 49] for each \mathbf{y} , whose computational cost is independent of N_h .

3.4.4 Stable RB-PG Compression

Construction of the RB trial space \mathcal{X}_N by both POD and greedy algorithm ensures the consistency of the RB-PG compression. For its stability, a suitable RB test space \mathcal{Y}_N needs to be constructed depending on \mathcal{X}_N . In the case that $\mathcal{X} = \mathcal{Y}$, $\mathcal{X}_h = \mathcal{Y}_h$, and the linear problem with (27.73) is coercive, the choice $\mathcal{Y}_N := \mathcal{X}_N$ guarantees the coercivity (or stability) of the RB Galerkin compression.

In the case of saddle point variational formulations of the forward problem, such as time-harmonic acoustic or electromagnetic wave propagation, or when $\mathcal{X}_h \neq \mathcal{Y}_h$, MOR requires in addition to a reduction of the trial spaces also the numerical computation of a suitable inf-sup stable testfunction space. To this end, the so-called “supremizer” approach was proposed in [64], which is described as: denote by

$T_y : \mathcal{X}_h \rightarrow \mathcal{Y}_h$ a parameter dependent supremizer operator, which is defined by

$$(T_y w_h, v_h)_\mathcal{Y} = a(w_h, v_h; \mathbf{y}) \quad \forall v_h \in \mathcal{Y}_h. \quad (27.91)$$

This definition implies $\sup_{v_h \in \mathcal{Y}_h} |a(w_h, v_h; \mathbf{y})| = |a(w_h, T_y w_h; \mathbf{y})|$, i.e. $T_y w_h$ is the supremizer of w_h in \mathcal{Y}_h w.r.t. the bilinear form a . Then the \mathbf{y} -dependent RB test space \mathcal{Y}_N^y is constructed as

$$\mathcal{Y}_N^y = \text{span}\{T_y w_N, w_N \in \mathcal{X}_N\}. \quad (27.92)$$

For this construction, it holds that (see [20])

$$\beta_N(\mathbf{y}) := \inf_{w_N \in \mathcal{X}_N} \sup_{v_N \in \mathcal{Y}_N^y} \frac{a(w_N, v_N; \mathbf{y})}{\|w_N\|_{\mathcal{X}} \|v_N\|_{\mathcal{Y}}} \geq \beta_h(\mathbf{y}). \quad (27.93)$$

This implies that *inf-sup stability of the HiFi-PG discretization is inherited by the corresponding PG-RB trial and test spaces*: all RB-PG compression problems are inf-sup stable under the stability assumption of the HiFi-PG approximation: **A1 stability** in Assumption 2. In particular, if the HiFi-PG discretizations are inf-sup stable uniformly with respect to the uncertain input parameter u (resp. its parametrization in terms of \mathbf{y}), so is any PG-RB method obtained with PG trial space \mathcal{X}_N obtained by a greedy search, and the corresponding PG test space (27.92).

Due to the affine structure (27.73), one can compute $T_y w_N$ for each $\mathbf{y} \in U$ as

$$T_y w_N = \sum_{j \in \mathbb{J}} y_j T_j w_N, \quad \text{where } (T_j w_N, v_h)_\mathcal{Y} = a_j(w_N, v_h) \quad \forall v_h \in \mathcal{Y}_h, \quad (27.94)$$

where $T_j w_N, w_N \in \mathcal{X}_N, j \in \mathbb{J}$ needs to be computed only once; given any \mathbf{y} , $T_y w_N$ can be assembled in $O(N)$ operations, which is independent of the number N_h of degrees of freedom in the HiFi-PG discretization. The compressed RB-PG discretization (27.79) can be written more explicitly as

$$\text{given } \mathbf{y} \in U, \text{ find } \mathbf{q}_N(\mathbf{y}) \in \mathbb{R}^N : \quad \sum_{j, j' \in \mathbb{J}} y_j y_{j'} \mathbb{A}_{j, j'}^N \mathbf{q}_N(\mathbf{y}) = \sum_{j, j' \in \mathbb{J}} y_j y_{j'} \mathbf{f}_{j, j'}^N, \quad (27.95)$$

where the RB compressed stiffness matrix $\mathbb{A}_{j, j'}^N \in \mathbb{R}^{N \times N}$ and the RB compressed load vector $\mathbf{f}_{j, j'}^N \in \mathbb{R}^N$ are given by

$$\mathbb{A}_{j, j'}^N = \mathbb{W}^\top (\mathbb{A}_{j'}^h)^\top \mathbb{M}_h^{-1} \mathbb{A}_j^h \mathbb{W} \text{ and } \mathbf{f}_{j, j'}^N = \mathbb{W}^\top (\mathbb{A}_{j'}^h)^\top \mathbb{M}_h^{-1} \mathbf{f}_j^h, \quad j, j' \in \mathbb{J}, \quad (27.96)$$

where \mathbb{M}_h denotes the mass matrix with $(\mathbb{M}_h^{-1})_{n, n'} = (v_h^n, v_h^{n'})_\mathcal{Y}, n, n' = 1, \dots, N_h$. Since all these quantities are independent of \mathbf{y} , one can precompute these quantities once and for all.

Remark 9. The stable RB-PG compression is equivalent to a least-squares RB-PG compression presented in [10]; see also [62]. Alternatively, a minimum residual approach known as double greedy algorithm [31] can be applied for the construction of \mathcal{Y}_N to ensure inf-sup stability.

3.5 Nonlinear and Nonaffine-Parametric Problems

The linearity of the (integral or differential) operator in the forward model and the affine parameter dependence play a crucial role in effective decomposition of the parameter-dependent and parameter-independent quantities. This, in turn, leads to a massive reduction in computational work for the RB-PG compression. For more general problems that involve nonlinear terms w.r.t. the state variable q and/or nonaffine terms w.r.t. the parameter y , for instance, Example 4, it is necessary to obtain an affine approximation of these terms in order to retain the effective decomposition and RB reduction. In this section, such an affine approximation based on empirical interpolation [2, 12, 18, 40, 57] is presented.

3.5.1 High-Fidelity Approximation

To solve the nonlinear parametric HiFi-PG approximation problem (27.49), one applies a Newton iteration method based on the parametric tangent operator of the nonlinear residual [23]: given any $y \in U$ and an initial guess of the solution $q_h^{(1)}(y) \in \mathcal{X}_h$, for $k = 1, 2, \dots$, one finds $\delta q_h^{(k)}(y) \in \mathcal{X}_h$ such that

$$y' \langle D_q \mathcal{R}(q_h^{(k)}(y); y)(\delta q_h^{(k)}(y)), v_h \rangle_{\mathcal{Y}} = -y' \langle \mathcal{R}(q_h^{(k)}(y); y), v_h \rangle_{\mathcal{Y}} \quad \forall v_h \in \mathcal{Y}_h; \quad (27.97)$$

then the solution is updated according to

$$q_h^{(k+1)}(y) = q_h^{(k)}(y) + \eta^{(k)} \delta q_h^{(k)}(y), \quad (27.98)$$

where $\eta^{(k)}$ is a constant determined by a line search [33]. The Newton iteration is stopped once

$$\|\delta q_h^{(k)}(y)\|_{\mathcal{X}} \leq \varepsilon_{tol} \quad \text{or} \quad \|\mathcal{R}(q_h^{(k)}(y); y)\|_{\mathcal{Y}'} \leq \varepsilon_{tol}, \quad (27.99)$$

being ε_{tol} a tolerance; then one sets $q_h(y) = q_h^{(k+1)}(y)$.

With the bases $\{w_h^n\}_{n=1}^{N_h}$ and $\{v_h^n\}_{n=1}^{N_h}$ of \mathcal{X}_h and \mathcal{Y}_h , respectively, one can write

$$q_h^{(k)}(y) = \sum_{n=1}^{N_h} q_{h,n}^{(k)}(y) w_h^n \quad \text{and} \quad \delta q_h^{(k)}(y) = \sum_{n=1}^{N_h} \delta q_{h,n}^{(k)}(y) w_h^n, \quad (27.100)$$

with the coefficient vectors $\mathbf{q}_h^{(k)}(\mathbf{y}) = \left(q_{h,1}^{(k)}(\mathbf{y}), \dots, q_{h,N_h}^{(k)}(\mathbf{y})\right)^\top$ and $\delta\mathbf{q}_h^{(k)}(\mathbf{y}) = \left(\delta q_{h,1}^{(k)}(\mathbf{y}), \dots, \delta q_{h,N_h}^{(k)}(\mathbf{y})\right)^\top$ so that the algebraic formulation of the parametric HiFi-PG approximation problem (27.97) reads: find the coefficient vector $\delta\mathbf{q}_h^{(k)}(\mathbf{y}) := \left(\delta q_{h,1}^{(k)}(\mathbf{y}), \dots, \delta q_{h,N_h}^{(k)}(\mathbf{y})\right)^\top \in \mathbb{R}^{N_h}$ such that

$$\mathbb{J}_h \left(\mathbf{q}_h^{(k)}(\mathbf{y}); \mathbf{y} \right) \delta\mathbf{q}_h^{(k)}(\mathbf{y}) = -\mathbf{r}_h \left(\mathbf{q}_h^{(k)}(\mathbf{y}); \mathbf{y} \right), \quad (27.101)$$

where the Jacobian matrix $\mathbb{J}_h \left(\mathbf{q}_h^{(k)}(\mathbf{y}); \mathbf{y} \right) \in \mathbb{R}^{N_h \times N_h}$ is given by

$$\left(\mathbb{J}_h \left(\mathbf{q}_h^{(k)}(\mathbf{y}); \mathbf{y} \right) \right)_{nn'} = {}_{\mathcal{Y}'} \left\langle D_q \mathcal{R}(q_h^{(k)}(\mathbf{y}); \mathbf{y})(w_h^{n'}), v_h^n \right\rangle_{\mathcal{Y}}, \quad n, n' = 1, \dots, N_h, \quad (27.102)$$

and the residual vector $\mathbf{r}_h \left(\mathbf{q}_h^{(k)}(\mathbf{y}); \mathbf{y} \right) \in \mathbb{R}^{N_h}$ takes the form

$$\left(\mathbf{r}_h \left(\mathbf{q}_h^{(k)}(\mathbf{y}); \mathbf{y} \right) \right)_n = {}_{\mathcal{Y}'} \left\langle \mathcal{R} \left(q_h^{(k)}(\mathbf{y}); \mathbf{y} \right), v_h^n \right\rangle_{\mathcal{Y}}, \quad n = 1, \dots, N_h. \quad (27.103)$$

3.5.2 Reduced Basis Compression

To solve the nonlinear parametric RB-PG compression problem, one applies the same Newton iteration method as for solving the HiFi-PG approximation problem. More specifically, starting from an initial guess of the solution $q_N^{(1)}(\mathbf{y}) \in \mathcal{X}_N$ for any given $\mathbf{y} \in U$, for $k = 1, 2, \dots$, one finds $\delta q_N^{(k)} \in \mathcal{X}_N$ such that

$$\begin{aligned} & {}_{\mathcal{Y}'} \langle D_q \mathcal{R} \left(q_N^{(k)}(\mathbf{y}); \mathbf{y} \right) \left(\delta q_N^{(k)}(\mathbf{y}) \right), v_N \rangle_{\mathcal{Y}} \\ &= -{}_{\mathcal{Y}'} \langle \mathcal{R} \left(q_N^{(k)}(\mathbf{y}); \mathbf{y} \right), v_N \rangle_{\mathcal{Y}} \quad \forall v_N \in \mathcal{Y}_N; \end{aligned} \quad (27.104)$$

then the RB solution is updated by

$$q_N^{(k+1)}(\mathbf{y}) = q_N^{(k)}(\mathbf{y}) + \eta^{(k)} \delta q_N^{(k)}(\mathbf{y}), \quad (27.105)$$

where again $\eta^{(k)}$ is a constant determined by a line search method [33]. The stopping criterion is

$$\|\delta q_N^{(k)}(\mathbf{y})\|_{\mathcal{X}} \leq \varepsilon_{\text{tol}} \quad \text{or} \quad \|\mathcal{R}(q_N^{(k)}(\mathbf{y}); \mathbf{y})\|_{\mathcal{Y}'} \leq \varepsilon_{\text{tol}}, \quad (27.106)$$

With the notation of the basis $(w_N^n)_{n=1}^N$ and $(v_N^n)_{n=1}^N$ for the RB trial and test spaces \mathcal{X}_N and \mathcal{Y}_N , one can expand the RB solution $q_N^{(k)}(\mathbf{y})$ and its update $\delta q_N^{(k)}$ as

$$q_N^{(k)}(\mathbf{y}) = \sum_{n=1}^N q_N^{(n,k)}(\mathbf{y}) w_N^n \text{ and } \delta q_N^{(k)}(\mathbf{y}) = \sum_{n=1}^N \delta q_N^{(n,k)}(\mathbf{y}) w_N^n \quad (27.107)$$

with the coefficient vectors $\mathbf{q}_N^{(k)} = (q_N^{(1,k)}(\mathbf{y}), \dots, q_N^{(N,k)}(\mathbf{y}))^\top$ and $\delta \mathbf{q}_N^{(k)} = (\delta q_N^{(1,k)}(\mathbf{y}), \dots, \delta q_N^{(N,k)}(\mathbf{y}))^\top$. Then the algebraic formulation of the RB-PG compression (27.104) reads: find $\delta \mathbf{q}_N^{(k)} \in \mathbb{R}^N$ such that

$$\mathbb{J}_N(\mathbf{q}_N^{(k)}(\mathbf{y}); \mathbf{y}) \delta \mathbf{q}_N^{(k)}(\mathbf{y}) = -\mathbf{r}_N(\mathbf{q}_N^{(k)}(\mathbf{y}); \mathbf{y}), \quad (27.108)$$

where the parametric RB Jacobian matrix $\mathbb{J}_N(\mathbf{q}_N^{(k)}(\mathbf{y}); \mathbf{y}) \in \mathbb{R}^{N \times N}$ and the parametric RB residual vector $\mathbf{r}_N(\mathbf{q}_N^{(k)}(\mathbf{y}); \mathbf{y}) \in \mathbb{R}^N$ are given (through the transformation matrix \mathbb{W} and \mathbb{V}) by

$$\begin{aligned} \mathbb{J}_N(\mathbf{q}_N^{(k)}(\mathbf{y}); \mathbf{y}) &= \mathbb{V}^\top \mathbb{J}_h(\mathbb{W} \mathbf{q}_N^{(k)}(\mathbf{y}); \mathbf{y}) \mathbb{W} \\ \text{and } \mathbf{r}_N(\mathbf{q}_N^{(k)}(\mathbf{y}); \mathbf{y}) &= \mathbb{V}^\top \mathbf{r}_h(\mathbb{W} \mathbf{q}_N^{(k)}(\mathbf{y}); \mathbf{y}) \end{aligned} \quad (27.109)$$

One can observe that, due to the nonlinearity (and/or nonaffinity) of the residual operator, neither the residual vector nor the Jacobian matrix allows affine decomposition into parameter-dependent and parameter-independent terms. This obstructs effective RB-PG compression.

3.5.3 Empirical Interpolation

The empirical interpolation method (EIM) was originally developed for affine decomposition of nonaffine parametric functions [2]. It was later applied to decompose nonaffine parametric discrete function [12] (known as discrete EIM) and nonaffine-parametric operator [40, 55]. In this presentation, it is applied to decompose the residual vector $\mathbf{r}_h^{(k)}$ and its tangent derivative in (27.103) and (27.102).

For notational simplicity, suppose one has M_t training (residual) vectors

$$\mathbf{r}_m^t \in \mathbb{R}^{N_h}, \quad m = 1, \dots, M_t, \quad (27.110)$$

for instance, collected from the residual vectors $\mathbf{r}_h(\mathbf{q}_h^{(k)}; \mathbf{y})$ at successive iteration steps enumerate with the index k and at different samples \mathbf{y} . A *greedy algorithm* is

applied to construct the empirical interpolation for the approximation of any given $\mathbf{r} \in \mathbb{R}^{N_h}$: one picks the first EI basis $\mathbf{r}_1 \in \mathbb{R}^{N_h}$ as

$$\mathbf{r}_1 = \mathbf{r}_{m^*}^t, \quad \text{where } m^* = \operatorname{argmax}_{1 \leq m \leq M_t} \|\mathbf{r}_m^t\|_\infty, \quad (27.111)$$

where $\|\cdot\|_\infty$ can also be replaced by $\|\cdot\|_2$; then one chooses the first index $n_1 \in \{1, \dots, N_h\}$, such that

$$n_1 = \operatorname{argmax}_{1 \leq n \leq N_h} |(\mathbf{r}_1)_n|, \quad (27.112)$$

where $(\mathbf{r}_1)_n$ is the n -th entry of the vector \mathbf{r}_1 . The number of EI basis is set as M , and $M = 1$ for the time being. For any $\mathbf{r} \in \mathbb{R}^{N_h}$, it is approximated by the (empirical) interpolation

$$\mathcal{I}_M \mathbf{r} = \sum_{m=1}^M c_m \mathbf{r}_m, \quad (27.113)$$

where the coefficient vector $\mathbf{c} = (c_1, \dots, c_M)^\top$ is obtained by solving the interpolation problem

$$(\mathbf{r})_{m'} = \sum_{m=1}^M c_m (\mathbf{r}_m)_{m'}, \quad m' = n_1, \dots, n_M. \quad (27.114)$$

More explicitly, let $\mathbb{P}_M \in \{0, 1\}^{M \times N_h}$ denote an index indicator matrix with nonzero entries $(\mathbb{P}_M)_{m,n_m} = 1, m = 1, \dots, M$; let $\mathbb{R}_M \in \mathbb{R}^{N_h \times M}$ denote the EI basis matrix whose m -th column is $\mathbf{r}_m, m = 1, \dots, M$. Then, the coefficient vector \mathbf{c} can be written as

$$\mathbf{c} = (\mathbb{P}_M \mathbb{R}_M)^{-1} (\mathbb{P}_M \mathbf{r}), \quad (27.115)$$

and the empirical interpolation becomes

$$\mathcal{I}_M \mathbf{r} = \mathbb{R}_M (\mathbb{P}_M \mathbb{R}_M)^{-1} \mathbb{P}_M \mathbf{r}. \quad (27.116)$$

For $M = 1, 2, \dots$, the next EI basis $\mathbf{r}_{M+1} \in \mathbb{R}^{N_h}$ is constructed as

$$\mathbf{r}_{M+1} = \frac{\mathbf{r}_{m^*}^t - \mathcal{I}_M \mathbf{r}_{m^*}^t}{\|\mathbf{r}_{m^*}^t - \mathcal{I}_M \mathbf{r}_{m^*}^t\|_\infty}, \quad \text{where } m^* = \operatorname{argmax}_{1 \leq m \leq M_t} \|\mathbf{r}_m^t - \mathcal{I}_M \mathbf{r}_m^t\|_\infty, \quad (27.117)$$

and find the next index n_{M+1} as

$$n_{M+1} = \operatorname{argmax}_{1 \leq n \leq N_h} |(\mathbf{r}_{M+1})_n|. \quad (27.118)$$

The greedy algorithm is terminated when $|(\mathbf{r}_{M+1})_{n_{M+1}}| \leq \varepsilon_{\text{tol}}$. The empirical interpolation is consistent in that when $M \rightarrow N_h$, one has $\mathbf{r}_M \rightarrow \mathbf{0}$ due to the interpolation property. Moreover, an a priori error analysis shows that the greedy algorithm for EI construction leads to the same result for the convergence of the EI compression error in comparison with the Kolmogorov width as the bound stated in Theorem 5, except for a Lebesgue constant depending on M , see [23, 56] for more details.

For any $\mathbf{y} \in U$, let $\mathbf{q}_{N,M}(\mathbf{y}) \in \mathbb{R}^N$ denote the coefficient of the solution $q_{N,M}(\mathbf{y}) \in \mathcal{X}_N$ of the RB-PG compression problem with the empirical interpolation. By the empirical interpolation of the HiFi residual vector in (27.109), one can approximate the RB residual vector as

$$\mathbf{r}_N(\mathbf{q}_N^{(k)}; \mathbf{y}) \approx \mathbf{r}_{N,M}(\mathbf{q}_{N,M}^{(k)}; \mathbf{y}) := \mathbb{V}^\top \mathbb{R}_M (\mathbb{P}_M \mathbb{R}_M)^{-1} \mathbb{P}_M \mathbf{r}_h(\mathbb{W} \mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y}), \quad (27.119)$$

where the \mathbf{y} -independent quantity $\mathbb{V}^\top \mathbb{R}_M (\mathbb{P}_M \mathbb{R}_M)^{-1} \in \mathbb{R}^{M \times M}$ can be computed once and for all, and the \mathbf{y} -dependent quantity $\mathbb{P}_M \mathbf{r}_h(\mathbb{W} \mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y})$ can be evaluated in $O(MN)$ operations as long as locally supported HiFi basis functions are used, e.g., Finite Element basis functions.

Similarly, one can approximate the HiFi Jacobian matrix in (27.109) as

$$\mathbb{J}_N(\mathbb{W} \mathbf{q}_N^{(k)}(\mathbf{y}); \mathbf{y}) \approx \mathbb{R}_M (\mathbb{P}_M \mathbb{R}_M)^{-1} \mathbb{P}_M \mathbb{J}_h(\mathbb{W} \mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y}), \quad (27.120)$$

so that the RB Jacobian matrix in (27.109) can be approximated by

$$\begin{aligned} \mathbb{J}_N(\mathbf{q}_N^{(k)}(\mathbf{y}); \mathbf{y}) &\approx \mathbb{J}_{N,M}(\mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y}) \\ &:= \mathbb{V}^\top \mathbb{R}_M (\mathbb{P}_M \mathbb{R}_M)^{-1} \mathbb{P}_M \mathbb{J}_h(\mathbb{W} \mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y}) \mathbb{W}, \end{aligned} \quad (27.121)$$

where the \mathbf{y} -dependent quantity $\mathbb{P}_M \mathbb{J}_h(\mathbb{W} \mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y}) \mathbb{W}$ can be computed efficiently with $O(M^2N)$ operations, as long as the Jacobian matrix $\mathbb{J}_h(\mathbb{W} \mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y})$ is sparse. This is typically the case for PG PDE approximation with locally supported (e.g., Finite Element) basis functions. Direct approximation of the HiFi Jacobian matrix \mathbb{J}_h by empirical interpolation has also been studied in [10].

By the above EI compression, $\mathbf{q}_{N,M}(\mathbf{y})$ is the solution of the problem

$$\mathbb{V}^\top \mathcal{I}_M \mathbf{r}_h(\mathbb{W} \mathbf{q}_{N,M}(\mathbf{y}); \mathbf{y}) = 0. \quad (27.122)$$

One observes that the RB solution (with EI) $\mathbf{q}_N(\mathbf{y}) \neq \mathbf{q}_{N,M}(\mathbf{y})$ due to the empirical interpolation error. Moreover, the RB-EI solution $q_{N,M}(\mathbf{y})$ converges to the RB solution $q_N(\mathbf{y})$ as $M \rightarrow N_h$.

3.5.4 Computable a Posterior Error Indicator

For the derivation of a posterior error indicator of the RB-EI solution $q_{N,M}(\mathbf{y})$ at any \mathbf{y} , recall the HiFi-PG problem in the algebraic formulation with slight abuse of notation: given any $\mathbf{y} \in U$, find $q_h(\mathbf{y}) \in \mathcal{X}_h$, such that

$$\mathbf{r}_h(q_h(\mathbf{y}); \mathbf{y}) = 0. \quad (27.123)$$

Analogously, recall the RB-EI-PG problem with slight abuse of notation: given any $\mathbf{y} \in U$, find $q_{N,M}(\mathbf{y}) \in \mathcal{X}_N$, such that

$$\mathbb{V}^\top \mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) = 0. \quad (27.124)$$

Subtracting (27.123) from (27.124), inserting two zero terms, one has by rearranging

$$\begin{aligned} \mathbf{r}_h(q_h(\mathbf{y}); \mathbf{y}) - \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) &= -(\mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) - \mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y})) \\ &\quad - (\mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) - \mathbb{V}^\top \mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y})). \end{aligned} \quad (27.125)$$

Taking a suitable vector norm $||\cdot||_*$ on both sides (preferably equivalent to the dual norm \mathcal{Y} which could be realized by Riesz representation, multilevel preconditioning or wavelet bases in the HiFi space)

$$\begin{aligned} ||\mathbf{r}_h(q_h(\mathbf{y}); \mathbf{y}) - \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y})||_* &= ||D_q \mathbf{r}_h((q_h(\mathbf{y}); \mathbf{y})(q_h(\mathbf{y}) - q_{N,M}(\mathbf{y})))||_* \\ &\quad + o(||q_h(\mathbf{y}) - q_{N,M}(\mathbf{y})||_{\mathcal{X}}) \\ &\geq \tilde{\beta}_h ||q_h(\mathbf{y}) - q_{N,M}(\mathbf{y})||_{\mathcal{X}}. \end{aligned} \quad (27.126)$$

The constant $\tilde{\beta}_h$ can be estimated numerically, e.g., at some extreme realization $\mathbf{y} = -\mathbf{1}$ or $\mathbf{1}$, or by SCM [48, 49]. On the other hand, the right hand side (RHS) of (27.126) can be bounded by

$$\begin{aligned} \text{RHS} &\leq ||\mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) - \mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y})||_* \\ &\quad + ||\mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) - \mathbb{V}^\top \mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y})||_*, \end{aligned} \quad (27.127)$$

where the first term accounts for the empirical interpolation error, which can be approximated by

$$\begin{aligned} &||\mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) - \mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y})||_* \\ &\approx ||\mathcal{I}_{M+M'} \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) - \mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y})||_* \text{ (by (27.113))} \\ &= \left\| \sum_{m=M+1}^{M+M'} c_m \mathbf{r}_m \right\|_*, \end{aligned} \quad (27.128)$$

where one assumes that $\mathcal{I}_{M+M'}$ for some constant $M' \in \mathbb{N}$, e.g., $M' = 2$, is a more accurate EI compression operator for the residual, so that $(\mathcal{I} - \mathcal{I}_M)\mathbf{r}_h \approx (\mathcal{I}_{M+M'} - \mathcal{I}_M)\mathbf{r}_h$. For any $\mathbf{y} \in U$, the coefficients $c_m, m = M + 1, \dots, M + M'$, can be evaluated by (27.115) with $O(M + M')$ operations. The quantity (27.128) can be computed with operations depending only on M and M' as long as the HiFi terms are assembled for only once.

The second term of (27.127) represents the RB compression error, which can be evaluated as (by noting that (27.124) holds)

$$\begin{aligned} & \| \mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) - \mathbb{V}^\top \mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) \|_* = \| \mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) \|_* \\ &= \| \mathbb{R}_M (\mathbb{P}_M \mathbb{R}_M)^{-1} \mathbb{P}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) \|_* \end{aligned} \quad (27.129)$$

where the HiFi terms can be computed for only once; given any $\mathbf{y} \in U$, evaluation of $\mathbb{P}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y})$ takes $O(MN)$ operations. Therefore, once the \mathbf{y} -independent quantities are (pre)computed, evaluation of the a posteriori error indicators for both the EI compression error and the RB compression error can be achieved efficiently, with cost depending only on N and M for each given $\mathbf{y} \in U$.

Finally, one can define the a posteriori error indicator of the RB-EI compression error as

$$\Delta_N(\mathbf{y}) := \frac{1}{\beta_h} (\| \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) - \mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) \|_* + \| \mathcal{I}_M \mathbf{r}_h(q_{N,M}(\mathbf{y}); \mathbf{y}) \|_*), \quad (27.130)$$

which can be efficiently evaluated for each $\mathbf{y} \in U$ with cost independent of the HiFi dof N_h .

3.5.5 RB-EI-PG Compression

By following the same procedure as in the linear and affine case in Sect. 3.4.4, a stable RB-EI-PG compression problem can be obtained by least-squares formulation as: given $\mathbf{y} \in U$, with some initial solution $\mathbf{q}_{N,M}^{(1)} \in \mathbb{R}^N$, for $k = 1, 2$, find $\delta \mathbf{q}_{N,M}^{(k)}(\mathbf{y}) \in \mathbb{R}^N$, such that

$$\mathbb{J}_{N,M}^s \left(\mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y} \right) \delta \mathbf{q}_{N,M} = -\mathbf{r}_h^s \left(\mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y} \right), \quad (27.131)$$

where the Jacobian matrix $\mathbb{J}_{N,M}^s(\mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y})$ with stabilization is given by

$$\begin{aligned} & \left(\mathbb{P}_M \mathbb{J}_h \left(\mathbb{W} \mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y} \right) \mathbb{W} \right)^\top (\mathbb{R}_M (\mathbb{P}_M \mathbb{R}_M)^{-1})^\top \mathbb{M}_h^{-1} \mathbb{R}_M (\mathbb{P}_M \mathbb{R}_M)^{-1} \mathbb{P}_M \mathbb{J}_h \\ & \left(\mathbb{W} \mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y} \right) \mathbb{W}, \end{aligned} \quad (27.132)$$

with $(\mathbb{R}_M(\mathbb{P}_M \mathbb{R}_M)^{-1})^\top \mathbb{M}_h^{-1} \mathbb{R}_M(\mathbb{P}_M \mathbb{R}_M)^{-1}$ evaluated once and for all and with $\mathbb{P}_M \mathbb{J}_h(\mathbb{W} \mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y}) \mathbb{W}$ evaluated in $O(M^2 N)$ operations. The stabilized RB-EI residual vector $\mathbf{r}_h^s \left(\mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y} \right)$ is given by

$$\begin{aligned} & \left(\mathbb{P}_M \mathbb{J}_h(\mathbb{W} \mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y}) \mathbb{W} \right)^\top (\mathbb{R}_M(\mathbb{P}_M \mathbb{R}_M)^{-1})^\top \mathbb{M}_h^{-1} \mathbb{R}_M(\mathbb{P}_M \mathbb{R}_M)^{-1} \mathbb{P}_M \mathbf{r}_h \\ & \left(\mathbb{W} \mathbf{q}_{N,M}^{(k)}(\mathbf{y}); \mathbf{y} \right), \end{aligned} \quad (27.133)$$

which can also be efficiently evaluated for each given \mathbf{y} with an additional $O(MN)$ operations. Then until a suitable termination criterion is met, e.g., $\|\delta \mathbf{q}_{N,M}^{(k)}\|_2 \leq \varepsilon_{\text{tol}}$, for a prescribed tolerance ε_{tol} and for a suitable vector norm $\|\cdot\|_*$ (cp. Section 3.5.4) the solution is updated as $\mathbf{q}_{N,M}^{(k+1)} = \mathbf{q}_{N,M}^{(k)} + \eta^{(k)} \delta \mathbf{q}_{N,M}^{(k)}$ with suitable constant $\eta^{(k)}$ obtained by a line search method.

3.6 Sparse Grid RB Construction

For the construction of the RB space \mathcal{X}_N , one can directly solve the optimization problem (27.69) with the true error replaced by suitable a posteriori error estimate, for instance,

$$\mathbf{y}^{N+1} := \underset{\mathbf{y} \in U}{\operatorname{argsup}} \Delta_N(\mathbf{y}). \quad (27.134)$$

This approach has been adopted in [9] by solving model-constrained optimization problems with Lagrangian formulation, which requires both full and reduced solution of adjoint problems, leading to possibly many more expensive solution of HiFi problems than the number of reduced basis functions. In very high- or infinite-dimensional parameter space, the optimization problem is typically very difficult to solve as there might be many local maximal points.

A more common approach is to replace the parameter space U by a training set Ξ_t , which consists of a finite number of samples that are rich enough to construct the most representative RB space, yet should be limited due to the constraint of computational cost. Hence, it remains to seek the next sample according to

$$\mathbf{y}^{N+1} := \underset{\mathbf{y} \in \Xi_t}{\operatorname{argmax}} \Delta_N(\mathbf{y}). \quad (27.135)$$

To choose the training samples, random sampling methods have been mostly used in practice [63]; adaptive sampling with certain saturation criteria [43] has also been developed recently to remove and add samples from the training set. In the present setting of uncertainty parametrization as introduced in Sect. 2.2, one takes advantage of the sparsity of the parametric data-to-solution map which is implied

by (b, p) -holomorphy. This sparsity allows for dimension-independent convergence rates of adaptive sparse grid sampling based on an adaptive construction of a generalized/anisotropic sparse grid in the high-dimensional parameter space. The basic idea is to build the RB space \mathcal{X}_N (and EI basis for nonlinear and nonaffine problems) in tandem with the adaptive construction of the sparse grid; see [15, 17] for more details. The advantages of this approach are threefold: the first is that the training samples as well as the sparse grid nodes for RB construction are “the most representative ones”; the second is that the computational cost for the sparse grid construction is reduced by replacing the HiFi solution at each sparse grid node by its RB surrogate solution. This provides a new algorithm for fast sparse grid construction with certificated accuracy; third, one can obtain an explicitly computable a priori error estimate for the RB compression error based on a computable bound of the sparse grid interpolation error, as stated in Theorem 2. However, these advantages are less pronounced if the parameter dependence of the parametric solution family of the forward UQ problem is less sparse; specifically, if the sparsity parameter p being $0 < p < 1$ in the (b, p) -holomorphic property becomes large and close to 1.

4 Inverse UQ

The abstract, parametric problems which arise in forward UQ in Sect. 2 consisted in computing, for given, admissible uncertain input datum $u \in X$ (respective for any parameter sequence y in the parametrization (27.13) of u , an approximate response $q(u) \in X$, respectively a *Quantity of Interest (QoI for short)* $\phi(q) \in \mathcal{Z}$ where $\phi(\cdot) : \mathcal{X} \rightarrow \mathcal{Z}$ is a continuous mapping, and \mathcal{Z} denotes a suitable space containing realizations of the QoI. If, for example, solution values $q(u)$ are of interest, one chooses $\mathcal{Z} = \mathcal{X}$, if $\phi(\cdot) \in \mathcal{X}'$, one has $\mathcal{Z} = \mathbb{R}$. The sparsity results in Sect. 2, in particular the constructive interpolation approximation result Theorem 2 and the MOR results in

4.1 Bayesian Inverse Problems for Parametric Operator Equations

Following [32, 66, 68, 71, 73], one equips the space of uncertain inputs X and the space of solutions \mathcal{X} of the forward maps with norms $\|\cdot\|_X$ and with $\|\cdot\|_{\mathcal{X}}$, respectively. Consider the abstract (possibly nonlinear) operator equation (27.5) where the uncertain operator $A(\cdot; u) \in C^1(\mathcal{X}, \mathcal{Y}')$ is assumed to be boundedly invertible, at least locally for the uncertain input u sufficiently close to a nominal input $\langle u \rangle \in X$, i.e. for $\|u - \langle u \rangle\|_X$ sufficiently small so that, for such u , the response of the forward problem (27.5) is uniquely defined. Define the *forward response map*, which relates a given uncertain input u and a given forcing F to the response q in (27.5) by

$$X \ni u \mapsto q(u) := G(u; F(u)), \text{ where } G(u, F) : X \times \mathcal{Y} \mapsto \mathcal{X}. \quad (27.136)$$

To ease notation, one does not list the dependence of the response on F and simply denotes the dependence of the forward solution on the uncertain input as $q(u) = G(u)$. Assume given an observation functional $\mathcal{O}(\cdot) : \mathcal{X} \rightarrow Y$, which denotes a *bounded linear observation operator* on the space \mathcal{X} of observed system responses in Y . Throughout the remainder of this paper, one assumes that there is a finite number K of sensors, so that $Y = \mathbb{R}^K$ with $K < \infty$. Then $\mathcal{O} \in \mathcal{L}(\mathcal{X}; Y) \simeq (\mathcal{X}')^K$. One equips $Y = \mathbb{R}^K$ with the Euclidean norm, denoted by $|\cdot|$. For example, if $\mathcal{O}(\cdot)$ is a K -vector of observation functionals $\mathcal{O}(\cdot) = (o_k(\cdot))_{k=1}^K$.

In this setting, one wishes to predict *computationally* an expected (under the Bayesian posterior) system response of the QoI, conditional on given, noisy measurement data δ . Specifically, the data δ is assumed to consist of observations of system responses in the data space Y , corrupted by additive observation noise, e.g., by a realization of a random variable η taking values in Y with law \mathbb{Q}_0 . One assumes additive, centered Gaussian noise on the observed data $\delta \in Y$. That is, the data δ is composed of the observed system response and the additive noise η according to $\delta = \mathcal{O}(G(u)) + \eta \in Y$. One assumes that $Y = \mathbb{R}^K$ and η is Gaussian, i.e., a random vector $\eta \sim \mathbb{Q}_0 \sim \mathcal{N}(0, \Gamma)$ with a positive definite covariance Γ on $Y = \mathbb{R}^K$ (i.e., a symmetric, positive definite covariance matrix $\Gamma \in \mathbb{R}_{\text{sym}}^{K \times K}$ which is assumed to be known. The *uncertainty-to-observation map* of the system $\mathcal{G} : X \rightarrow Y = \mathbb{R}^K$ is $\mathcal{G} = \mathcal{O} \circ G$, so that

$$\delta = \mathcal{G}(u) + \eta = (\mathcal{O} \circ G)(u) + \eta \in Y, \quad (27.137)$$

where $Y = L_\Gamma^2(\mathbb{R}^K)$ denotes random vectors taking values in $Y = \mathbb{R}^K$ which are square integrable with respect to the Gaussian measure on $Y = \mathbb{R}^K$. Bayes' formula [32, 73] yields a density of the Bayesian posterior with respect to the prior whose negative log-likelihood equals the observation noise covariance-weighted, least-squares functional (also referred to as "potential" in what follows) $\Phi_\Gamma : X \times Y \rightarrow \mathbb{R}$ by $\Phi_\Gamma(u; \delta) = \frac{1}{2} |\delta - \mathcal{G}(u)|_\Gamma^2$, i.e.,

$$\Phi_\Gamma(u; \delta) = \frac{1}{2} |\delta - \mathcal{G}(u)|_\Gamma^2 := \frac{1}{2} ((\delta - \mathcal{G}(u))^\top \Gamma^{-1} (\delta - \mathcal{G}(u))). \quad (27.138)$$

In [32, 73], an infinite-dimensional version of Bayes' rule was shown to hold in the present setting. In particular, the local Lipschitz assumption (27.12) on the solutions' dependence on the data implies a corresponding Lipschitz dependence of the Bayesian potential (27.138) on $u \in X$. Specifically, there holds the following version of Bayes' theorem. Bayes' Theorem states that, under appropriate continuity conditions on the uncertainty-to-observation map $\mathcal{G} = (\mathcal{O} \circ G)(\cdot)$ and on the prior measure π_0 on $u \in X$, for positive observation noise covariance Γ in (27.138), the posterior π^δ of $u \in X$ given data $\delta \in Y$ is absolutely continuous with respect to the prior π_0 .

Theorem 6 ([32, Thm. 3.3]). Assume that the potential $\Phi_\Gamma : X \times Y \mapsto \mathbb{R}$ is, for given data $\delta \in Y$, π_0 measurable on $(X, \mathcal{B}(X))$ and that, for \mathbb{Q}_0 -a.e. data $\delta \in Y$ there holds

$$Z := \int_X \exp(-\Phi(u; \delta)) \pi_0(du) > 0.$$

Then the conditional distribution of $u|\delta$ exists and is denoted by π^δ . It is absolutely continuous with respect to π_0 and there holds

$$\frac{d\pi^\delta}{d\pi_0}(u) = \frac{1}{Z} \exp(-\Phi(u; \delta)). \quad (27.139)$$

In particular, then, the Radon-Nikodym derivative of the Bayesian posterior w.r.t. the prior measure admits a bounded density w.r.t. the prior π_0 which is denoted by Θ , and which is given by (27.139).

4.2 Parametric Bayesian Posterior

The uncertain datum u in the forward equation (27.5) is parametrized as in (27.13). Motivated by [66, 68], the basis for the presently proposed deterministic quadrature approaches for Bayesian estimation via the computational realization of Bayes' formula is a *parametric, deterministic representation* of the derivative of the posterior measure π^δ with respect to the *uniform prior measure π_0 on the set U of coordinates in the uncertainty parametrization* (27.25). The prior measure π_0 being uniform, one admits in (27.13) sequences y which take values in the parameter domain $U = [-1, 1]^\mathbb{J}$, with an index set $\mathbb{J} \subset \mathbb{N}$. Consider the countably-parametric, deterministic forward problem in the probability space

$$(U, \mathcal{B}, \pi_0). \quad (27.140)$$

To ease notation, one assumes throughout what follows that the prior measure π_0 on the uncertain input $u \in X$, parametrized in the form (27.13), is the uniform measure (the ensuing derivations are still applicable if π_0 is absolutely continuous with respect to the uniform measure, with a smooth and bounded density). Being π_0 a countable product probability measure, this assumption implies the statistical independence of the coordinates y_j in the parametrization (27.13). With the parameter domain U as in (27.140) the parametric uncertainty-to-observation map $\Xi : U \rightarrow Y = \mathbb{R}^K$ is given by

$$\Xi(y) = \mathcal{G}(u) \Big|_{u=(u) + \sum_{j \in \mathbb{J}} y_j \psi_j}. \quad (27.141)$$

Our reduced basis approach is based on a parametric version of Bayes' theorem 6, in terms of the uncertainty parametrization (27.13). To present it, one views U as the unit ball in $\ell^\infty(\mathbb{J})$, the Banach space of bounded sequences taking values in U .

Theorem 7. Assume that $\Xi : \bar{U} \rightarrow Y = \mathbb{R}^K$ is bounded and continuous. Then $\pi^\delta(d\mathbf{y})$, the distribution of $\mathbf{y} \in U$ given data $\delta \in Y$, is absolutely continuous with respect to $\pi_0(d\mathbf{y})$, i.e. there exists a parametric density $\Theta(\mathbf{y})$ such that

$$\frac{d\pi^\delta}{d\pi_0}(\mathbf{y}) = \frac{1}{Z} \Theta(\mathbf{y}) \quad (27.142)$$

with $\Theta(\mathbf{y})$ given by

$$\Theta(\mathbf{y}) = \exp(-\Phi_\Gamma(u; \delta)) \Big|_{u=\langle u \rangle + \sum_{j \in \mathbb{J}} y_j \psi_j}, \quad (27.143)$$

with Bayesian potential Φ_Γ as in (27.138) and with normalization constant Z given by

$$Z = \mathbb{E}^{\pi_0}[\Theta] = \int_U \Theta(\mathbf{y}) d\pi_0(\mathbf{y}) > 0. \quad (27.144)$$

Bayesian inversion is concerned with the approximation of a “most likely” system response $\phi : X \rightarrow \mathcal{Z}$ (sometimes also referred to as *quantity of interest (QoI)* which may take values in a Banach space \mathcal{Z}) of the QoI ϕ , conditional on given (noisy) observation data $\delta \in Y$. In particular the choice $\phi(u) = G(u)$ (with $\mathcal{Z} = \mathcal{X}$) facilitates computation of the “most likely” (as expectation under the posterior, given data δ) system response. With the QoI ϕ one associates the countably-parametric map

$$\Psi(\mathbf{y}) = \Theta(\mathbf{y}) \phi(u) \Big|_{u=\langle u \rangle + \sum_{j \in \mathbb{J}} y_j \psi_j} = \exp(-\Phi_\Gamma(u; \delta)) \phi(u) \Big|_{u=\langle u \rangle + \sum_{j \in \mathbb{J}} y_j \psi_j} : U \rightarrow \mathcal{Z}. \quad (27.145)$$

Then the Bayesian estimate of the QoI ϕ , given noisy observation data δ , reads

$$\mathbb{E}^{\pi^\delta}[\phi] = Z'/Z, \quad Z' := \int_{\mathbf{y} \in U} \Psi(\mathbf{y}) \pi_0(d\mathbf{y}), \quad Z := \int_{\mathbf{y} \in U} \Theta(\mathbf{y}) \pi_0(d\mathbf{y}). \quad (27.146)$$

The task in computational Bayesian estimation is therefore to approximate the ratio $Z'/Z \in \mathcal{Z}$ in (27.146). In the parametrization with respect to $\mathbf{y} \in U$, Z and Z' take the form of infinite-dimensional, iterated integrals with respect to the prior $\pi_0(d\mathbf{y})$.

4.3 Well-Posedness and Approximation

For the computational viability of Bayesian inversion, the quantity $\mathbb{E}^{\pi^\delta}[\phi]$ should be stable under perturbations of the data δ and under changes in the forward problem stemming, for example, from discretizations as considered in Sects. 3.1 and 3.2.

Unlike deterministic inverse problems where the data-to-solution maps can be severely ill-posed, for $\Gamma > 0$ the expectations (27.146) are Lipschitz continuous with respect to the data δ , *provided that the potential Φ_Γ in (27.138) is locally Lipschitz with respect to the data δ* in the following sense.

Assumption 4. *Let $\tilde{X} \subseteq X$ and assume $\Phi_\Gamma \in C(\tilde{X} \times Y; \mathbb{R})$ is Lipschitz on bounded sets. Assume also that there exist functions $M_i : \mathbb{R}_+ \times \mathbb{R}_+ \rightarrow \mathbb{R}_+$ (depending on $\Gamma > 0$) which are monotone, non-decreasing separately in each argument, such that for all $u \in \tilde{X}$, and for all $\delta, \delta_1, \delta_2 \in B_Y(0, r)$*

$$\Phi(u; \delta) \geq -M_1(r, \|u\|_X), \quad (27.147)$$

and

$$|\Phi_\Gamma(u; \delta_1) - \Phi_\Gamma(u; \delta_2)| \leq M_2(r, \|u\|_X) \|\delta_1 - \delta_2\|_Y. \quad (27.148)$$

Under Assumption 4, the expectation (27.146) depends Lipschitz on δ (see [32, Sec. 4.1] for a proof):

$$\forall \phi \in L^2(\pi^{\delta_1}, X; \mathbb{R}) \cap L^2(\pi^{\delta_2}, X; \mathbb{R}) \quad \|\mathbb{E}^{\pi^{\delta_1}}[\phi] - \mathbb{E}^{\pi^{\delta_2}}[\phi]\|_{\mathcal{Z}} \leq C(\Gamma, r) \|\delta_1 - \delta_2\|_Y. \quad (27.149)$$

Below, one shall be interested in the impact of approximation errors in the forward response of the system (e.g., due to discretization and approximate numerical solution of system responses) on the Bayesian predictions (27.146). For continuity of the expectations (27.146) w.r.t. changes in the potential, the following assumption is imposed.

Assumption 5. *Let $\tilde{X} \subseteq X$ and assume $\Phi \in C(\tilde{X} \times Y; \mathbb{R})$ is Lipschitz on bounded sets. Assume also that there exist functions $M_i : \mathbb{R}_+ \times \mathbb{R}_+ \rightarrow \mathbb{R}_+$ which are monotonically non-decreasing separately in each argument, such that for all $u \in \tilde{X}$, and all $\delta \in B_Y(0, r)$, Eq. (27.147) is satisfied and*

$$|\Phi_\Gamma(u; \delta) - \Phi_\Gamma^N(u; \delta)| \leq M_2(r, \|u\|_X) \|\delta\|_Y \psi(N) \quad (27.150)$$

where $\psi(N) \rightarrow 0$ as $N \rightarrow \infty$.

By π_N^δ one denotes the Bayesian posterior, given data $\delta \in Y$, with respect to Φ_Γ^N .

Proposition 3. Under Assumption 5, and the assumption that for $\tilde{X} \subseteq X$ and for some bounded $B \subset X$ one has $\pi_0(\tilde{X} \cap B) > 0$ and

$$X \ni u \mapsto \exp(M_1(\|u\|_X))(M_2(\|u\|_X))^2 \in L^1_{\pi_0}(X; \mathbb{R}),$$

there holds, for every QoI $\phi : X \rightarrow \mathcal{Z}$ such that, although the convergence rate s can be substantially higher than the rate $1/2$ afforded by MCMC methods (cp. Sect. 4.4 and [32, Sections 5.1, 5.2]) that $\phi \in L^2_{\pi^\delta}(X; \mathcal{Z}) \cap L^2_{\pi_N^\delta}(X; \mathcal{Z})$ uniformly w.r.t. N , that $Z > 0$ in (27.144) and

$$\|\mathbb{E}^{\pi^\delta}[\phi] - \mathbb{E}^{\pi_N^\delta}[\phi]\|_{\mathcal{Z}} \leq C(\Gamma, r)\|\delta\|_Y \psi(N). \quad (27.151)$$

For a proof of Proposition 3, see [32, Thm. 4.7, Rem. 4.8].

Below, concrete choices are presented for the convergence rate function $\psi(N)$ in estimates (27.150), (27.151) in terms of i) “dimension truncation” of the uncertainty parametrization (27.13), i.e., to a finite number of $s \geq 1$ terms in (27.13), and ii) Petrov–Galerkin discretization of the dimensionally truncated problem, and iii) generalized polynomial chaos (gpc) approximation of the dimensionally truncated problem for particular classes of forward problems. The verification of the consistency condition (27.150) in either of these cases will be based on (cf. [35]).

Proposition 4. Assume given a sequence $\{q^N\}_{N \geq 1}$ of approximations to the parametric forward response $X \ni u \mapsto q(u) \in \mathcal{X}$ such that, with the parametrization (27.13),

$$\sup_{y \in U} \|(q - q^N)(y)\|_{\mathcal{X}} \leq \psi(N) \quad (27.152)$$

with a consistency error bound $\psi \downarrow 0$ as $N \rightarrow \infty$ monotonically and uniformly w.r.t. $u \in \tilde{X}$ (resp. w.r.t. $y \in U$). By G^N one denotes the corresponding (Galerkin) approximations of the parametric forward maps. Then the approximate Bayesian potential

$$\Phi^N(u; \delta) = \frac{1}{2}(\delta - \mathcal{G}^N(u))^\top \Gamma^{-1}(\delta - \mathcal{G}^N(u)) : X \times Y \mapsto \mathbb{R}, \quad (27.153)$$

where $\mathcal{G}^N := \mathcal{O} \circ G^N$, satisfies (27.150).

The preceding result shows that the consistency condition (27.152) for the approximate forward map q^N ensures corresponding consistency of the Bayesian estimate $\mathbb{E}^{\pi_N^\delta}[\phi]$, due to (27.151). Note that so far, no specific assumption on the nature of approximation of the forward map has been made. Using a MOR surrogate of the parametric forward model, Theorem 5 allows to bound $\psi(N)$ in (27.152) by the

corresponding worst-case RB compression error σ_N in (27.72) which, is bound by the convergence rate of the corresponding N -width:

$$\psi(N) \leq \sigma_N \lesssim d_N(\mathcal{M}_h; \mathcal{X}_h) \quad (27.154)$$

in the various cases indicated in Theorem 5. Under Assumption 4, Proposition 4 ensures that Assumption 5 holds, with (27.154). One concludes in particular that replacing the forward model by a reduced basis surrogate will result in an error in the Bayesian estimate of the same asymptotic order of magnitude, as $N \rightarrow \infty$. This justifies, for example, running Markov chains on the surrogate forward model obtained from MOR. In doing this, however, care must be taken to account for the constants implied by \lesssim in (27.154): the constants do not depend on N , but large values of these constants can imply prohibitive errors for the (small) values N of the number of RB degrees of freedom employed in PG projections of MOR forward surrogates. In addition, it is pointed out that the estimate (27.151) depends on the observation noise covariance Γ , as well as on the size r of the observation data δ (measured in Y).

4.4 Reduced Basis Acceleration of MCMC

Markov chain Monte Carlo (MCMC) methods compute the expectation $\mathbb{E}^{\pi^\delta}[\phi]$ in (27.146) under the posterior by sampling from the posterior density. They proceed in approximation of the constant Z' in (27.146) by sample averages where, however, *the posterior distribution from which samples are to be drawn is itself to be determined during the course of the sampling process*. MCMC methods start by sampling from the (known) prior π_0 , and by updating, in the course of sampling, both numerator Z' as well as the normalizing constant Z in (27.146). Several variants exist; see [32, Sections 5.1,5.2] for a derivation of the *Metropolis-Hastings MCMC*, and to [32, Section 5.3] for *sequential Monte Carlo (sMC) methods*. A convergence theory in terms of certain *spectral gaps* is provided in [32, Thm. 5.13], resulting in the convergence rate $N^{-1/2}$ with N denoting the number of increments of the chain. In the context of the present paper, N denotes the number of (approximate) solves of the parametric forward problem (27.4), resp. of a discretization of it. Due to the low rate of convergence $1/2$ of the MCMC methods (and due to the high rejection rate of the samplers during burn-in), generally a very large number of samples is required. Moreover, successive updates of the MCMC samplers have an intrinsically serial structure which, in turn, foils massive parallelism to compensate for the slow convergence rate. It is therefore of high interest to examine the possibility of accelerating MCMC methods. In [47], the impact of various discretization and acceleration techniques for MCMC methods were analyzed for the computation of the expectation $\mathbb{E}^{\pi^\delta}[\phi]$ in (27.146); among them a generalized polynomial chaos (gpc) surrogate of the parametric forward map

$U \ni y \rightarrow q(y) \in \mathcal{X}$. The theory in [47] can be extended using the consistency error bound Assumption 5 in the Bayesian potential, and Proposition 4 for the RB error in the forward map. Practical application and implementation of RB with MCMC for (Bayesian) inverse problems can be found, for instance, in [30, 51].

4.5 Dimension and Order Adaptive, Deterministic Quadrature

The parametric, deterministic infinite-dimensional integrals Z' and Z in (27.146) are, in principle, accessible to any quadrature strategy which is able to deal efficiently with the high dimension of the integration domain, and which is able to exploit (b, p) sparsity of the parametric integrand functions.

Following [25, 42], a greedy strategy based on reduced sets of indices which are neighboring the currently active set Λ , defined by

$$\mathcal{N}(\Lambda) := \{\nu \notin \Lambda : \nu - e_j \in \Lambda, \forall j \in \mathbb{I}_\nu \text{ and } \nu_j = 0, \forall j > j(\Lambda) + 1\}$$

for any downward closed index set $\Lambda \subset \mathcal{F}$ of currently active gpc modes, where $j(\Lambda) := \max\{j : \nu_j > 0 \text{ for some } \nu \in \Lambda\}$. This heuristic approach aims at controlling the global approximation error by locally collecting indices of the current set of neighbors with the largest estimates error contributions. In the following, the resulting algorithm to recursively build the downward closed index set Λ in the Smolyak quadrature which is adapted to the posterior density (and, due to the explicit expression (27.143) from Bayes' formula, also to the observation data δ) is summarized. The reader is referred to [42, 66, 68] for details and numerical results. Development and analysis of the combination of RB, MOR and ASG for Bayesian inversion are described in depth in [21–23], for both linear and nonlinear, both affine and nonaffine parametric problems.

```

1: function ASG
2:   Set  $\Lambda_1 = \{0\}$ ,  $k = 1$  and compute  $\Delta_0(\Xi)$ .
3:   Determine the reduced set (27.155) of neighbors  $\mathcal{N}(\Lambda_1)$ .
4:   Compute  $\Delta_\nu(\Xi)$ ,  $\forall \nu \in \mathcal{N}(\Lambda_1)$ .
5:   while  $\sum_{\nu \in \mathcal{N}(\Lambda_k)} \|\Delta_\nu(\Xi)\|_{\mathcal{S}} > tol$  do
6:     Select  $\nu$  from  $\mathcal{N}(\Lambda_k)$  with largest  $\|\Delta_\nu\|_{\mathcal{S}}$  and set  $\Lambda_{k+1} = \Lambda_k \cup \{\nu\}$ .
7:     Determine the reduced set (27.155) of neighbors  $\mathcal{N}(\Lambda_{k+1})$ .
8:     Compute  $\Delta_\nu(\Xi)$ ,  $\forall \nu \in \mathcal{N}(\Lambda_{k+1})$ .
9:     Set  $k = k + 1$ .
10:   end while
11: end function
```

4.6 Quasi-Monte Carlo Quadrature

The adaptive, deterministic quadrature based on active multiindex sets determined by the algorithm ASG in Section 12 realizes, in practical experiments [66, 68], convergence rates $s = 1/p - 1$ which are determined only by the summability exponent p of the sequence \mathbf{b} of (X -norms of) the basis Ψ adopted for the space X , in order to parametrize the uncertain input data u as in (27.13). The downside/drawback of Algorithm 12 is that although the (dimension-independent) convergence rate s can be substantially higher than the rate $1/2$ afforded by MCMC methods (cp. Sect. 4.4), provided the summability exponent p is sufficiently small, it is intrinsically sequential in nature, due to the recursive construction of the active index sets; in this respect, it is analogous to MCMC methods which access the forward model (or a surrogate of it) through uncertainty instances produced by the sampler along the Markov chains. An alternative to these approaches which allows for dimension-independent convergence rate $s = 1/p$ in terms of the number of samples *and* which allows simultaneous, parallel access to the forward model in all instances of the uncertainty is the recently developed, higher-order quasi-Monte Carlo integration. It allows fully parallel evaluation of the integrals Z' and Z in the Bayesian estimate (27.146). The reader is referred to [38] for a general survey and numerous references. It has recently been shown that (\mathbf{b}, p) sparsity implies, indeed, the dimension-independent convergence rate $s = 1/p$ for certain types of higher order QMC integration; see [36] for the theory for linear, affine parametric operator equations $q \mapsto A(\mathbf{y})q$, [37] for multilevel extensions, and [39] for the verification of the convergence conditions in [36] implied by (\mathbf{b}, p) holomorphy. Computational construction of higher-order QMC integration rules on the bounded parameter domain U is described in [41]. There exist also QMC integration methods for unbounded parameter regions. Such arise typically for *Gaussian random field (GRF for short) inputs* u taking values in X . Upon uncertainty parametrization with, for example, a Karhunen–Loève expansion into eigenfunctions of the covariance operator of the GRF (27.17), there result parametric deterministic problems with unbounded parameter ranges (consisting, for GRF's, of countable cartesian products of real lines, i.e., $U = \mathbb{R}^{\mathbb{N}}$). In this case, the present theory still is applicable; however, *all stability and equivalence constants will depend, generally, on the parameter \mathbf{y} with the parametric dependence degenerating for “extremal events,” i.e., realizations of u whose parameters in the tail of the prior π_0 . This is particularly relevant for uncertain input data which involve a gaussian random field (27.17) in some form.*

5 Software

- **rbMIT:** The general algorithms of RB based on Finite Element are implemented in the software package rbMIT ©MIT in MATLAB. It is implemented mainly for demonstration and education. However, it is also friendly to use for development

and test of new algorithms. The code and an accompanying textbook [59] are available through the link:

http://augustine.mit.edu/methodology/methodology_rbMIT_System.htm

- **RBnICS:** An RB extension of the Finite Element software package FEniCS [53] is under development and public domain through the link:<http://mathlab.sissa.it/rbnics>. Implementation includes POD and greedy algorithm for coercive problems, which is suited for an introductory course of RB together with the book [44].
- **Dune-RB:** It is a module for the Dune (Distributed and Unified Numerics Environment) library in C++. Template classes are available for RB construction based on several HiFi discretizations, including Finite Element and Finite Volume. Parallelization is available for RB construction too. Tutorials and code are available at <http://www.dune-project.org/>.
- **pyMOR:** pyMOR is implemented in Python for MOR for parameterized PDE. It has friendly interfaces and proper integration with external high-dimensional PDE solvers. Finite element and finite volume discretizations implemented based on the library of NumPy/SciPy are available. For more information, see <http://pymor.org>.
- **AKSELLOS:** MOR remains the core technology for the startup company AKSELLOS in several engineering fields, such as port infrastructure and industrial machinery. Different components are included such as FEA and CAD. The HiFi solution in AKSELLOS is implemented with a HPC and cloud-based simulation platform and is available for commercial use. For more information see <http://www.akselos.com>.
- For further libraries/software packages, we refer to <http://www.ians.uni-stuttgart.de/MoRePaS/software/>.

6 Conclusion

In this work, both mathematical and computational foundations of model order reduction techniques for UQ problems with distributed uncertainties are surveyed. Based on the recent development of sparse polynomial approximation in infinite dimensions, the convergence property of MOR constructed by greedy algorithm is established. In particular, under the sparsity of the uncertainties and the holomorphy of the forward solution maps w.r.t. the parameters, the dimension-independent convergence rate of the RB compression error can be achieved. Details of the construction and the compression of MOR are provided for both affine and nonaffine and linear and nonlinear problems modelled by parametric operator equations. Stability of the HiFi approximation and the RB compression is fulfilled by Petrov–Galerkin formulation with suitably constructed test spaces. Efficient MOR construction is realized by a greedy search algorithm with sparse sampling scheme, which further leads to a fast method for sparse grid construction. The MOR techniques are applied for both forward and inverse UQ problems, leading

to considerable computational reduction in the *many-query* context for evaluation of statistics, and in the *real-time* context for fast Bayesian inversion.

MOR has been demonstrated to be very effective in reducing the computational cost for solving large-scale “smooth” problems, namely, the solution map depends rather smoothly on the input parameters, as characterized by parametric holomorphy Definition 1 in high- or even infinite dimensions. However, this smoothness is not a necessary condition for the effectiveness of MOR. As long as the solution lives in an intrinsically low-dimensional manifold, MOR can reasonably be expected to accelerate numerical forward solves. See, for instance, [13] where the solution is discontinuous w.r.t. the input parameter. As for more general problems where the solution is not contained in a low-dimensional manifold, as observed in some hyperbolic problems, it is a remarkable challenge to apply MOR. Development of MOR to deal with problems of this kind is an emerging and active research field [1, 24, 31, 40, 65, 74]. Another development of MOR in computational UQ is parallel sampling and construction of the reduced order model in order to take advantage of parallel computing, such as using quasi Monte Carlo sampling [35] and parallel construction of the sparse grid based MOR via a priori information. In particular, for inverse UQ problems, sampling according to the posterior distribution or the related Hessian information [8, 67] would lead to potentially much faster construction and better efficiency of MOR.

7 Glossary

List of used abbreviations and definition of technical terms:

- UQ: uncertainty quantification
- MOR: model order reduction
- PDE: partial differential equations
- POD: proper orthogonal decomposition
- RB: reduced basis
- EI: empirical interpolation
- SG: sparse grid
- FEM: finite element method
- PG: Petrov–Galerkin
- QoI: quantity of interest
- Fidelity (of a mathematical model): notion of quality of responses of a computational **surrogate** model for a given mathematical model
- HiFi: high fidelity
- SCM: successive constraint method
- Surrogate model: numerical model obtained by various numerical approximation of a mathematical model

Multifidelity Uncertainty Quantification Using Spectral Stochastic Discrepancy Models

28

Stefan P. Domino

Abstract

When faced with a restrictive evaluation budget that is typical of today's high-fidelity simulation models, the effective exploitation of lower-fidelity alternatives within the uncertainty quantification (UQ) process becomes critically important. Herein, we explore the use of multifidelity modeling within UQ, for which we rigorously combine information from multiple simulation-based models within a hierarchy of fidelity, in seeking accurate high-fidelity statistics at lower computational cost. Motivated by correction functions that enable the provable convergence of a multifidelity optimization approach to an optimal high-fidelity point solution, we extend these ideas to discrepancy modeling within a stochastic domain and seek convergence of a multifidelity uncertainty quantification process to globally integrated high-fidelity statistics. For constructing stochastic models of both the low-fidelity model and the model discrepancy, we employ stochastic expansion methods (non-intrusive polynomial chaos and stochastic collocation) computed by integration/interpolation on structured sparse grids or regularized regression on unstructured grids. We seek to employ a coarsely resolved grid for the discrepancy in combination with a more finely resolved

grid for the low-fidelity model. The resolutions of these grids may be defined statically or determined through uniform and adaptive refinement processes. Adaptive refinement is particularly attractive, as it has the ability to preferentially target stochastic regions where the model discrepancy becomes more complex, i.e., where the predictive capabilities of the low-fidelity model start to break down and greater reliance on the high-fidelity model (via the discrepancy) is necessary. These adaptive refinement processes can either be performed separately for the different grids or within a coordinated multifidelity algorithm. In particular, we present an adaptive greedy multifidelity approach in which we extend the generalized sparse grid concept to consider candidate index set refinements drawn from multiple sparse grids, as governed by induced changes in the statistical quantities of interest and normalized by relative computational cost. Through a series of numerical experiments using statically defined sparse grids, adaptive multifidelity sparse grids, and multifidelity compressed sensing, we demonstrate that the multifidelity UQ process converges more rapidly than a single-fidelity UQ in cases where the variance of the discrepancy is reduced relative to the variance of the high-fidelity model (resulting in reductions in initial stochastic error), where the spectrum of the expansion coefficients of the model discrepancy decays more rapidly than that of the high-fidelity model (resulting in accelerated convergence rates), and/or where the discrepancy is more sparse than the high-fidelity model (requiring the recovery of fewer significant terms).

1 Introduction

The rapid advancement of both computer hardware and physics simulation capabilities has revolutionized science and engineering, placing computational simulation on an equal footing with theoretical analysis and physical experimentation. This rapidly increasing reliance on the predictive capabilities of computational models has created the need for rigorous quantification of the effect that all types of uncertainties have on these predictions, in order to inform decisions and design processes with critical information on quantified variability and risk. A variety of challenges arise when deploying uncertainty quantification (UQ) to ever more complex physical systems. Foremost among these is the intersection of UQ problem scale with simulation resource constraints. When pushing the boundaries of computational science using complex three-dimensional (multi-)physics simulation capabilities, a common result is a highest-fidelity simulation that can be performed only a very limited number of times, even when executing on leadership-class parallel computers. Combining this state with the significant number of uncertainty sources (often in the hundreds, thousands, or beyond) that exist in these complex applications can result in an untenable proposition for UQ or at least a state of significant imbalance in which resolution of spatiotemporal physics has been given much higher priority over resolution of quantities of interest (QoIs) throughout the stochastic domain. This primary challenge can be further compounded by a number of factors, including (*i*) the presence of a mixture of aleatory and epistemic uncertainties, (*ii*) the need to evaluate the probability of rare events, and/or (*iii*) the presence of nonsmoothness in the variation of the response QoIs over the range of the random parameters. In these challenging cases, our most sophisticated UQ algorithms may be inadequate on their own for affordably generating accurate high-fidelity statistics; we need to additionally exploit opportunities that exist within a hierarchy of model fidelity.

The computational simulation of a particular physical phenomenon often has multiple discrete model selection possibilities. Here, we will broadly characterize this situation into two classes: a hierarchy of model fidelity and an ensemble of model peers. In the former case of a hierarchy, a clear preference structure exists among the models such that “high-fidelity” and “low-fidelity” judgments are readily assigned. Here, the goal is to manage the trade-off between accuracy and expense among the different model fidelities in order to achieve high-quality statistical results at lower cost. In the latter case, a clear preference structure is lacking and there is additional uncertainty created by the lack of a best model. In this case, the goal becomes one of management and propagation of this model form uncertainty [15] or, in the presence of experimental data for performing inference, reducing the model form uncertainty through formal model selection processes [10, 37]. Taking computational fluid dynamics (CFD) applied to a canonical cavity flow as an example, Fig. 28.1 depicts a multifidelity hierarchy that may include inviscid and boundary-element-based simulations, Reynolds averaged Navier-Stokes (RANS), unsteady RANS, large-eddy simulation (LES), and direct numerical simulation (DNS). Peers at a given level (e.g., RANS and LES) involve a variety

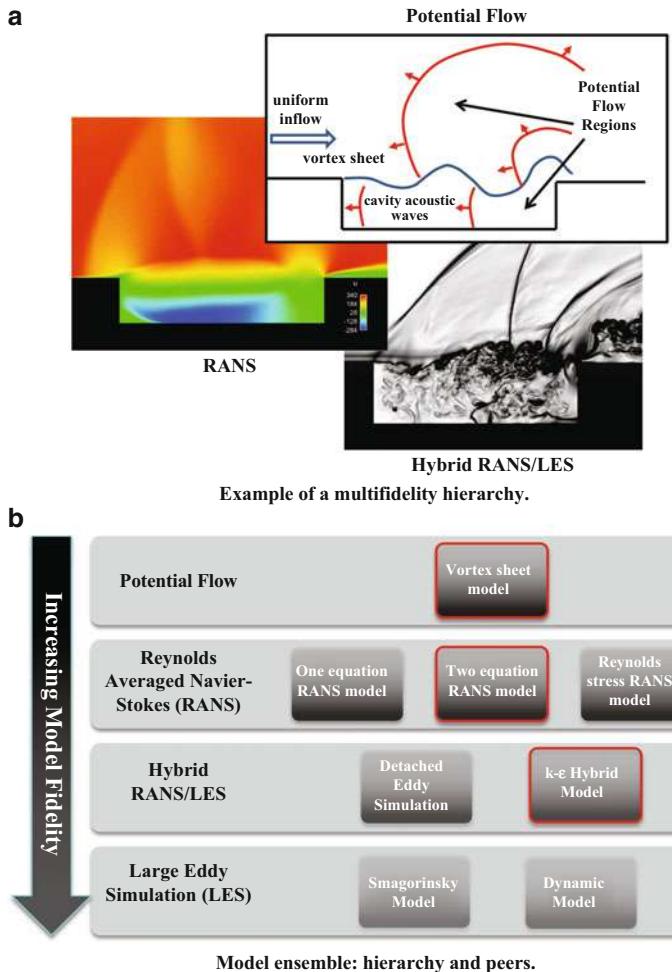

Fig. 28.1 Example of an ensemble of CFD models for a cavity flow problem (a) and hierarchy and ensemble of peer alternatives (b). Observational data can be used to inform model selection among peers (red boxes)

of turbulence (Spalart-Allmaras, $k-\epsilon$, $k-\omega$, etc.) and sub-grid scale (Smagorinsky, dynamic Smagorinsky, etc.) model formulations, as depicted in Fig. 28.1b.

In this work (an extension of [36]) we address the model hierarchy case where the system responses can be obtained accurately by evaluating an expensive high-fidelity model or less accurately by evaluating an inexpensive low-fidelity model. Extension to a deeper hierarchy that includes mid-fidelity options is straightforward (each additional mid-fidelity model introduces an additional level of model discrepancy), but here we focus on two fidelities for simplicity of exposition. The low-fidelity model may be based on simplified physics, coarser discretization of the

high-fidelity model, projection-based reduced-order models (e.g., proper orthogonal decomposition), or other techniques that exchange accuracy for reduced cost. We investigate a multifidelity approach to compute high-fidelity statistics without the expense of relying exclusively on high-fidelity model evaluations. Such multifidelity approaches have previously been developed for the *optimization* of expensive high-fidelity models. In the multifidelity trust-region model-management approach [3], the optimization is performed on a corrected low-fidelity model. The correction function can be additive, multiplicative, or a combination of the two [16] and is updated periodically using high-fidelity model evaluations. First- or second-order polynomials are used to enforce local first- or second-order consistency, respectively, at high-fidelity model evaluation points [3, 16]. Other variations have employed global correction functions (typically enforcing zeroth-order consistency) based on the interpolation of the discrepancy between the high-fidelity model evaluations and the low-fidelity model evaluations [18, 26, 33, 38]. The central concept is that a surrogate based on a physics-based low-fidelity model and a model of the discrepancy may provide a more cost-effective approximation of the high-fidelity model than a surrogate based only on fitting limited sets of high-fidelity data. We carry this idea over to uncertainty propagation and form a stochastic approximation for the discrepancy model as well as a separate stochastic approximation for the low-fidelity model. Both approximations employ expansions of global polynomials defined in terms of the stochastic parameters. After forming the low-fidelity and discrepancy expansions, we combine their polynomial terms to create a multifidelity stochastic expansion that approximates the high-fidelity model, and we use this expansion to generate the desired high-fidelity statistics. Compared to a single-fidelity expansion formed exclusively from high-fidelity evaluations, the multifidelity expansion will typically carry more terms after combination due to the greater resolution used in creating the low-fidelity expansion. If the low-fidelity model is sufficiently predictive, then less computational effort is required to resolve the discrepancy, reducing the number of high-fidelity model evaluations necessary to obtain the high-fidelity response statistics to a desired accuracy. Depending on the specific formulation, we may choose to strictly enforce zeroth- and first-order consistency (values and first derivatives) of our combined approximation with the high-fidelity results at each of the high-fidelity collocation points, mirroring the convergence theory requirements for surrogate-based optimization methods.

Our foundation for multifidelity UQ is provided by stochastic expansion methods, using either multivariate orthogonal polynomials in the case of non-intrusive polynomial chaos or multivariate interpolation polynomials in the case of stochastic collocation. In the former case, polynomial chaos expands the system response as a truncated series of polynomials that are orthogonal with respect to the probability density functions of the stochastic parameters [22, 43]. Exponential convergence in integrated statistical quantities (e.g., mean, variance) can be achieved for smooth functions with finite variance. The chaos coefficients can be obtained by either projecting the system response onto each basis and then computing the coefficients by multidimensional numerical integration or by solving for the coefficients using regression approaches with either least squares for overdetermined or ℓ_1 -regularized

regression [27] for under-determined systems. Stochastic collocation is a related stochastic expansion method which constructs multidimensional interpolation polynomials over the system responses evaluated at a structured set of collocation points [5, 42]. If the collocation points are selected appropriately, then similar performance can be achieved, and in the limiting case of tensor-product Gaussian quadrature rules corresponding to the density functions of the random variables, the two approaches generate identical polynomial forms.

Many other choices for stochastic approximation are possible, and Gaussian process (GP) models have been used extensively for discrepancy modeling in the context of Bayesian inference [30], including multifidelity Bayesian inference approaches [24, 29]. GPs would be a particularly attractive choice in the case of resolution of rare events, as adaptive refinement of GPs to resolve failure domains [8] would provide an effective single-fidelity framework around which to tailor a multifidelity strategy for adaptively refining GP surrogates for the low-fidelity and discrepancy models.

Another related multifidelity capability is multilevel Monte Carlo (MLMC [6, 23]), which relies on correlation among the QoI predictions that are produced for different discretization levels within a model hierarchy. This correlation manifests as a reduction in variance for statistical estimators applied to model discrepancies, which in turn leads to a reduction in the leading constant for the $\frac{1}{\sqrt{N}}$ convergence rates of Monte Carlo methods. Finally, recent work [35, 44] has explored an approach in which lower-fidelity models are used to inform how to most effectively sample the high-fidelity model as well as for reconstructing approximate high-fidelity evaluations. These different approaches place differing requirements on the predictive capability of lower-fidelity models, which have important ramifications on the efficacy of the multifidelity approaches. For example, the requirement of correlation between QoI prediction levels in MLMC and control variate approaches is expected to relax smoothness requirements that are present when explicitly resolving model discrepancy based on polynomial expansion. Conversely, when smoothness is present, its effective exploitation should lead to superior multifidelity convergence rates. Herein, we focus on the spectral stochastic discrepancy modeling approach, with relative comparisons reserved as an important subject for future study.

In the following, we first review our foundation of stochastic expansion methods and their multidimensional construction via sparse grids or compressed sensing. Next, we present the extension to the multifidelity case and provide an algorithmic framework. Finally, we demonstrate our approach with a variety of computational experiments and provide concluding remarks.

2 Stochastic Expansions

In this section, we briefly review the non-intrusive polynomial chaos expansion (PCE) and stochastic collocation (SC) methods. Both methods construct a global polynomial approximation to the system response and have been shown to be

pointwise equivalent if non-nested Gaussian quadrature nodes are used [11]. However, one form of the polynomial expansion may be preferred over the other, depending on the needs of the application (e.g., support for unstructured grids, fault tolerance, and/or local error estimation).

2.1 Non-intrusive Polynomial Chaos

In polynomial chaos, one must estimate the chaos coefficients for a set of basis functions. To reduce the nonlinearity of the expansion and improve convergence, the polynomial bases are chosen such that their orthogonality weighting functions match the probability density functions of the stochastic parameters up to a constant factor [43]. The basis functions are typically obtained from the Askey family of hypergeometric orthogonal polynomials [4], and Table 28.1 lists the appropriate polynomial bases for some commonly used continuous probability distributions. If the stochastic parameters do not follow these standard probability distributions, then the polynomial bases may be generated numerically [19, 25, 41]. Alternatively, or if correlations are present, variable transformations [1, 12, 39] may be used. These transformations provide support for statistical independence (e.g., decorrelation of standard normal distributions as in [12]) and can also enable the use of nested quadrature rules such as Gauss-Patterson and Genz-Keister for uniform and normal distributions, respectively, within the transformed space.

Let $R(\xi)$ be a “black box” that takes d stochastic parameters $\xi = (\xi_1, \dots, \xi_d)$ as inputs and return the system response R as the output.

The system response is approximated by the expansion

$$R(\xi) \approx \sum_{\mathbf{i} \in \mathcal{I}_p} \alpha_{\mathbf{i}} \Psi_{\mathbf{i}}(\xi), \quad (28.1)$$

where the basis functions $\Psi_{\mathbf{i}}(\xi)$ with multi-index $\mathbf{i} = (i_1, \dots, i_d)$, $i_k = 0, 1, 2, \dots$ are the product of the appropriate one-dimensional orthogonal polynomial basis of

Table 28.1 Some standard continuous probability distributions and their corresponding Askey polynomial bases. $B(\alpha, \beta)$ is the Beta function and $\Gamma(\alpha)$ is the Gamma function

From *Multifidelity Uncertainty Quantification Using Non-Intrusive Polynomial Chaos and Stochastic Collocation*, by Ng and Eldred, 2012, AIAA-2012-1852, published in the Proceedings of the 53rd SDM conference; reprinted by permission of the American Institute of Aeronautics and Astronautics, Inc.

order i_k in each dimension $k = 1, \dots, d$. The series is typically truncated in one of two ways. For the total-order expansion of order p , the index set is defined as

$$\mathcal{I}_p = \{\mathbf{i} : |\mathbf{i}| \leq p\}, \quad (28.2)$$

where $|\mathbf{i}| = i_1 + \dots + i_d$, while for the tensor-product expansion of order $\mathbf{p} = (p_1, \dots, p_d)$, the index set is defined as

$$\mathcal{I}_{\mathbf{p}} = \{\mathbf{i} : i_k \leq p_k, k = 1, \dots, d\}. \quad (28.3)$$

The number of terms required in each case is

$$M_{TO} = \frac{(d+p)!}{d! p!} = \binom{d+p}{d}, \quad (28.4)$$

and

$$M_{TP} = \prod_{k=1}^d (p_k + 1), \quad (28.5)$$

respectively.

One approach to calculate the chaos coefficients $\alpha_{\mathbf{i}}$ is the spectral projection method that takes advantage of the orthogonality of the bases. This results in

$$\alpha_{\mathbf{i}} = \frac{\langle R(\xi), \Psi_{\mathbf{i}}(\xi) \rangle}{\langle \Psi_{\mathbf{i}}^2(\xi) \rangle} = \frac{1}{\langle \Psi_{\mathbf{i}}^2(\xi) \rangle} \int_{\Omega} R(\xi) \Psi_{\mathbf{i}}(\xi) \rho(\xi) d\xi, \quad (28.6)$$

where $\rho(\xi) = \prod_{k=1}^d \rho_k(\xi_k)$ is the joint probability density of the stochastic parameters over the support $\Omega = \Omega_1 \times \dots \times \Omega_d$ and $\langle \Psi_{\mathbf{i}}^2(\xi) \rangle$ is available in closed form. Thus, the bulk of the work is in evaluating the multidimensional integral in the numerator. Tensor-product quadrature may be employed to evaluate these integrals or, if d is more than a few parameters, sparse grid quadrature may be employed as described in Eqs. 28.19–28.21 to follow.

Once the chaos coefficients are known, the statistics of the system response can be estimated directly and inexpensively from the expansion. For example, the mean and the variance can be obtained analytically as

$$\mu_R = \langle R(\xi) \rangle \approx \sum_{\mathbf{i} \in \mathcal{I}_{\mathbf{p}}} \alpha_{\mathbf{i}} \langle \Psi_{\mathbf{i}}(\xi) \rangle = \alpha_0 \quad (28.7)$$

and

$$\sigma_R^2 = \langle R(\xi)^2 \rangle - \mu_R^2 \approx \sum_{\mathbf{i} \in \mathcal{I}_{\mathbf{p}}} \sum_{\mathbf{j} \in \mathcal{I}_{\mathbf{p}}} \alpha_{\mathbf{i}} \alpha_{\mathbf{j}} \langle \Psi_{\mathbf{i}}(\xi) \Psi_{\mathbf{j}}(\xi) \rangle - \alpha_0^2 = \sum_{\mathbf{i} \in \mathcal{I}_{\mathbf{p}} \setminus \mathbf{0}} \alpha_{\mathbf{i}}^2 \langle \Psi_{\mathbf{i}}^2(\xi) \rangle \quad (28.8)$$

where $\mathbf{0}$ is a vector of zeros (i.e., the first multi-index). Other statistics such as probabilities and quantiles can be estimated by sampling the polynomial expansion.

2.2 Stochastic Collocation

In stochastic collocation, a multivariate polynomial interpolant is formed over the system responses evaluated at a set of collocation points. In one-dimension, a degree $n - 1$ expansion (identified by the index i) has the form

$$R(\xi) \approx \mathcal{U}_i(R) \stackrel{\text{def}}{=} \sum_{j=1}^n R(\xi^{(j)}) \ell^{(j)}(\xi) \quad (28.9)$$

where $R(\xi^{(j)})$ is the system response evaluated at collocation points $\xi^{(j)}$, $j = 1, \dots, n$. The basis functions $\ell^{(j)}(\xi)$ can be either local or global and either value based or gradient enhanced [1], but the most common option is the global Lagrange polynomial based on interpolation of values:

$$\ell^{(j)}(\xi) = \prod_{k=1, k \neq j}^n \frac{\xi - \xi^{(k)}}{\xi^{(j)} - \xi^{(k)}}. \quad (28.10)$$

The collocation points can be chosen for accuracy in interpolation (as indicated by the Lebesgue measure) or integration (as indicated by polynomial exactness). Here, we emphasize the latter and choose Gaussian quadrature nodes that correspond to the same orthogonal polynomial selections used for the polynomial chaos expansion. In the multivariate case, we start from a tensor-product formulation with the multi-index $\mathbf{i} = (i_1, \dots, i_d)$, $i_k = 0, 1, 2, \dots$:

$$\begin{aligned} R(\xi) &\approx \mathcal{U}_{\mathbf{i}}(R) \stackrel{\text{def}}{=} (\mathcal{U}_{i_1} \otimes \dots \otimes \mathcal{U}_{i_d})(R) \\ &= \sum_{j_1=1}^{n_1} \dots \sum_{j_d=1}^{n_d} R(\xi_1^{(j_1)}, \dots, \xi_d^{(j_d)}) \ell_1^{(j_1)}(\xi_1) \dots \ell_d^{(j_d)}(\xi_d). \end{aligned} \quad (28.11)$$

Statistics of the system response such as the mean and the variance of a tensor-product expansion can be obtained analytically as

$$\begin{aligned} \mu_R &= \langle R(\xi) \rangle \approx \sum_{j_1=1}^{n_1} \dots \sum_{j_d=1}^{n_d} R(\xi_1^{(j_1)}, \dots, \xi_d^{(j_d)}) \langle \ell_1^{(j_1)}(\xi_1) \dots \ell_d^{(j_d)}(\xi_d) \rangle \\ &= \sum_{j_1=1}^{n_1} \dots \sum_{j_d=1}^{n_d} R(\xi_1^{(j_1)}, \dots, \xi_d^{(j_d)}) w_1^{(j_1)} \dots w_d^{(j_d)} \\ &\stackrel{\text{def}}{=} \mathcal{Q}_{\mathbf{i}}(R) \end{aligned} \quad (28.12)$$

and

$$\begin{aligned}
\sigma_R^2 &= \left\langle R(\xi)^2 \right\rangle - \mu_R^2 \\
&\approx \sum_{j_1=1}^{n_1} \cdots \sum_{j_d=1}^{n_d} \sum_{k_1=1}^{n_1} \cdots \sum_{k_d=1}^{n_d} R\left(\xi_1^{(j_1)}, \dots, \xi_d^{(j_d)}\right) R\left(\xi_1^{(k_1)}, \dots, \xi_d^{(k_d)}\right) \\
&\quad \left\langle \ell_1^{(j_1)}(\xi_1) \dots \ell_d^{(j_d)}(\xi_d) \ell_1^{(k_1)}(\xi_1) \dots \ell_d^{(k_d)}(\xi_d) \right\rangle - \mu_R^2 \\
&= \sum_{j_1=1}^{n_1} \cdots \sum_{j_d=1}^{n_d} R^2\left(\xi_1^{(j_1)}, \dots, \xi_d^{(j_d)}\right) w_1^{(j_1)} \dots w_d^{(j_d)} - \mu_R^2 \\
&\stackrel{\text{def}}{=} \mathbf{Q}_i(R^2) - \mu_R^2,
\end{aligned} \tag{28.13}$$

where the expectation integrals of the basis polynomials use the property that $\ell^{(s)}(\xi^{(t)}) = \delta_{s,t}$, such that numerical quadrature of these integrals leaves only the quadrature weights w . Higher moments can be obtained analytically in a similar manner, and other statistics such as probabilities and quantiles can be estimated by sampling the expansion.

We can collapse these tensor-product sums by moving to a multivariate basis representation

$$R(\xi) \approx \sum_{j=1}^{N_{TP}} R(\xi^{(j)}) \mathbf{L}^{(j)}(\xi) \tag{28.14}$$

where N_{TP} is the number of tensor-product collocation points in the multidimensional grid and the multivariate interpolation polynomials are defined as

$$\mathbf{L}^{(j)}(\xi) = \prod_{k=1}^n \ell^{(c_k^j)}(\xi_k) \tag{28.15}$$

where c_k^j is a collocation multi-index (similar to the polynomial chaos multi-index in Eqs. 28.1–28.3). The corresponding moment expressions are then

$$\mu_R = \sum_{j=1}^{N_{TP}} R(\xi^{(j)}) \mathbf{w}^{(j)} \tag{28.16}$$

$$\sigma_R^2 = \sum_{j=1}^{N_{TP}} R^2(\xi^{(j)}) \mathbf{w}^{(j)} - \mu_R^2 \tag{28.17}$$

where the multivariate weight is

$$\mathbf{w}^{(j)} = \prod_{k=1}^n w^{(c_k^j)}. \tag{28.18}$$

A sparse interpolant and its moments are then formed from a linear combination of these tensor products, as described in the following section.

2.3 Sparse Grid Construction

If d is moderately large, then a sparse grid construction may be used to alleviate the exponential increase in the number of collocation points with respect to d . As employed in numerical integration [20, 21] and interpolation [7, 9], sparse grids are constructed from a linear combination of tensor-product grids with relatively small numbers of grid points in such a way that preserves a high level of accuracy.

2.3.1 Isotropic Sparse Grids

The isotropic sparse grid at level q where $q = 0, 1, 2, \dots$ is defined as

$$\mathcal{A}_{q,d}(R) = \sum_{q-d+1 \leq |\mathbf{i}| \leq q} (-1)^{q-|\mathbf{i}|} \binom{d-1}{q-|\mathbf{i}|} \mathcal{U}_{\mathbf{i}}(R), \quad (28.19)$$

where the tensor-product interpolation formulas $\mathcal{U}_{\mathbf{i}}(R)$, $\mathbf{i} = (i_1, \dots, i_d)$, $i_k = 0, 1, 2, \dots$ can be replaced by tensor-product quadrature formulas $\mathcal{Q}_{\mathbf{i}}(R)$ for the case of sparse grid integration. Alternatively, Eq. 28.19 may be expressed in terms of the difference formulas:

$$\mathcal{A}_{q,d}(R) = \sum_{|\mathbf{i}| \leq q} \Delta_{\mathbf{i}}(R), \quad (28.20)$$

where $\Delta_{\mathbf{i}}(R) = (\Delta_{i_1} \otimes \dots \otimes \Delta_{i_d})(R)$ and $\Delta_{i_k} = \mathcal{U}_{i_k} - \mathcal{U}_{i_k-1}$ with $\mathcal{U}_{-1} = 0$. Thus, the tensor-product grids used in the isotropic sparse grid construction are those whose multi-indices lie within a simplex defined by the sparse grid level q .

The relationship between the index i_k and the number of collocation points n_k in each dimension $k = 1, \dots, d$ is called the growth rule and is an important detail of the sparse grid construction. If the collocation points are chosen based on a fully nested quadrature rule, then a nonlinear growth rule that approximately doubles n_k with every increment in i_k (e.g., $n_k = 2^{i_k+1} - 1$ for open nested rules such as Gauss-Patterson) is used to augment existing model evaluations. If the collocation points are based on a weakly nested or non-nested quadrature rule, then a linear growth rule (e.g., $n_k = 2i_k + 1$) may alternatively be used to provide finer granularity in the order of the rule and associated degree of the polynomial basis.

2.3.2 Generalized Sparse Grids

The generalized sparse grid construction relaxes the simplex constraint on the multi-indices in Eq. 28.20 to provide flexibility for adaptive refinement. In the relaxed constraint, the set of multi-indices \mathcal{J} is admissible if $\mathbf{i} - \mathbf{e}_k \in \mathcal{J}$ for all $\mathbf{i} \in \mathcal{J}$, $i_k \geq 1$, $k = 1, \dots, d$, where \mathbf{e}_k is the k^{th} unit vector [21]. This admissibility criterion is depicted graphically in Fig. 28.2. In the left graphic, both children of the current

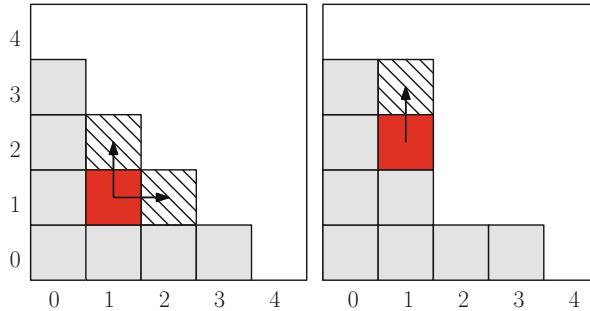

Fig. 28.2 Identification of the admissible forward neighbors for an index set (red). The indices of the reference basis are gray and admissible forward indices are hashed. An index set is admissible only if its backward neighbors exist in every dimension

index are admissible, because their backward neighbors exist in every dimension. In the right graphic only the child in the vertical dimension is admissible, as not all parents of the horizontal child exist.

Thus, admissible multi-indices can be added one by one starting from an initial reference grid, often the level 0 grid ($\mathbf{i} = \mathbf{0}$) corresponding to a single point in parameter space. The refinement process is governed by a greedy algorithm, where each admissible index set is evaluated for promotion into the reference grid based on a refinement metric. The best index set is selected for promotion and used to generate additional admissible index sets, and the process is continued until convergence criteria are satisfied. The resulting generalized sparse grid is then defined from

$$\mathcal{A}_{\mathcal{J},d}(R) = \sum_{\mathbf{i} \in \mathcal{J}} \Delta_{\mathbf{i}}(R). \quad (28.21)$$

2.3.3 Sparse Projection

When forming a polynomial chaos expansion from isotropic, anisotropic, or generalized sparse grids, the expansion terms should be composed from a sum of tensor expansions, where the coefficients for each tensor expansion should be computed from the corresponding tensor-product quadrature rule that is defined from each term in the sparse grid summation (e.g., Eq. 28.19). This integrate-then-combine approach avoids numerical noise in the coefficients of higher-order terms [11].

2.3.4 Sparse Interpolation

For computing moments, the tensor-product mean and variance definitions in Eqs. 28.12–28.13 can be extended to estimate the mean and variance of the sparse grid interpolant using a linear combination of $\mathcal{Q}_{\mathbf{i}}(R)$ or $\mathcal{Q}_{\mathbf{i}}(R^2)$, respectively, at multi-indices \mathbf{i} corresponding to the sparse grid construction. The result can be collapsed to the form of Eqs. 28.16–28.17 (with N_{TP} replaced with the number

of unique points in the sparse grid, N_{SG}), where the weights $w^{(j)}$ are now the sparse weights defined by the linear combination of all tensor-product weights applied to the same collocation point $\xi^{(j)}$. Note that while each tensor-product expansion interpolates the system responses at the collocation points, the sparse grid expansion will not interpolate in general unless a nested set of collocation points is used [7]. Another important detail in the non-nested case is that the summations in Eqs. 28.16–28.17 correspond to sparse numerical integration of R and R^2 , differing slightly from expectations of the sparse interpolant and its square.

Hierarchical interpolation on nested grids [2, 31] is particularly useful in an adaptive refinement setting, where we are interested in measuring small increments in statistical QoI due to small increments (e.g., candidate index sets in generalized sparse grids) in the sparse grid definition. By reformulating using hierarchical interpolants, we mitigate the loss of precision due to subtractive cancelation. In hierarchical sparse grids, the Δ_i in Eqs. 28.20 and 28.21 are tensor products of the one-dimensional difference interpolants defined over the increment in collocation points:

$$\Delta_i(R) = \sum_{j_1=1}^{n_{\Delta_1}} \cdots \sum_{j_d=1}^{n_{\Delta_d}} s \left(\xi_{j_1}^{\Delta_1}, \dots, \xi_{j_d}^{\Delta_d} \right) \left(L_{j_1}^{\Delta_1} \otimes \cdots \otimes L_{j_d}^{\Delta_d} \right) \quad (28.22)$$

where s are the hierarchical surpluses computed from the difference between the newly added response value and the value predicted by the previous interpolant level. Hierarchical increments in expected value are formed simply from the expected value of the new Δ_i contributions induced by a refinement increment (a single Δ_i for each candidate index set in the case of generalized sparse grids). Hierarchical increments in a variety of other statistical QoI may also be derived in a manner that preserves precision [1], starting from increments in response mean μ and covariance Σ :

$$\Delta\mu_i = \Delta\mathbb{E}[R_i] \quad (28.23)$$

$$\Delta\Sigma_{ij} = \Delta\mathbb{E}[R_i R_j] - \mu_i \Delta\mathbb{E}[R_j] - \mu_j \Delta\mathbb{E}[R_i] - \Delta\mathbb{E}[R_i] \Delta\mathbb{E}[R_j] \quad (28.24)$$

where $\Delta\mathbb{E}[\cdot]$ denotes a hierarchical increment in expected value, involving summation of hierarchical surpluses combined with the quadrature weights across the collocation point increments.

2.4 Compressed Sensing

PCE may also be constructed through regression by solving the following $N \times M$ linear system of equations over an *unstructured* set of ξ_j :

$$\begin{bmatrix} \psi_1(\xi_1) & \psi_2(\xi_1) & \dots & \psi_M(\xi_1) \\ \psi_1(\xi_2) & \psi_2(\xi_2) & \dots & \psi_M(\xi_2) \\ \vdots & \vdots & \ddots & \vdots \\ \psi_1(\xi_N) & \psi_2(\xi_N) & \dots & \psi_M(\xi_N) \end{bmatrix} \begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \vdots \\ \alpha_M \end{bmatrix} = \Psi\alpha = \mathbf{R} = \begin{bmatrix} R_1 \\ R_2 \\ \vdots \\ R_N \end{bmatrix}. \quad (28.25)$$

This system may be over-, under-, or uniquely determined, based on the number of candidate basis terms M and the number of response QoI observations N . We are particularly interested in the under-determined case $N \ll M$, for which the problem is ill-posed and a regularization is required to enforce solution uniqueness. One approach is to apply the pseudo-inverse of Ψ , which returns the solution with minimum 2-norm $\|\alpha\|_{\ell_2}$. However, if the solution is sparse (many terms are zero) or compressible (many terms are small due to rapid solution decay), then an effective alternative is to seek the solution with the minimum number of terms. This sparse solution is the minimum zero-norm solution

$$\alpha = \arg \min \|\alpha\|_{\ell_0} \quad \text{such that} \quad \|\Psi\alpha - \mathbf{R}\|_{\ell_2} \leq \varepsilon, \quad (28.26)$$

which can be solved using the orthogonal matching pursuit (OMP), a greedy heuristic algorithm that iteratively constructs the solution vector term by term. Other approaches such as basis pursuit denoising (BPDN) compute a sparse solution using the minimum one norm

$$\alpha = \arg \min \|\alpha\|_{\ell_1} \quad \text{such that} \quad \|\Psi\alpha - \mathbf{R}\|_{\ell_2} \leq \varepsilon, \quad (28.27)$$

which allows for computational efficiency within optimization-based approaches by replacing expensive combinatorial optimization with continuous optimization. In both cases, the noise parameter ε can be tuned through cross-validation to avoid overfitting the observations \mathbf{R} .

3 Multifidelity Extensions

Let $R_{\text{high}}(\xi)$ be the system response obtained by evaluating the expensive high-fidelity model and $R_{\text{low}}(\xi)$ be the system response obtained by evaluating the inexpensive low-fidelity model. In a multifidelity stochastic expansion, the low-fidelity model values are corrected to match the high-fidelity model values (and potentially their derivatives) at the high-fidelity collocation points.

3.1 Corrected Low-Fidelity Model

We investigate additive correction, multiplicative correction, and combined additive and multiplicative correction for the low-fidelity model. Defining the additive correction function and multiplicative correction function as

$$\delta_A(\xi) = R_{\text{high}}(\xi) - R_{\text{low}}(\xi) \quad (28.28)$$

and

$$\delta_M(\xi) = \frac{R_{\text{high}}(\xi)}{R_{\text{low}}(\xi)}, \quad (28.29)$$

respectively, then

$$R_{\text{high}}(\xi) = R_{\text{low}}(\xi) + \delta_A(\xi) \quad (28.30)$$

or

$$R_{\text{high}}(\xi) = R_{\text{low}}(\xi)\delta_M(\xi). \quad (28.31)$$

In the case of a combined correction

$$R_{\text{high}}(\xi) = \gamma(R_{\text{low}}(\xi) + \delta_A(\xi)) + (1 - \gamma)R_{\text{low}}(\xi)\delta_M(\xi), \quad (28.32)$$

the parameter $\gamma \in [0, 1]$ defines a convex combination that determines the proportion of additive correction or multiplicative correction employed in the combined correction. γ provides a tuning parameter that can be optimized to prevent overfitting. One approach is to employ cross-validation to select from among preselected γ values, as described previously for the compressed sensing noise tolerance ε in Eqs. 28.26–28.27. Another option is to compute γ based on a regularization of the combined correction function by minimizing the magnitude of the additive and multiplicative correction in the mean-square sense

$$\min_{\gamma \in [0,1]} \left\langle \gamma^2 \delta_A^2(\xi) + (1 - \gamma)^2 \delta_M^2(\xi) \right\rangle. \quad (28.33)$$

This gives the solution

$$\gamma = \frac{\langle \delta_M^2(\xi) \rangle}{\langle \delta_A^2(\xi) \rangle + \langle \delta_M^2(\xi) \rangle}, \quad (28.34)$$

where the second moments of the $\delta_A(\xi)$ and $\delta_M(\xi)$ can be estimated analytically from their stochastic expansions as described in Eqs. 28.7–28.8 and Eqs. 28.16–

28.17. This choice of γ balances the additive correction and the multiplicative correction such that neither becomes too “large.”

3.2 Sparse Grids with Predefined Offset

Let $S_{q,d}[R]$ be the stochastic expansion (non-intrusive polynomial chaos or stochastic collocation) of $R(\xi)$ at sparse grid level q with dimension d . We add the superscript “pc” or “sc” when we refer specifically to non-intrusive polynomial chaos or stochastic collocation, respectively. Also, let $N_{q,d}$ be the number of model evaluations required to construct $S_{q,d}[R]$. Thus, $R_{\text{high}}(\xi) \approx S_{q,d}[R_{\text{high}}](\xi)$. We further approximate the stochastic expansion of the high-fidelity model with $S_{q,d}[R_{\text{high}}](\xi) \approx \tilde{R}_{\text{high}}(\xi)$, where $\tilde{R}_{\text{high}}(\xi)$ is the multifidelity stochastic expansion based on the additive, multiplicative, or combined correction of the low-fidelity model

$$\tilde{R}_{\text{high}} = S_{q,d}[R_{\text{low}}] + S_{q-r,d}[\delta_A], \quad (28.35)$$

$$\tilde{R}_{\text{high}} = S_{q,d}[R_{\text{low}}]S_{q-r,d}[\delta_M], \quad (28.36)$$

$$\tilde{R}_{\text{high}} = \gamma(S_{q,d}[R_{\text{low}}] + S_{q-r,d}[\delta_A]) + (1 - \gamma)S_{q,d}[R_{\text{low}}]S_{q-r,d}[\delta_M], \quad (28.37)$$

respectively, where r is a sparse grid level offset between the stochastic expansion of the low-fidelity model and the stochastic expansion of the correction function and $r \leq q$. Thus, the multifidelity stochastic expansion at sparse grid level q can be constructed with $N_{q-r,d}$ instead of $N_{q,d}$ high-fidelity model evaluations plus $N_{q,d}$ low-fidelity model evaluations. If the low-fidelity model is significantly less expensive to evaluate than the high-fidelity model, then significant computational savings will be obtained. Furthermore, if the low-fidelity model is sufficiently predictive, then accuracy comparable to the single-fidelity expansion with $N_{q,d}$ high-fidelity model evaluations can be achieved. This notion of a predetermined sparse grid level offset enforces computational savings explicitly, with less regard to managing the accuracy in $\tilde{R}_{\text{high}}(\xi)$. In the case of adaptive refinement, to be discussed in the following section, we instead manage the accuracy explicitly by investing resources where they are most needed for resolving statistics of $\tilde{R}_{\text{high}}(\xi)$ and the computational savings that result are achieved indirectly.

3.3 Adaptive Sparse Grids

The goal of an adaptive refinement procedure applied to multifidelity modeling should be to preferentially refine where the model discrepancy has the greatest complexity. This corresponds to regions of the stochastic domain where the low-fidelity model becomes less predictive. It is often the case in real-world applications that

low-fidelity models may be predictive for significant portions of a parameter space, but, in other portions of the space, the simplifying assumptions break down and a higher-fidelity model must be relied upon. By selectively targeting these regions, we rely more on the low-fidelity model where it is effective and more faithfully resolve the discrepancy where it is not. Thus, adaptive refinement procedures can extend the utility of multifidelity uncertainty quantification approaches in cases where the predictive capability of low-fidelity models is strongly parameter dependent.

For adaptive refinement in a multifidelity context, we will employ a greedy adaptation based on the generalized sparse grid procedure described with Eq. 28.21. One option is to separately adapt the low-fidelity and discrepancy models for accuracy in their individual statistics; however, this performs the refinements in isolation from one another, which may result in a non-optimal allocation of resources. Rather, we prefer to assess the effects of the individual candidate refinements within the aggregated multifidelity context, i.e., their effect on the high-fidelity statistical QoIs such as variance or failure probability. To accomplish this, we present a further generalization to generalized sparse grids in which we consider candidate index sets from multiple sparse grids simultaneously and measure their effects within the aggregated context using appropriate cost normalization. The algorithmic steps can be summarized as:

1. *Initialization:* Starting from an initial reference sparse grid (e.g., level $q = 0$) for the lowest-fidelity model and each level of model discrepancy within a multifidelity hierarchy, aggregate active index sets from each grid using the admissible forward neighbors of all reference index sets.
2. *Trial set evaluation:* For each trial active index set, perform the tensor grid evaluations for the corresponding low-fidelity or discrepancy model, form the tensor polynomial chaos expansion or tensor interpolant corresponding to the grid, combine the trial expansion with the reference expansion for the particular level in the multifidelity hierarchy to which it corresponds (update $S_{\mathcal{J}_{low,d}}[R_{low}]$, $S_{\mathcal{J}_A,d}[\delta_A]$, or $S_{\mathcal{J}_M,d}[\delta_M]$), and then combine each of the levels to generate a trial high-fidelity expansion (\tilde{R}_{high}). Note that index sets associated with discrepancy expansions require evaluation of two levels of fidelity, so caching and reuse of the lowest and all intermediate fidelity evaluations should be performed among the different sparse grids. Bookkeeping should also be performed to allow efficient restoration of previously evaluated tensor expansions, as they will remain active until either selected or processed in the finalization step.
3. *Trial set selection:* From among all of the candidates, select the trial index set that induces the largest change in the high-fidelity statistical QoI, normalized by the cost of evaluating the trial index set (as indicated by the number of new collocation points and the relative model run time(s) per point). Initial estimates of relative simulation cost among the different fidelities (which we will denote as the ratio ρ_{work}) are thus required to appropriately bias the adaptation. To exploit greater coarse-grained parallelism or to achieve load balancing targets, multiple index sets may be selected, resulting in additional trial sets to evaluate on the following cycle. When multiple QoIs exist, trial sets may be rank-ordered using

a norm of QoI increments, or multiple sets could be selected that are each the best for at least one QoI (a non-dominated Pareto set).

4. *Update sets:* If the largest change induced by the active trial sets exceeds a specified convergence tolerance, then promote the selected trial set(s) from the active set to the reference set and update the active set with new admissible forward neighbors; return to step 2 and evaluate all active trial sets with respect to the new reference grid. If the convergence tolerance is satisfied, advance to step 5. An important algorithm detail for this step involves recursive set updating. In one approach, the selection of a discrepancy set could trigger the promotion of that set for both the discrepancy grid and the grid level(s) below it, in support of the notion that the grid refinements should be strictly hierarchical and support a spectrum from less to more resolved. Alternatively, one could let the sparse grid at each level evolve without constraint and ensure only the caching and reuse of evaluations among related levels. In this work, we employ the latter approach, as we wish to preserve the ability to under-resolve levels that are not providing predictive utility.
5. *Finalization:* Promote all remaining active sets to the reference set, update all expansions within the hierarchy, and perform a final combination of the low-fidelity and discrepancy expansions to arrive at the final result for the high-fidelity statistical QoI.

Figure 28.3 depicts a multifidelity sparse grid adaptation in process, for which the low-fidelity grid has three active index sets under evaluation and the discrepancy grid has four. These seven candidates are evaluated for influence on the statistical QoI(s), normalized by relative cost, in step 2 above. It is important to emphasize that all trial set evaluations (step 2) involve sets of actual model evaluations. That is, this algorithm does not identify the best candidates based on any a priori estimation; rather, the algorithm incrementally constructs sparse grids based on greedy selection of the best evaluated candidates in an a posteriori setting, followed by subsequent augmentation with new index sets that are the children of the selected index sets. In the end, the multi-index frontiers for the sparse grids have been advanced only in the regions with the greatest influence on the QoI, and all of the model evaluations (including index sets that were evaluated but never selected) contribute to the final answer, based on step 5.

In the limiting case where the low-fidelity model provides little useful information, this algorithm will prefer refinements to the model discrepancy and will closely mirror the single-fidelity case, with the penalty of carrying along the low-fidelity evaluations needed to resolve the discrepancy. This suggests an additional adaptive control, in which one drops low (and intermediate)-fidelity models from the hierarchy that are adding expense but not adding value (as measured by their frequency of selection in step 3). In addition, this general framework can be extended to include pointwise local refinement [28] (for handling nonsmoothness) as well as adjoint-enhanced approaches [1, 17] (for improving scalability with respect to random input dimension).

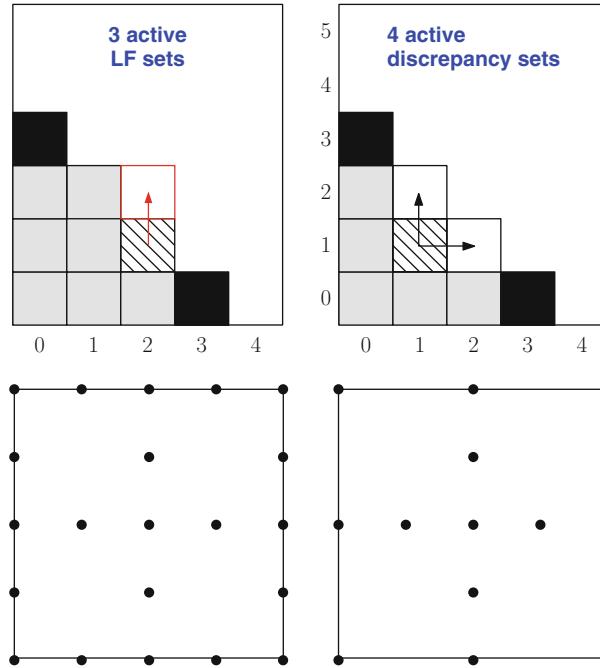

Fig. 28.3 Multifidelity generalized sparse grid with reference index sets in gray (existing) and hashed (newly promoted) and active index sets in black (existing) and white (newly created). Newton-Cotes grid points associated with the reference index sets are shown at bottom

3.4 Compressed Sensing

In the case of compressed sensing, we control the relative refinement of the low-fidelity model and the discrepancy model via the number of points within each sample set. We define a ratio $\rho_{\text{points}} = \frac{m_{\text{low}}}{m_{\text{high}}} \geq 1$, where the high-fidelity points must be contained within the low-fidelity point set to support the definition of the model discrepancy at these points.

We now revisit our surrogate high-fidelity expansions produced from additive, multiplicative, or combined correction to the low-fidelity model. Replacing our previous sparse grid operator $S_{q,d}[\cdot]$ in Eqs. 28.35–28.37 with a compressed sensing operator, we obtain

$$\tilde{R}_{\text{high}} = CS_{m_{\text{low}}, p^*, \varepsilon^*, d}[R_{\text{low}}] + CS_{m_{\text{high}}, p^*, \varepsilon^*, d}[\delta_A], \quad (28.38)$$

$$\tilde{R}_{\text{high}} = CS_{m_{\text{low}}, p^*, \varepsilon^*, d}[R_{\text{low}}]CS_{m_{\text{high}}, p^*, \varepsilon^*, d}[\delta_M], \quad (28.39)$$

$$\tilde{R}_{\text{high}} = \gamma(CS_{m_{\text{low}}, p^*, \varepsilon^*, d}[R_{\text{low}}] + CS_{m_{\text{high}}, p^*, \varepsilon^*, d}[\delta_A]) + (1 - \gamma)$$

$$CS_{m_{\text{low}}, p^*, \varepsilon^*, d}[R_{\text{low}}]CS_{m_{\text{high}}, p^*, \varepsilon^*, d}[\delta_M], \quad (28.40)$$

where $CS[.]$ is dependent on sample size m , total-order p of candidate basis, noise tolerance ε , and dimension d . We employ cross-validation separately for the low-fidelity model and each discrepancy in order to select the best p and ε for each of these sparse recoveries, as denoted by p^* and ε^* above.

3.5 Analytic Moments

In order to compute the moments of the multifidelity stochastic expansion analytically, we collapse the sum or product of the expansion of the low-fidelity model and the expansion of the discrepancy function into a single expansion and then employ the standard moment calculation techniques from Eqs. 28.7–28.8 and Eqs. 28.16–28.17.

3.5.1 Moments of Multifidelity PCE with Additive Discrepancy

This is most straightforward for polynomial chaos expansions with additive discrepancy, and we will start with this case using a predefined sparse grid offset. Let $\mathcal{J}_{q,d}$ be the set of multi-indices of the d -dimensional polynomial chaos expansion bases at sparse grid level q . Then,

$$S_{q,d}^{\text{pc}}[R_{\text{low}}](\xi) = \sum_{\mathbf{i} \in \mathcal{J}_{q,d}} \alpha_{\text{low}\mathbf{i}} \Psi_{\mathbf{i}}(\xi) \quad (28.41)$$

and

$$S_{q-r,d}^{\text{pc}}[\delta_A](\xi) = \sum_{\mathbf{i} \in \mathcal{J}_{q-r,d}} \alpha_{\delta_A \mathbf{i}} \Psi_{\mathbf{i}}(\xi). \quad (28.42)$$

Since the $\mathcal{J}_{q-r,d} \subset \mathcal{J}_{q,d}$, the bases $\Psi_{\mathbf{i}}(\xi)$, $\mathbf{i} \in \mathcal{J}_{q-r,d}$ are common between $S_{q,d}^{\text{pc}}[R_{\text{low}}]$ and $S_{q-r,d}^{\text{pc}}[\delta_A]$. Therefore, the chaos coefficients of those bases can be added to produce a single polynomial chaos expansion

$$S_{q,d}^{\text{pc}}[R_{\text{low}}](\xi) + S_{q-r,d}^{\text{pc}}[\delta_A](\xi) = \sum_{\mathbf{i} \in \mathcal{J}_{q-r,d}} (\alpha_{\text{low}\mathbf{i}} + \alpha_{\delta_A \mathbf{i}}) \Psi_{\mathbf{i}}(\xi) + \sum_{\mathbf{i} \in \mathcal{J}_{q,d} \setminus \mathcal{J}_{q-r,d}} \alpha_{\text{low}\mathbf{i}} \Psi_{\mathbf{i}}(\xi). \quad (28.43)$$

The mean and the variance can be computed directly from this multifidelity expansion by simply collecting terms for each basis and applying Eqs. 28.7 and 28.8:

$$\mu_R \approx \alpha_{\text{low}\mathbf{0}} + \alpha_{\delta_A \mathbf{0}} \quad (28.44)$$

$$\sigma_R^2 \approx \sum_{\mathbf{i} \in \mathcal{J}_{q-r,d} \setminus \mathbf{0}} (\alpha_{\text{low}\mathbf{i}} + \alpha_{\delta_A \mathbf{i}})^2 \langle \Psi_{\mathbf{i}}^2(\xi) \rangle + \sum_{\mathbf{i} \in \mathcal{J}_{q,d} \setminus \mathcal{J}_{q-r,d}} \alpha_{\text{low}\mathbf{i}}^2 \langle \Psi_{\mathbf{i}}^2(\xi) \rangle. \quad (28.45)$$

In the adaptive sparse grid and compressed sensing cases, the primary difference is the loss of a strict subset relationship between the discrepancy and low-fidelity multi-indices, which we will represent in generalized form as \mathcal{J}_{δ_A} and \mathcal{J}_{low} , respectively. We introduce a new multi-index for the set intersection $\mathcal{J}_I = \mathcal{J}_{\delta_A} \cap \mathcal{J}_{\text{low}}$. Eq. 28.44 remains the same, as all approaches retain the $\mathbf{0}$ term, but Eq. 28.45 becomes generalized as follows:

$$\sigma_R^2 \approx \sum_{\mathbf{i} \in \mathcal{J}_I \setminus \mathbf{0}} (\alpha_{\text{low}\mathbf{i}} + \alpha_{\delta_A \mathbf{i}})^2 \langle \Psi_{\mathbf{i}}^2(\xi) \rangle + \sum_{\mathbf{i} \in \mathcal{J}_{\text{low}} \setminus \mathcal{J}_I} \alpha_{\text{low}\mathbf{i}}^2 \langle \Psi_{\mathbf{i}}^2(\xi) \rangle + \sum_{\mathbf{i} \in \mathcal{J}_{\delta_A} \setminus \mathcal{J}_I} \alpha_{\delta_A \mathbf{i}}^2 \langle \Psi_{\mathbf{i}}^2(\xi) \rangle. \quad (28.46)$$

3.5.2 Moments of Multifidelity PCE with Multiplicative Discrepancy

In the multiplicative discrepancy case for non-intrusive polynomial chaos, we again combine the low-fidelity and discrepancy expansions and then compute the moments from the aggregated expansion. Multiplication of chaos expansions is a kernel operation within stochastic Galerkin methods. The coefficients of a product expansion are computed as follows (shown generically for $z = xy$ where x , y , and z are each expansions of arbitrary form):

$$\sum_{k=0}^{P_z} z_k \Psi_k(\xi) = \sum_{i=0}^{P_x} \sum_{j=0}^{P_y} x_i y_j \Psi_i(\xi) \Psi_j(\xi) \quad (28.47)$$

$$z_k = \frac{\sum_{i=0}^{P_x} \sum_{j=0}^{P_y} x_i y_j \langle \Psi_i \Psi_j \Psi_k \rangle}{\langle \Psi_k^2 \rangle} \quad (28.48)$$

where three-dimensional tensors of one-dimensional basis triple products $\langle \psi_i \psi_j \psi_k \rangle$ are typically sparse and can be efficiently precomputed using one-dimensional quadrature for fast lookup within the multidimensional basis triple products $\langle \Psi_i \Psi_j \Psi_k \rangle$. The form of the high-fidelity expansion (enumerated by P_z in Eq. 28.47) must first be defined to include all polynomial orders indicated by the products of each of the basis polynomials in the low-fidelity and discrepancy expansions, in order to avoid any artificial truncation in the product expansion. These are readily estimated from total-order, tensor, or sum of tensor expansions since they involve simple polynomial order additions for each tensor or total-order expansion product.

3.5.3 Moments of Multifidelity SC

Evaluating the moments for stochastic collocation with either additive or multiplicative discrepancy involves forming a new interpolant on the more refined (low-fidelity) grid. Therefore, we perform an additional step to create a single stochastic expansion

$$S_{q,d}^{\text{sc}} \left\{ S_{q,d}^{\text{sc}} [R_{\text{low}}] + S_{q-r,d}^{\text{sc}} [\delta_A] \right\} \quad (28.49)$$

$$S_{q,d}^{\text{sc}} \left\{ S_{q,d}^{\text{sc}} [R_{\text{low}}] S_{q-r,d}^{\text{sc}} [\delta_M] \right\} \quad (28.50)$$

from which the variance and higher moments can be obtained analytically. This requires evaluating $S_{q,d}^{\text{sc}}[R_{\text{low}}]$ and either $S_{q-r,d}^{\text{sc}}[\delta_A]$ or $S_{q-r,d}^{\text{sc}}[\delta_M]$ at the collocation points associated with the multi-indices in $\mathcal{J}_{q,d}$. For the former, the low-fidelity model values at all of the collocation points are readily available and can be used directly. For the latter, the discrepancy expansion $S_{q-r,d}^{\text{sc}}[\delta_A]$ or $S_{q-r,d}^{\text{sc}}[\delta_M]$ must be evaluated. Since the discrepancy function values are available at collocation points associated with the multi-indices of $\mathcal{J}_{q-r,d}$, it may be tempting to only evaluate $S_{q-r,d}^{\text{sc}}[\delta_A]$ or $S_{q-r,d}^{\text{sc}}[\delta_M]$ at collocation points associated with the multi-indices in $\mathcal{J}_{q,d} \setminus \mathcal{J}_{q-r,d}$. However, because sparse grid stochastic collocation does not interpolate unless the set of collocation points are nested [7], the function values from δ_A and δ_M and from $S_{q-r,d}^{\text{sc}}[\delta_A]$ and $S_{q-r,d}^{\text{sc}}[\delta_M]$ should not be mixed together when they are not consistent.

To generalize to adaptive sparse grid cases that could lack the strict subset relationship $\mathcal{J}_{q-r,d} \subset \mathcal{J}_{q,d}$ provided by a predefined level offset, we introduce a multi-index union \mathcal{J}_U and form a new interpolant on the union grid:

$$S_U^{\text{sc}} \{ S_{\text{low}}^{\text{sc}}[R_{\text{low}}] + S_{\delta_A}^{\text{sc}}[\delta_A] \} \quad \text{for } \mathcal{J}_U = \mathcal{J}_{\text{low}} \cup \mathcal{J}_{\delta_A} \quad (28.51)$$

$$S_U^{\text{sc}} \{ S_{\text{low}}^{\text{sc}}[R_{\text{low}}] S_{\delta_M}^{\text{sc}}[\delta_M] \} \quad \text{for } \mathcal{J}_U = \mathcal{J}_{\text{low}} \cup \mathcal{J}_{\delta_M}. \quad (28.52)$$

Similar to the predefined offset case, the new interpolant is formed by evaluating $S_{\text{low}}^{\text{sc}}[R_{\text{low}}]$, $S_{\delta_A}^{\text{sc}}[\delta_A]$, and/or $S_{\delta_M}^{\text{sc}}[\delta_M]$ at the collocations points associated with the multi-indices in \mathcal{J}_U and computing the necessary sum or product.

4 Computational Results

We compare the performance of multifidelity stochastic expansion and single-fidelity stochastic expansion for several algebraic and PDE models of increasing complexity. We demonstrate cases for which the multifidelity stochastic expansion converges more quickly than the single-fidelity stochastic expansion as well as cases for which the multifidelity stochastic expansion offers little to no efficiency gain.

4.1 Simple One-Dimensional Example

First, we present a simple example to motivate the approach and demonstrate the efficiency improvements that are possible when an accurate low-fidelity model is available. The system responses of the high-fidelity model and the low-fidelity model are, respectively,

$$R_{\text{high}}(\xi) = e^{-0.05\xi^2} \cos 0.5\xi - 0.5e^{-0.02(\xi-5)^2}$$

$$R_{\text{low}}(\xi) = e^{-0.05\xi^2} \cos 0.5\xi,$$

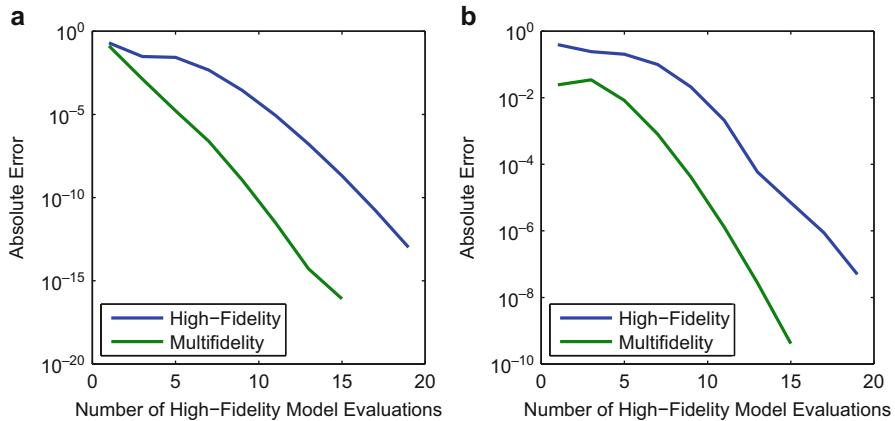

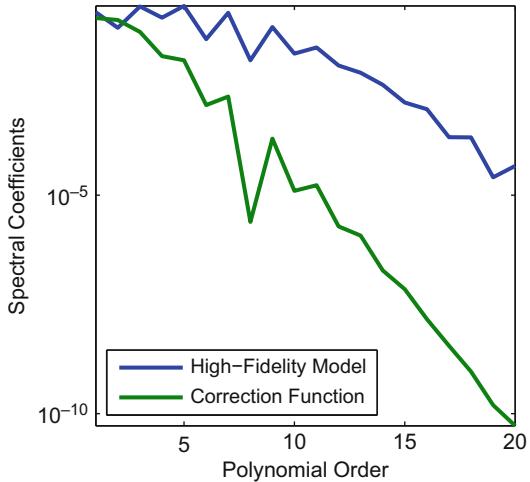

Fig. 28.4 Convergence of single-fidelity PCE and multifidelity PCE with additive discrepancy for the one-dimensional example. (a) Error in mean. (b) Error in standard deviation (From *Multifidelity Uncertainty Quantification Using Non-Intrusive Polynomial Chaos and Stochastic Collocation*, by Ng and Eldred, 2012, AIAA-2012-1852, published in the Proceedings of the 53rd SDM conference; reprinted by permission of the American Institute of Aeronautics and Astronautics, Inc.)

where $\xi \sim \text{Uniform}[-8, 12]$. An additive discrepancy $\delta_\alpha(\xi) = R_{\text{high}}(\xi) - R_{\text{low}}(\xi)$ is used, which is just the second term of $R_{\text{high}}(\xi)$. In Fig. 28.4, we compare the convergence in mean and standard deviation of the single (high)-fidelity PCE with the convergence of the multifidelity PCE. The multifidelity PCE is constructed from a PCE of the discrepancy function at order 1 to 20 combined with a PCE of the low-fidelity model at order 60 (for which the low-fidelity statistics are converged to machine precision). This corresponds to a case where low-fidelity expense can be considered to be negligible, and by eliminating any issues related to low-fidelity accuracy, we can focus more directly on comparing the convergence of the discrepancy function with convergence of the high-fidelity model (in the next example, we will advance to grid level offsets that accommodate nontrivial low-fidelity expense). The error is plotted against the number of high-fidelity model evaluations and is measured with respect to an overkill single-fidelity PCE solution at order 60. It is evident that the multifidelity stochastic expansion converges much more rapidly because the additive discrepancy function in the example has lower complexity than the high-fidelity model. This can be seen from comparison of the decay of the normalized spectral coefficients as plotted in Fig. 28.5, which shows that the discrepancy expansion decays more rapidly allowing the statistics of the discrepancy expansion to achieve a given accuracy using fewer PCE terms than that required by the high-fidelity model.

4.2 Short Column Example

The short column example [32] demonstrates a higher-dimensional algebraic problem involving multifidelity models. For this example, we will employ predefined

Fig. 28.5 Normalized spectral coefficients of the high-fidelity model and the additive discrepancy function for the one-dimensional example (From *Multifidelity Uncertainty Quantification Using Non-Intrusive Polynomial Chaos and Stochastic Collocation*, by Ng and Eldred, 2012, AIAA-2012-1852, published in the Proceedings of the 53rd SDM conference; reprinted by permission of the American Institute of Aeronautics and Astronautics, Inc.)

sparse grid level offsets between low fidelity and high fidelity, which are more appropriate for cases where the low-fidelity model expense is non-negligible. Let the system response of the high-fidelity model be

$$R_{\text{high}}(\xi) = 1 - \frac{4M}{bh^2Y} - \left(\frac{P}{bhY} \right)^2, \quad (28.53)$$

where $\xi = (b, h, P, M, Y)$, $b \sim \text{Uniform}(5, 15)$, $h \sim \text{Uniform}(15, 25)$, $P \sim \text{Normal}(500, 100)$, $M \sim \text{Normal}(2000, 400)$, and $Y \sim \text{Lognormal}(5, 0.5)$ and we neglect the traditional correlation between P and M for simplicity. We consider three artificially constructed low-fidelity models of varying predictive quality, which yield additive discrepancy forms of varying complexity:

$$R_{\text{low1}}(\xi) = 1 - \frac{4P}{bh^2Y} - \left(\frac{P}{bhY} \right)^2, \quad \delta_{A1}(\xi) = \frac{4(P - M)}{bh^2Y}, \quad (28.54)$$

$$R_{\text{low2}}(\xi) = 1 - \frac{4M}{bh^2Y} - \left(\frac{M}{bhY} \right)^2, \quad \delta_{A2}(\xi) = \frac{M^2 - P^2}{(bhY)^2}, \quad (28.55)$$

$$R_{\text{low3}}(\xi) = 1 - \frac{4M}{bh^2Y} - \left(\frac{P}{bhY} \right)^2 - \frac{4(P - M)}{bhY}, \quad \delta_{A3}(\xi) = \frac{4(P - M)}{bhY}. \quad (28.56)$$

4.2.1 Isotropic Sparse Grids

In Fig. 28.6, PCE with isotropic sparse grids is used, and the offset r in the sparse grid level between the low-fidelity model and the discrepancy function is fixed at one. It can be seen that the multifidelity case using $R_{\text{low}1}(\xi)$ results in a reduction in the number of high-fidelity model evaluations required for a given error compared to the single-fidelity case using $R_{\text{high}}(\xi)$. For example, at 10^{-5} error, the number of high-fidelity model evaluations is reduced from about 500 to about 100. While still a rational function with broad spectral content, the discrepancy function, $\delta_{A1}(\xi)$, is similar to the middle term in Eq. 28.53 and has eliminated the final term possessing the greatest nonlinearity. Conversely, the discrepancy function for the second low-fidelity model, $\delta_{A2}(\xi)$, is similar to the final term in Eq. 28.53 and has expanded it to include an additional dimension, resulting in a larger number of high-fidelity model evaluations for a given error compared to the single-fidelity case. For the third low-fidelity model, the convergence rate is faster than the single-fidelity case but the starting error is also larger, resulting in a break-even point at about 11 high-fidelity model evaluations. This suggests that while a less complex discrepancy results in more rapid convergence, it is also important to consider the magnitude and resulting variance of the discrepancy function.

We modify $R_{\text{low}3}(\xi)$ by changing the scalar in the last term from 4 to 0.4 and label it $R_{\text{low}4}(\xi)$. Similarly, we also change the scalar in the last term from 4 to 40 and label it $R_{\text{low}5}(\xi)$. Thus, the discrepancy functions $\delta_{A3}(\xi)$, $\delta_{A4}(\xi)$, and $\delta_{A5}(\xi)$ have the same smoothness and spectral content, but the magnitude of the discrepancy is an order of magnitude smaller for $\delta_{A4}(\xi)$ and an order of magnitude larger for $\delta_{A5}(\xi)$. As plotted in Fig. 28.7, the means have similar convergence rates, but a smaller discrepancy results in lower error.

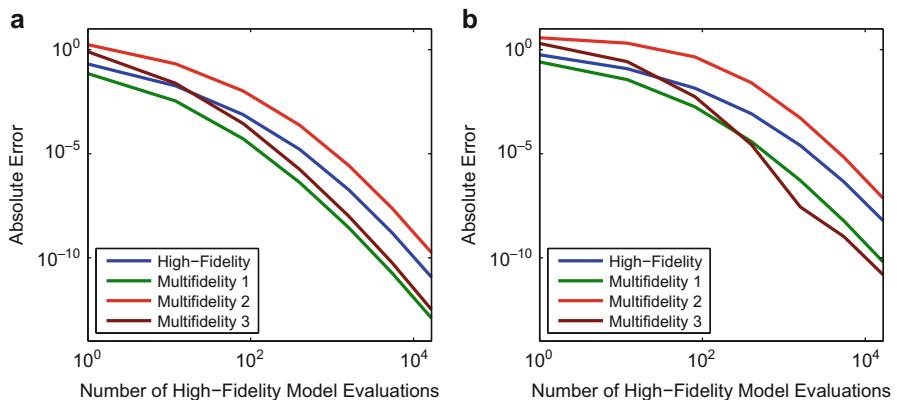

Fig. 28.6 Convergence of single-fidelity and multifidelity PCE with isotropic sparse grids and additive discrepancy for the short column example. The multifidelity sparse grid level offset $r = 1$. **(a)** Error in mean. **(b)** Error in standard deviation

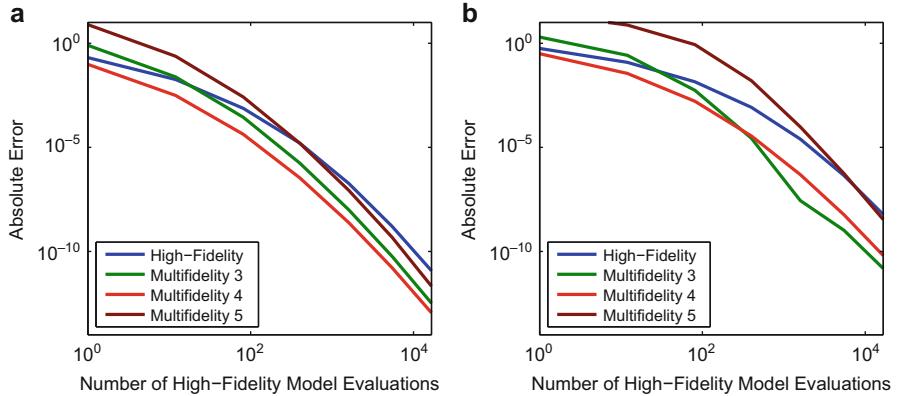

Fig. 28.7 Convergence of single-fidelity PCE and multifidelity PCE with isotropic sparse grids and additive discrepancy for the short column example. The multifidelity sparse grid level offset $r = 1$. (a) Error in mean. (b) Error in standard deviation (From *Multifidelity Uncertainty Quantification Using Non-Intrusive Polynomial Chaos and Stochastic Collocation*, by Ng and Eldred, 2012, AIAA-2012-1852, published in the Proceedings of the 53rd SDM conference; reprinted by permission of the American Institute of Aeronautics and Astronautics, Inc.)

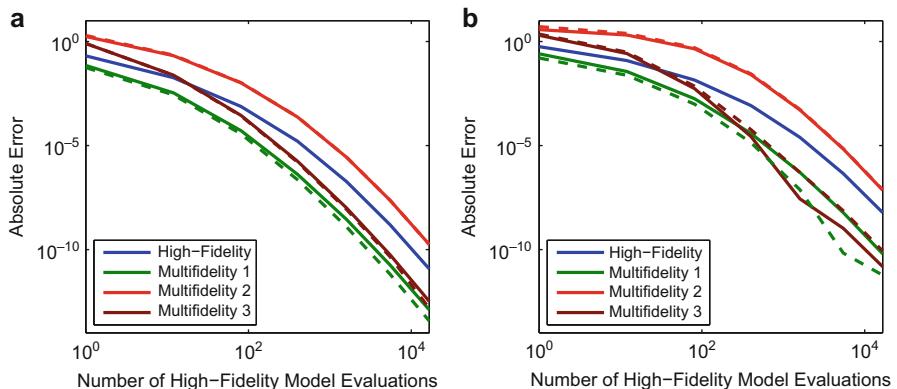

Fig. 28.8 Convergence of single-fidelity PCE and multifidelity PCE with isotropic sparse grids and additive discrepancy for the short column example. The multifidelity sparse grid level offset is compared using $r = 1$ from Fig. 28.6 (solid lines) and $r = 2$ (dashed lines). (a) Error in mean. (b) Error in standard deviation (From *Multifidelity Uncertainty Quantification Using Non-Intrusive Polynomial Chaos and Stochastic Collocation*, by Ng and Eldred, 2012, AIAA-2012-1852, published in the Proceedings of the 53rd SDM conference; reprinted by permission of the American Institute of Aeronautics and Astronautics, Inc.)

Finally, we investigate the effect of the sparse grid level offset r . Figure 28.8 is the same as Fig. 28.6 but with r increased from one to two, resulting in greater resolution in the low-fidelity expansion for a particular discrepancy expansion resolution. The results from Fig. 28.6 are included as solid lines, and the new results with $r = 2$ are shown as dashed lines. A small improvement can be seen

in the mean convergence for multifidelity using $R_{\text{low}1}(\xi)$ and $R_{\text{low}3}(\xi)$ and for standard deviation convergence using $R_{\text{low}1}(\xi)$, but results are mixed and it is unclear whether the benefit of increasing the offset is worth the additional low-fidelity evaluations, especially in the case where their expense is nontrivial. Thus, it appears that an automated procedure will be needed to optimize these offsets accounting for relative cost. This motivates the multifidelity adaptive sparse grid algorithm described previously (Fig. 28.3).

4.2.2 Compressed Sensing

In Fig. 28.9, we compare the results of applying compressed sensing (CS) for resolving the low-fidelity and discrepancy expansions, using the OMP algorithm for solving Eq. 28.26 in combination with cross-validation for candidate basis order p and noise tolerance ε . The reference sparse grid results are for a level offset $r = 1$ and are consistent with those from Fig. 28.6. For CS, we employ a sampling ratio $\rho_{\text{points}} = 10$ between the low- and high-fidelity sample sets, and since these samples are randomly generated, we average the results of 10 runs for the reported errors. Monte Carlo results are provided as another reference point and are also averaged over 10 runs. The relative low-fidelity expense will differ when using a predefined sparse grid level offset r and a fixed CS sample ratio ρ_{points} due to the nonlinear growth in sparse grid size. Therefore, we introduce the cost of the low-fidelity model by selecting a representative cost ratio $\rho_{\text{work}} = 10$ and plot convergence against the number of equivalent high-fidelity evaluations, which is defined as $m_{\text{eqv}} = m_{\text{high}} + m_{\text{low}}/\rho_{\text{work}}$. We observe similar trends with CS as for sparse grids: multifidelity CS is an improvement over single-fidelity CS for $R_{\text{low}1}$ but not for $R_{\text{low}2}$, and multifidelity CS becomes more competitive for higher resolution levels in $R_{\text{low}3}$. It is also evident that neither the single-fidelity nor the multifidelity CS approaches outperform their sparse grid counterparts for this problem. This implies that the spectra of coefficients in these artificially constructed discrepancy models (Eqs. 28.54–28.56) are dense and relatively low order.

4.3 Elliptic PDE Example

Next, we consider the stochastic PDE in one spatial dimension

$$-\frac{d}{dx} \left[\kappa(x, \omega) \frac{du(x, \omega)}{dx} \right] = 1, \quad x \in (0, 1), \quad u(0, \omega) = u(1, \omega) = 0.$$

with coefficient κ described by the following 10-dimensional Karhunen-Loëve expansion

$$\kappa(x, \omega) = 0.1 + 0.03 \sum_{k=1}^{10} \sqrt{\lambda_k} \phi_k(x) Y_k(\omega), \quad Y_k \sim \text{Uniform}(-1, 1)$$

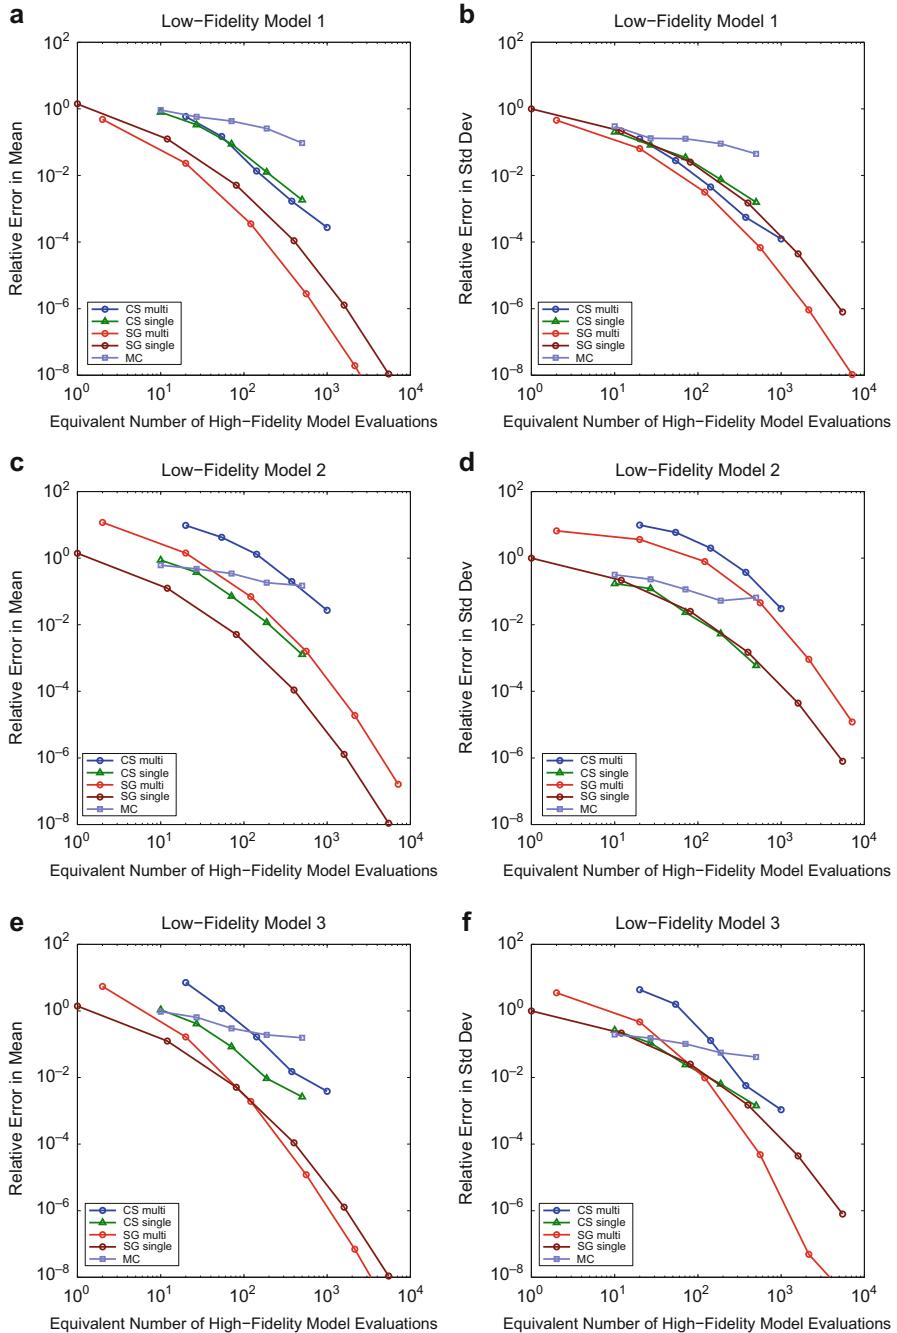

**Fig. 28.9** (continued)

Table 28.2 Comparison of the relative error and the number of model evaluations for the elliptic PDE example

	Relative error in mean	Relative error in std deviation	High fidelity evaluations	Low fidelity evaluations
Single fidelity ($q = 3$)	5.3×10^{-6}	2.7×10^{-4}	1981	—
Single fidelity ($q = 4$)	4.1×10^{-7}	2.3×10^{-5}	12,981	—
Multifidelity ($q = 4, r = 1$)	4.7×10^{-7}	2.6×10^{-5}	1981	12,981

From *Multifidelity Uncertainty Quantification Using Non-Intrusive Polynomial Chaos and Stochastic Collocation*, by Ng and Eldred, 2012, AIAA-2012-1852, published in the Proceedings of the 53rd SDM conference; reprinted by permission of the American Institute of Aeronautics and Astronautics, Inc.

for the Gaussian covariance kernel

$$C_{kk}(x, x') = \exp \left[-\left(\frac{x - x'}{0.2} \right)^2 \right].$$

The PDE is solved by finite elements and the output of interest is $u(0.5, \omega)$. We use a fine spatial grid with 500 states for the high-fidelity model and a coarse spatial grid with 50 states for the low-fidelity model. The ratio of average run time between the high-fidelity model and the low-fidelity model is $\rho_{\text{work}} = 40$.

4.3.1 Sparse Grids

We compute the mean and standard deviation using multifidelity PCE with sparse grid level 4 applied to the low-fidelity model and sparse grid level 3 applied to the additive correction function (i.e., sparse grid level offset $r = 1$). Table 28.2 compares the relative error of this multifidelity approach with single-fidelity PCE of the high-fidelity model at sparse grid levels 3 and 4. It can be seen that the multifidelity PCE is able to achieve an order of magnitude lower error than the single-fidelity PCE at sparse grid level 3 while using the same number of high-fidelity evaluations. The cost of low-fidelity evaluations is equivalent to about 325 additional high-fidelity evaluations, resulting in greater than an 80% reduction in total cost for comparable accuracy to the single-fidelity PCE result at sparse grid level 4.

Fig. 28.9 Convergence of single-fidelity and multifidelity PCE comparing compressed sensing with isotropic sparse grids for the short column example for R_{low1} , R_{low2} , and R_{low3} . Discrepancy is additive, multifidelity sparse grid level offset is $r = 1$, $\rho_{\text{work}} = 10$, and $\rho_{\text{points}} = 10$. (a) Error in mean for R_{low1} . (b) Error in standard deviation for R_{low1} . (c) Error in mean for R_{low2} . (d) Error in standard deviation for R_{low2} . (e) Error in mean for R_{low3} . (f) Error in standard deviation for R_{low3}

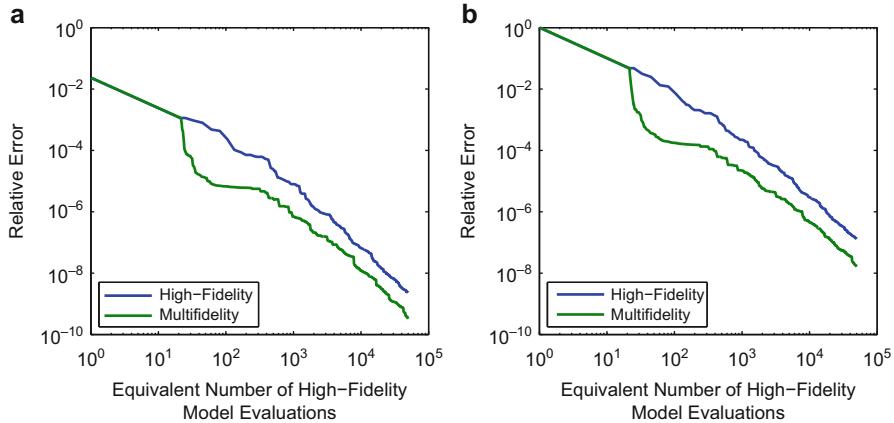

Fig. 28.10 Convergence of single-fidelity and multifidelity PCE with additive discrepancy using adaptive sparse grids for the elliptic PDE example. **(a)** Error in mean. **(b)** Error in standard deviation (From *Multifidelity Uncertainty Quantification Using Non-Intrusive Polynomial Chaos and Stochastic Collocation*, by Ng and Eldred, 2012, AIAA-2012-1852, published in the Proceedings of the 53rd SDM conference; reprinted by permission of the American Institute of Aeronautics and Astronautics, Inc.)

Figure 28.10 shows the convergence for the single-fidelity and multifidelity PCE with additive discrepancy based on adaptive refinement using generalized sparse grids. The single-fidelity case uses the standard generalized sparse grid procedure [21], whereas the multifidelity case uses the multifidelity adaptive sparse grid algorithm depicted in Fig. 28.3. The initial grid for both the low-fidelity model and the correction function is a level one sparse grid (requiring 11 model evaluations). We use the equivalent number of high-fidelity model evaluations (m_{eqv}) to include the additional cost of low-fidelity model evaluations in the comparison with the single-fidelity case. By considering the potential error reduction per unit cost of refining the sparse grid of the discrepancy versus that of refining the sparse grid of the low-fidelity model, the multifidelity adaptive algorithm is able to achieve a faster convergence than the single-fidelity adaptive generalized sparse grid. For achieving error levels consistent with the non-adapted multifidelity approach in Table 28.2, the adaptive multifidelity algorithm reduces the equivalent number of high-fidelity evaluations by 33% for the mean and by 62% for the standard deviation.

4.3.2 Compressed Sensing

Figure 28.11 compares the convergence in standard deviation for multifidelity compressed sensing with different point ratios ρ_{points} against single-fidelity compressed sensing, non-adaptive single-fidelity sparse grids, non-adaptive multifidelity sparse grids using level offset $r = 1$, and Monte Carlo sampling. As for the short column example, convergence plots for Monte Carlo sampling and CS are averaged over 10

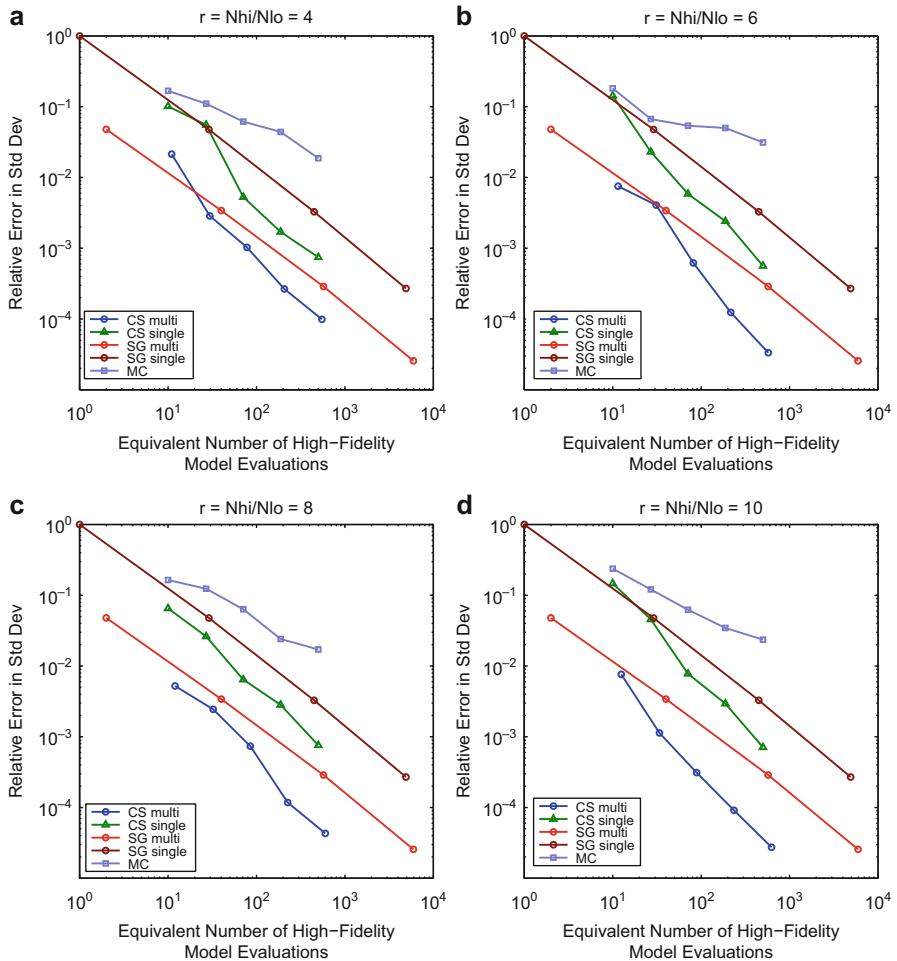

Fig. 28.11 Convergence of standard deviation in elliptic PDE problem using multifidelity compressed sensing with different ρ_{points} ratios. (a) $\rho_{\text{points}} = 4$. (b) $\rho_{\text{points}} = 6$. (c) $\rho_{\text{points}} = 8$. (d) $\rho_{\text{points}} = 10$

runs, and CS employs the OMP solver in combination with cross-validation to select the total-order polynomial degree p of the candidate basis and the noise tolerance ε . It is evident that CS-based approaches perform better for this problem than the sparse grid approaches, and the benefit of multifidelity CS over single-fidelity CS is comparable to that of multifidelity sparse grids over single-fidelity sparse grids. Finally, increasing ρ_{points} is advantageous for this problem, implying strong predictivity in the low-fidelity model and allowing for lower relative investment in resolving the discrepancy.

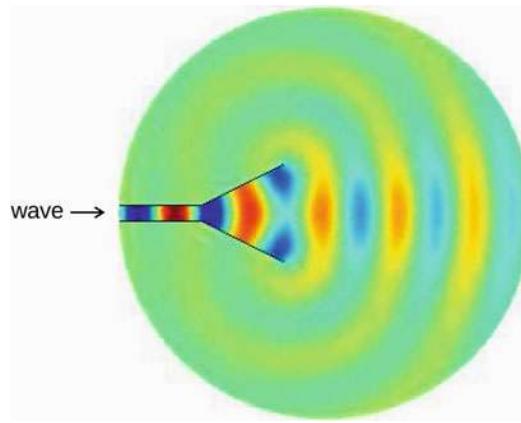

Fig. 28.12 2D horn geometry and the propagation of acoustic waves (From *Multifidelity Uncertainty Quantification Using Non-Intrusive Polynomial Chaos and Stochastic Collocation*, by Ng and Eldred, 2012, AIAA-2012-1852, published in the Proceedings of the 53rd SDM conference; reprinted by permission of the American Institute of Aeronautics and Astronautics, Inc.)

4.4 Horn Acoustics Example

We model the propagation of acoustic waves through a two-dimensional horn with the non-dimensional Helmholtz equation $\nabla^2 u + k^2 u = 0$ for wave number k . The incoming wave enters the waveguide and exits the flare of the horn into the exterior domain with a truncated absorbing boundary [14]. The horn geometry is illustrated in Fig. 28.12. The stochastic parameters are the wave number $k \sim \text{Uniform}(1.3, 1.5)$, upper horn wall impedance $z_u \sim \text{Normal}(50, 9)$, and lower horn wall impedance $z_l \sim \text{Normal}(50, 9)$, where the latter two represent imperfections in the horn wall. We compute the mean and standard deviation of the reflection coefficient, where a low reflection coefficient is desired for an efficient horn. The high-fidelity model solves the Helmholtz equation by finite elements using 35895 states, and the low-fidelity model is a reduced- basis model constructed from the finite-element discretization [40] using 50 bases. The ratio of average run time between the high-fidelity model and the low-fidelity model is $\rho_{\text{work}} = 40$.

4.4.1 Adaptive Sparse Grids

Figure 28.13 compares the convergence between single-fidelity and multifidelity PCE with an additive discrepancy based on adaptive refinement with generalized sparse grids. For this problem, the multifidelity adaptive sparse grid approach offers little discernable improvement over a single-fidelity adaptive sparse grid, with at best a slight reduction in standard deviation error at low resolution levels. The reduced-basis model (i.e., the low-fidelity model) interpolates the finite-element model at the 50 snapshots used to generated the bases, but despite its accuracy (the maximum discrepancy between the reduced-basis model and the finite-element

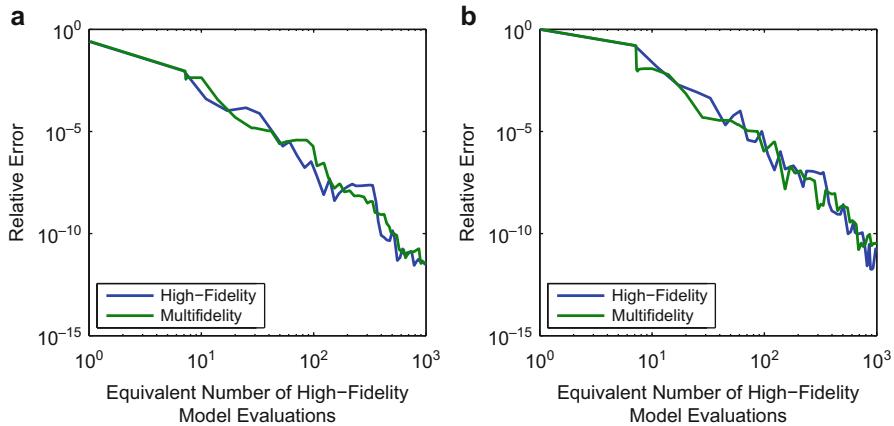

Fig. 28.13 Convergence of single-fidelity PCE and multifidelity PCE with additive correction using adaptive generalized sparse grids for the acoustic horn example. (a) Error in mean. (b) Error in standard deviation (From *Multifidelity Uncertainty Quantification Using Non-Intrusive Polynomial Chaos and Stochastic Collocation*, by Ng and Eldred, 2012, AIAA-2012-1852, published in the Proceedings of the 53rd SDM conference; reprinted by permission of the American Institute of Aeronautics and Astronautics, Inc.)

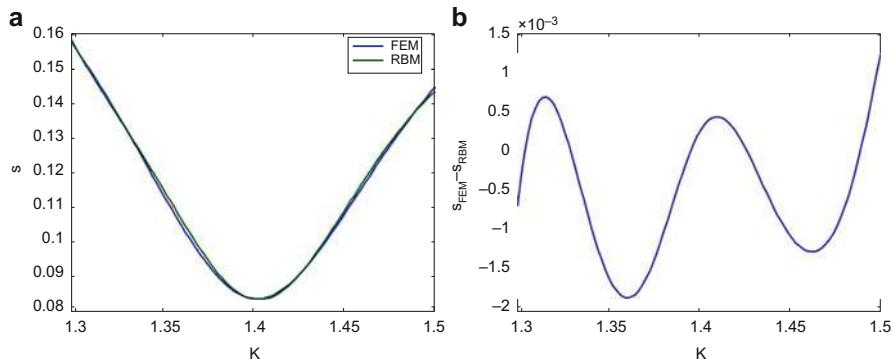

Fig. 28.14 Comparison of finite-element model (FEM) and reduced-basis model (RBM) results for the acoustic horn example. (a) Comparison of low- and high-fidelity QoI. (b) Model discrepancy

model is about 2%), its interpolatory nature results in oscillations that require a higher-order PCE expansion to resolve (Fig. 28.14). In addition, reduced-order modeling approaches based on projection of a truncated basis will in general tend to retain dominant lower-order effects and omit higher-order behavior. This highlights the primary weakness of a multifidelity sparse grid approach; it must step through lower grid levels to reach higher grid levels, such that a multifidelity sparse grid approach has difficulty benefiting from a low-fidelity model that only predicts low-order effects. The presence of similar high-order content within the discrepancy

and high-fidelity models then results in similar high-fidelity resolution requirements for the single-fidelity and multifidelity approaches. This is precisely the case that motivates methods that can utilize sparse recovery to more efficiently resolve high-order discrepancy terms.

4.4.2 Compressed Sensing

Figure 28.15 compares the convergence in standard deviation for multifidelity CS with different point ratios ρ_{points} against single-fidelity CS, non-adaptive single-fidelity sparse grids, non-adaptive multifidelity sparse grids using level offset $r = 1$,

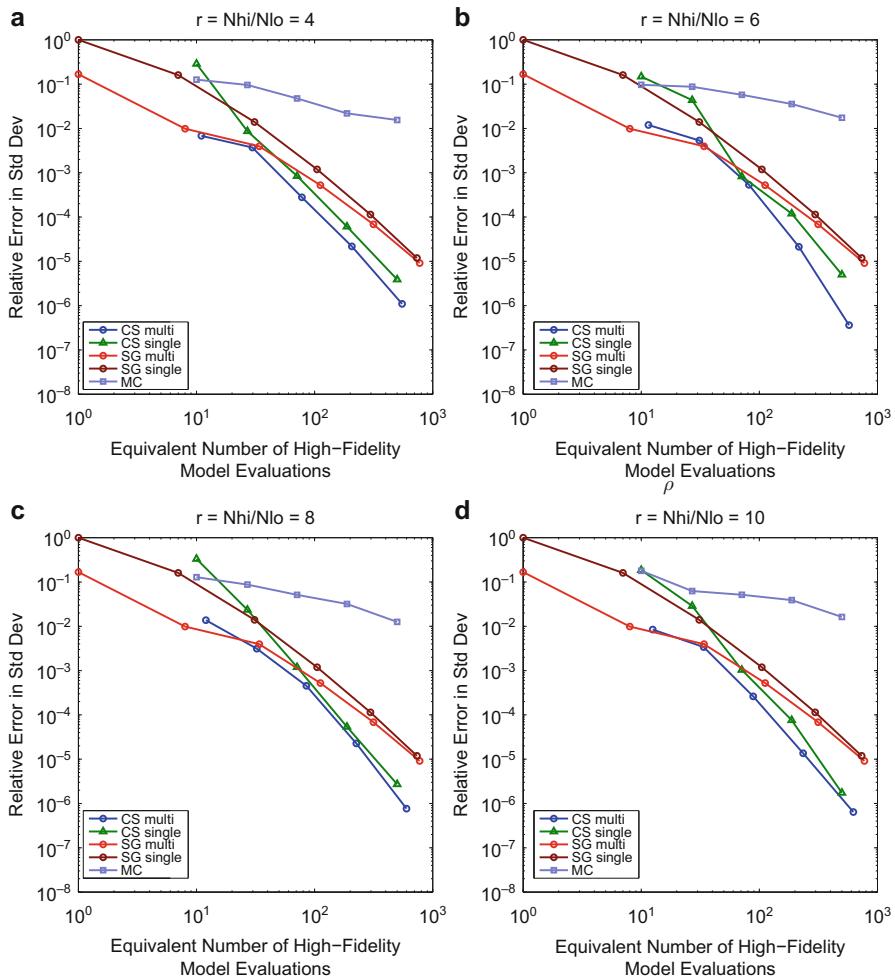

Fig. 28.15 Convergence of standard deviation in horn problem using multifidelity compressed sensing with different ρ_{points} values. (a) $\rho_{\text{points}} = 4$ (b) $\rho_{\text{points}} = 6$. (c) $\rho_{\text{points}} = 8$. (d) $\rho_{\text{points}} = 10$

and Monte Carlo sampling. As for previous examples, convergence plots for Monte Carlo sampling and CS are averaged over 10 runs, and CS employs the OMP solver in combination with cross-validation to select the total-order polynomial degree p of the candidate basis and the noise tolerance ε . For the non-adapted sparse grid approaches, the multifidelity PCE shows a small improvement relative to the single-fidelity approach, although the amount of improvement decreases with resolution level (similar to the adapted sparse grid result in Fig. 28.13b). For the CS approaches, more rapid convergence overall is evident than for the sparse grid approaches, indicating sparsity or compressibility in the coefficient spectrum. The multifidelity CS approaches show modest improvements relative to the single-fidelity approaches, with the greatest separation corresponding to $\rho_{\text{points}} = 6$. Comparing this observation to the elliptic PDE problem where the highest point ratios performed best, one could infer that solutions for the horn problem require greater reliance on the high-fidelity model for resolving the high-order discrepancy effects.

Figure 28.16 plots the spectrum of expansion coefficients α_i comparing single-fidelity with multifidelity CS for different point ratios ρ_{points} . The single-fidelity PCE coefficients recovered from $m = 200$ samples are compared to the multifidelity PCE coefficients using the same 200 high-fidelity samples in combination with 800, 1200, 1600, and 2000 low-fidelity samples for $\rho_{\text{points}} = 4, 6, 8$, and 10, respectively. These cases are plotted against reference single-fidelity cases for which 800, 1200, 1600, and 2000 samples are performed solely on the high-fidelity model. All CS solutions employ cross-validation to select the most accurate candidate basis order p and noise tolerance ε . It is evident that all cases are in agreement with respect to capturing the dominant terms with the largest coefficient magnitude (terms greater than approximately 10^{-5}). Differences manifest for the smaller coefficients, with the more resolved single-fidelity reference solutions (blue) recovering many additional terms relative to the 200-sample single-fidelity solutions (green), with some relative inaccuracy apparent in the smallest terms for the latter. Augmenting the 200 high-fidelity samples with low-fidelity simulations allows the multifidelity approach (red) to more effectively approximate these less-dominant terms, effectively extending the recovered spectrum to a level similar to that of the high-fidelity reference solution.

4.5 Production Engineering Example: Vertical-Axis Wind Turbine

Wind turbine reliability plays a critical role in the long-term prospects for cost-effective wind-based energy generation. The computational assessment of failure probability or life expectancy of turbine components is fundamentally hindered by the presence of large uncertainties in the environmental conditions, the blade structure, and in the form of turbulence closure models that are used to simulate complex flow. Rigorous quantification of the impact of such uncertainties can fundamentally improve the state of the art in computational predictions and, as a result, aid in the design of more cost-effective devices.

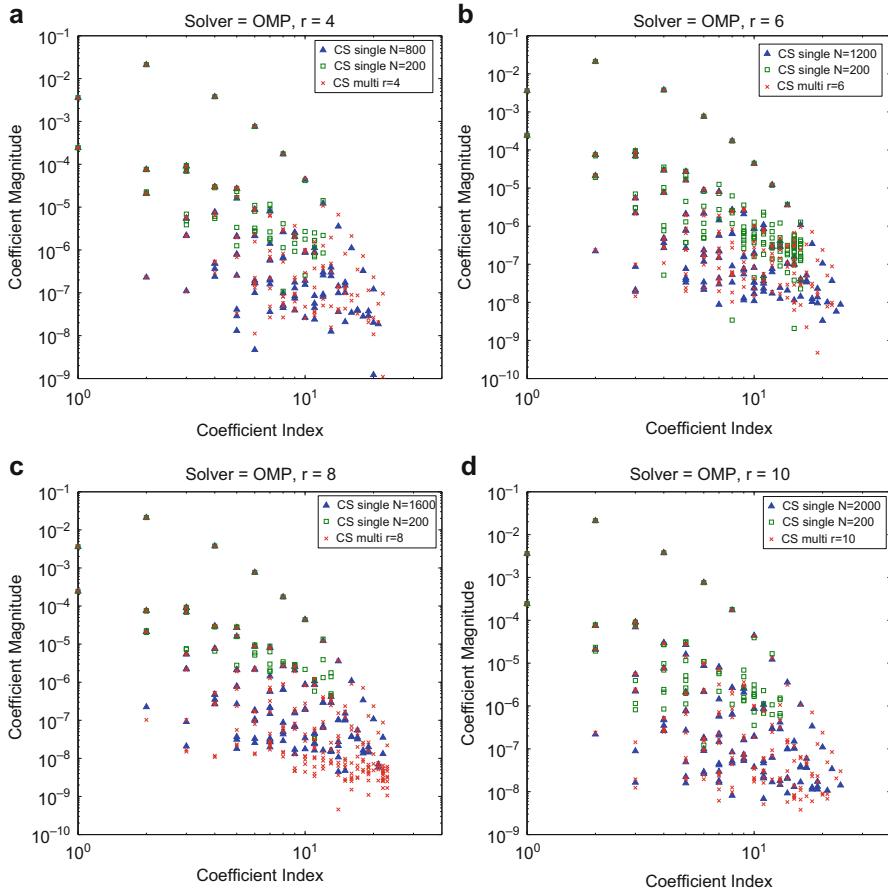

Fig. 28.16 Coefficient spectrum for horn problem using multifidelity compressed sensing with different ρ_{points} values. (a) $\rho_{\text{points}} = 4$. (b) $\rho_{\text{points}} = 6$. (c) $\rho_{\text{points}} = 8$. (d) $\rho_{\text{points}} = 10$

4.5.1 Simulation Tools

An aerodynamic model for a horizontal-axis wind turbine is necessarily three-dimensional, since it is comprised of two or three blades rotating about an axis parallel to the oncoming wind. A vertical-axis wind turbine (VAWT), where the axis of rotation is normal to the wind vector (Fig. 28.17a), allows for a meaningful two-dimensional analysis of one cross section of the rotor. This makes the VAWT a useful bridging problem for investigation of UQ methods employing high-fidelity simulation, since methods can be developed and verified using 2D problems before extension to 3D. In the current context, the 2D analysis of a VAWT subject to uncertain gust phenomena provides our final production-level demonstration of multifidelity UQ methods.

Our low-fidelity model is CACTUS (Code for Axial and Crossflow TURbine Simulation) [34]. CACTUS is a three-dimensional potential flow code developed

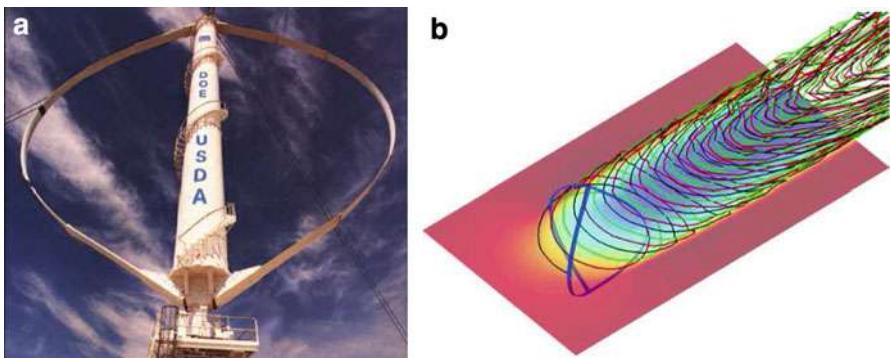

Fig. 28.17 Vertical-axis wind turbine test bed and two-dimensional CACTUS simulation. (a) VAWT test bed. (b) CACTUS simulation

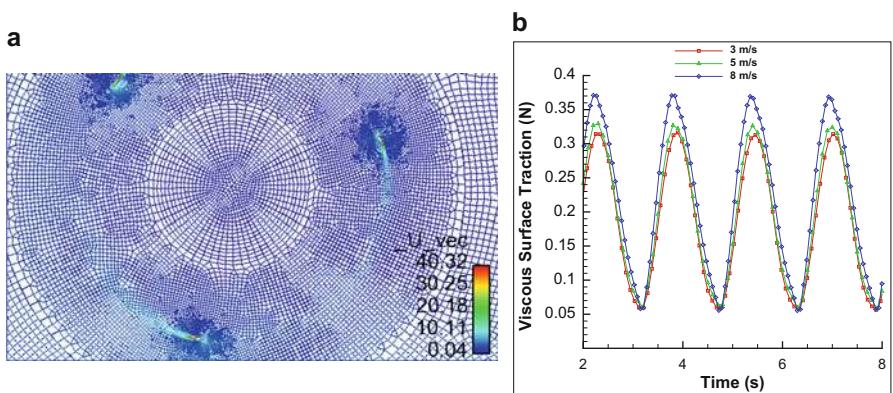

Fig. 28.18 VAWT geometry and leading edge viscous surface traction for three crosswind velocities. (a) Mesh geometry. (b) Integrated viscous surface traction

at Sandia that uses a lifting line/free-vortex formulation to generate predictions of rotor performance and unsteady blade loads (Fig. 28.17b).

Our high-fidelity model is Conchas, which is the module for low-Mach aerodynamics within the SIERRA thermal-fluids code suite. High-fidelity simulations for wind energy applications inherently involve the requirement to solve the turbulent form of the low-Mach Navier-Stokes equation set. The underlying mesh should be adequate to resolve the boundary layers on the blades within the context of a rotating blade scenario. The core methodology involves the use of sliding mesh boundaries between the inner VAWT mesh and the outer free stream mesh. The sliding mesh algorithm combines the control-volume finite-element method at interior domains with a discontinuous Galerkin (DG) implementation at the nonconformal mesh interface [13]. The low-Mach numerical scheme uses equal-order interpolation and a monolithic flow solver using explicit pressure stabilization. Figure 28.18

shows a sample simulation for a VAWT geometry of interest where the cross wind magnitude was varied in a fixed tip speed configuration of 40 m/s. Three different crosswinds were used, 3, 5, and 8 m/s, from which the integrated surface traction was computed (Fig. 28.18b). The mesh outlining the three blade configuration is shown in Fig. 28.18a.

This two-level hierarchy has extreme separation in cost. CACTUS executions for two-dimensional VAWT simulations are fast, typically requiring a few minutes of execution time on a single core of a workstation. Conchas simulations, on the other hand, require approximately 72 h on 48 cores for simulation with 2M finite elements, such that these simulations are strongly resource constrained. For this case, ρ_{work} is approximately 10^5 .

4.5.2 Quantities of Interest

In this final multifidelity UQ example, we focus on the prediction of various statistics for VAWT loads due to an uncertain gust. This has proven to be a challenging problem for PCE approximation using global basis polynomials due to the presence of nonsmooth QoI variations. Figure 28.19 shows an example of this behavior with CACTUS simulations where we overlay a set of centered one-dimensional parameter studies to provide a partial view of a three-dimensional parameter space. It is evident that the variations of these two response QoI are strongly multimodal with multiple slope discontinuities, due to the maximum response changing in space and/or time. In order to partially mitigate this nonsmoothness, we migrated to integrated metrics in subsequent studies.

To facilitate two-dimensional LES simulation of incompressible disturbances with Conchas, the uncertain gust for the multifidelity problem is modeled using

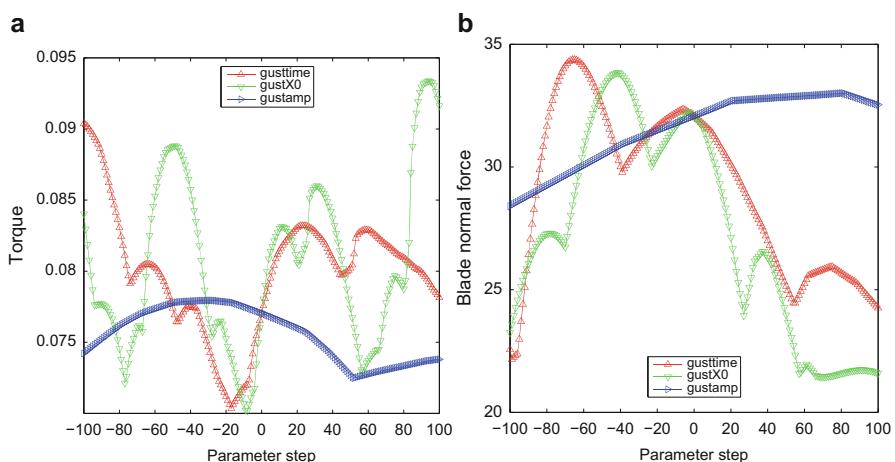

Fig. 28.19 Centered 1D parameter studies for initial formulation using the low-fidelity model. Maximum torque and maximum blade normal force are computed as functions of gust phasing, location, and amplitude. **(a)** Maximum torque. **(b)** Maximum blade normal force

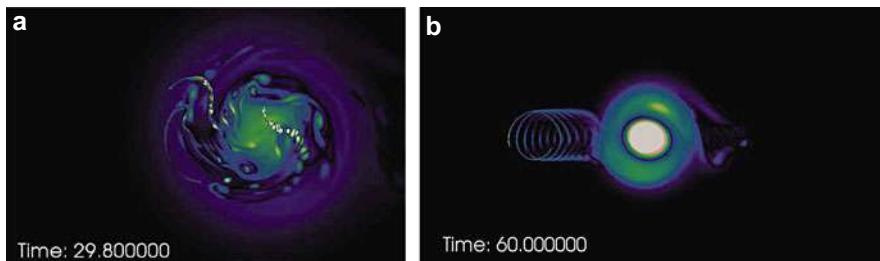

Fig. 28.20 Conchas simulation of a synthetic gust (inviscid Taylor Vortex) passing through a VAWT. (a) Closeup of vortex/rotor interaction. (b) Vortex passing downstream

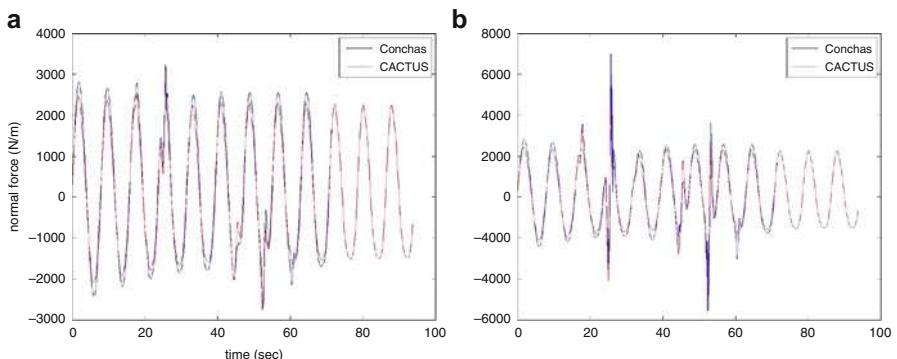

Fig. 28.21 Comparison of CACTUS and Conchas time histories for small and large gust amplitudes. (a) Small gust (amplitude = 5). (b) Large gust (amplitude = 20)

an inviscid Taylor vortex, as shown in Fig. 28.20. The random variables have been slightly modified from those in Fig. 28.19 to describe the vortex radius measured in rotor radii, the lateral position of the vortex in rotor radii, and the amplitude of the vortex. These three random variables are modeled using bounded normal ($\mu = 0.25, \sigma = 0.05, l = 0.0, u = 1.5$), uniform ($l = -1.5, u = 1.5$), and Gumbel ($\alpha = 7.106, \beta = 1.532$) probability distributions, respectively. Figure 28.21 overlays CACTUS and Conchas results for the time histories of blade normal force for two different values of vortex amplitude, where it is evident that there is qualitative agreement between the time histories. The details of flow separation for the large gust have important differences, as expected for the different physics models. Figure 28.22 displays a centered parameter study for the integrated impulse for blade normal force plotted against variations in the vortex radius, lateral position, and amplitude parameters. While the obvious discontinuities have been tamed by the migration to integrated metrics, the response quantity remains a complex function of its parameters.

4.5.3 Multifidelity Sparse Grid Results

For our numerical experiments, we evaluate the low-fidelity model with an isotropic sparse grid fixed at level 5 (1099 CACTUS simulations executing on a single core), and we evaluate the high-fidelity model at resolution up to level 2 (up to 44 Conchas simulations executing on 48 cores for 72 h each) for forming a low-order model of the discrepancy. Figure 28.23 shows the PCE coefficient magnitudes for the multifidelity spectrum (black) compared to the low-fidelity (green), discrepancy (blue), and high-fidelity (red) spectra. Compared to Fig. 28.16, the spectral decay rate is much slower, and important effects are occurring well beyond the resolution level of the discrepancy sparse grid. Therefore, the multifidelity expansion has to rely on the low-fidelity model for high-order terms which carry significant coefficient magnitudes. This implies that the study would strongly benefit from using less offset in the predefined sparse grid levels (i.e., reducing r in Eq. 28.35 by increasing the discrepancy sparse grid level), requiring many additional high-fidelity runs. Unfortunately, due to the expense of these large-scale LES simulations, this was impractical.

Figure 28.24 shows the evolution of the statistical results as the number of high-fidelity simulations is increased. Since there is no reference solution for this case, errors are not plotted and convergence can only be weakly inferred. While inconclusive at this level of resolution, it appears that the mean and standard deviation statistics are converging from below and that the multifidelity results are closer to their asymptotes. Moreover, the rate of change in the mean statistic is much

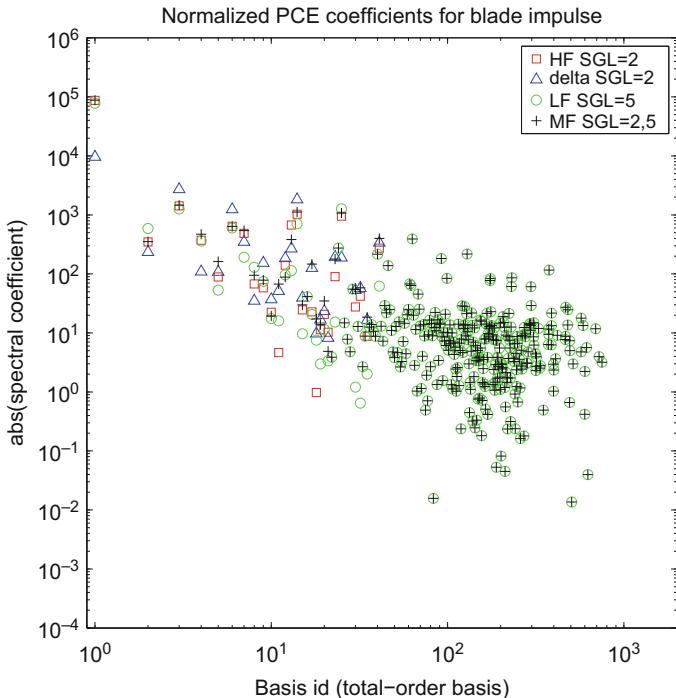

Fig. 28.23 Multifidelity coefficient spectrum: multifidelity coefficients (black) are composed from low fidelity (green) and discrepancy (blue) to extend spectrum from a single-fidelity approach (red)

lower for the multifidelity approaches, indicating more rapid relative convergence. Convergence in PDF and CCDF is less clear, with the most relevant observation being that, while the less resolved single-fidelity ($q = 1$ in red) and corresponding multifidelity results ($q_\delta, q_{\text{low}} = 1, 5$ in blue) are quite different, the more resolved single-fidelity ($q = 2$ in green) and corresponding multifidelity ($q_\delta, q_{\text{low}} = 2, 5$ in black) results have begun to coalesce. Thus, the augmentation with low-fidelity information appears to be providing utility, and the process overall appears to support the trends observed with previous examples, although it is clear that additional resolution is needed to achieve more conclusive statistical convergence.

5 Conclusions

We have presented a general framework for constructing stochastic expansions (non-intrusive polynomial chaos and stochastic collocation) in a multifidelity setting using a hierarchical approximation approach in which we resolve expansions for the low fidelity model and one or more levels of model discrepancy. Compared

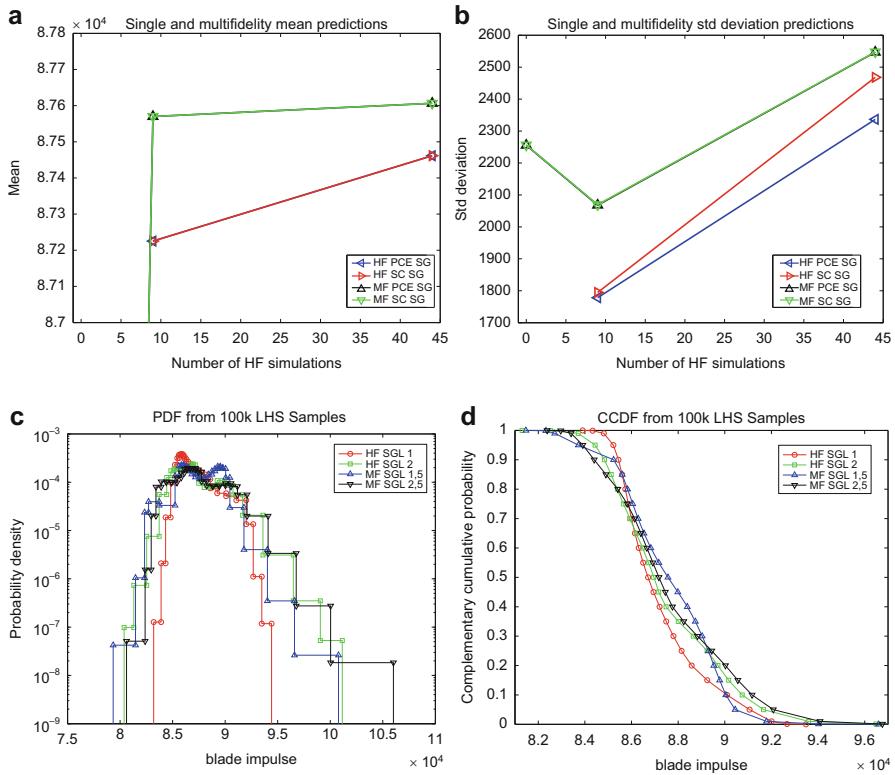

Fig. 28.24 Refinement of blade impulse statistics for multifidelity PCE/SC compared to single-fidelity PCE/SC. (a) Refinement of mean. (b) Refinement of standard deviation. (c) Refinement of PDF. (d) Refinement of CCDF

to the approach of directly estimating the statistics of the system response from a limited number of expensive high-fidelity model evaluations, greater accuracy can be obtained by incorporating information about the system response from a less expensive but still informative low-fidelity model.

Additive, multiplicative, and combined discrepancy formulations have been described within the context of polynomial chaos and stochastic collocation based on sparse grids and within the context of sparse polynomial chaos based on compressed sensing. Multifidelity sparse grid approaches can include simple pre-defined offsets in resolution level that enforce computational savings but do not explicitly manage accuracy, or adaptive approaches that seek the most cost-effective incremental refinements for accurately resolving statistical quantities of interest. Multifidelity compressed sensing approaches employ fixed sample sets but adapt the candidate basis and noise tolerance through the use of cross-validation to achieve an accurate recovery without overfitting.

In the area of adaptive multifidelity algorithms, we present an approach that extends the generalized sparse grid algorithm to consider candidate index sets from multiple sparse grids. Using normalization by the relative cost of the different model fidelities, this adaptive procedure can select the refinements that provide the greatest benefit per unit cost in resolving the high-fidelity statistics. This provides the capability to preferentially refine in dimensions or regions where the discrepancy is more complex, thereby extending the utility of multifidelity UQ to cases where the low-fidelity model is not uniformly predictive.

For the multifidelity UQ approach to be effective, we seek a low-fidelity model that is at least qualitatively predictive in terms of capturing important high-fidelity trends. Examples with good low-fidelity models have demonstrated significant reductions (e.g., 80% in the elliptic PDE example) in the computational expense required to achieve a particular accuracy, and the savings tend to grow as the relative resolution of the low-fidelity model (i.e., r for predefined sparse grid level offsets and ρ_{points} for compressed sensing) is increased. Even without exploitation of special structure (e.g., a priori models of estimator variance and discretization bias in traditional multilevel Monte Carlo), the close relationship between models with differing discretization levels appears to be fertile ground for effective use within multifidelity UQ approaches. On the other hand, low-fidelity models based on reduced-order modeling via projection of low-order singular modes may be a poor choice for multifidelity UQ approaches based on stochastic discrepancy models. The truncation process for defining the basis used in the projection may tend to resolve dominant low-order effects and leave behind a sparse high-order discrepancy function. In the horn problem, the adaptive multifidelity sparse grid approach showed negligible improvement relative to its single-fidelity peer, while the isotropic sparse grid and compressed sensing multifidelity approaches showed only modest gains relative to their benchmarks. Compressed sensing approaches were the best of the three options and are a logical choice for targeting the efficient resolution of sparse high-order discrepancy without requiring one to first resolve all supporting lower-order terms. And in cases where the low-fidelity model introduces additional discontinuities or generates spurious complexity in the model discrepancy that exceeds the original high-fidelity complexity (e.g., short column $R_{\text{low}2}$), it is evident that the multifidelity approaches can converge more slowly than their single-fidelity counterparts, unless this situation can be detected and mitigated by discarding non-informative models from the hierarchy. Finally, the multifidelity UQ approach was demonstrated for an industrial strength application in the statistical assessment of vertical-axis wind turbines subject to uncertain gust loading. While clear convergence evidence is much more challenging to obtain at this scale, affordable resolution levels nevertheless support the basic findings for previous examples in terms of observing accelerated relative convergence in the high-fidelity statistics.

In general, we expect that multifidelity UQ approaches based on spectral stochastic representations of model discrepancy can converge more rapidly than single-fidelity UQ in cases where the variance of the discrepancy is reduced relative to the variance of the high-fidelity model (resulting in reductions in initial stochastic error), where the spectrum of the expansion coefficients of the model discrepancy

decays more rapidly than that of the high-fidelity model (resulting in accelerated convergence rates), and/or where the discrepancy is sparse relative to the high-fidelity model (requiring the recovery of fewer significant terms).

Abstract

Determining the statistical properties of nonlinear random systems is a problem of major interest in many areas of physics and engineering. Even with recent theoretical and computational advancements, no broadly applicable technique has yet been developed for dealing with the challenging problems of high dimensionality, low regularity and random frequencies often exhibited by the system. The Mori-Zwanzig and the effective propagator approaches discussed in this chapter have the potential of overcoming some of these limitations, in particular the curse of dimensionality and the lack of regularity. The key idea stems from techniques of irreversible statistical mechanics, and it relies on developing exact evolution equations and corresponding numerical methods for quantities of interest, e.g., functionals of the solution to stochastic ordinary and partial differential equations. Such quantities of interest could be low-dimensional objects in infinite-dimensional phase spaces, e.g., the lift of an airfoil in a turbulent flow, the local displacement of a structure subject to random loads (e.g., ocean waves loading on an offshore platform), or the macroscopic properties of materials with random microstructure (e.g., modeled atomistically in terms of particles). We develop the goal-oriented framework in two different, although related, mathematical settings: the first one is based on the Mori-Zwanzig projection operator method, and it yields exact reduced-order equations for the quantity of interest. The second approach relies on effective propagators,

1 Introduction

Experiments on high-dimensional random systems provide observations of macroscopic phase variables such as the mass density in Newtonian fluids, the stress-strain relation in heterogeneous random materials (e.g., carbon fiber), or the velocity distribution in granular flows. These quantities can be related to a thorough microscopic description of the system by taking averages of real-valued (measurable) functions defined on a very high-dimensional phase space. To understand the dynamics of such phase-space functions, one often wishes to obtain closed equations of motion by eliminating the rest of the degrees of freedom. One of the most typical examples

for such contraction of state variables is the derivation of the Boltzmann equation from the Newton's law or from the Liouville equation [16, 118, 142]. Another example of a different type is the Brownian motion of a particle in a liquid, where the master equation governing the position and momentum of the particle is derived from first principles (Hamilton equations of motion of the full system), by eliminating the degrees of freedom of the liquid [17, 67]. In stochastic systems far from equilibrium, one often has to deal with the problem of eliminating macroscopic phase variables, i.e., phase variables with the same order of magnitude and dynamical properties as the ones of interest. For example, to define the turbulent viscosity in the inertial range of fully developed turbulence, one has to eliminate short wavelength components of the fluid velocity which are far from equilibrium. This problem arises more often than one would expect, and it is more challenging than the problem of contracting microscopic phase variables. For example, it arises when deriving the master equation for the series expansion of the solution to a nonlinear stochastic partial differential equation (SPDE), given any discretized form.

In this chapter we illustrate how to perform the contraction of state variables in nonequilibrium stochastic dynamical systems by using the Mori-Zwanzig projection operator method and the effective propagator approach. In particular, we will show how to develop computable evolution equations for quantities of interest in high-dimensional stochastic systems and how to determine their statistical properties. This problem received considerable attention in recent years. Well-known approaches to compute such properties are generalized polynomial chaos (gPC) [50, 154, 155], multilevel generalized polynomial chaos (ME-gPC) [138, 146], multilevel and sparse adaptive probabilistic collocation (ME-PCM) [32, 43, 44, 84], high-dimensional model representations [76, 112], stochastic biorthogonal expansions [131, 132, 137], and generalized spectral decompositions [100, 101]. These techniques can provide considerable speedup in computational time when compared to classical approaches such as Monte Carlo (MC) or quasi-Monte Carlo methods. However, there are still several important computational limitations that have not yet been overcome. They are related to:

1. *High Dimensionality*: Many problems of interest to physics and engineering can be modeled mathematically in terms of systems of nonlinear ODEs or nonlinear PDEs subject to random initial conditions, random parameters, random forcing terms, or random boundary conditions. The large number of phase variables involved in these problems and the high dimensionality of the random input vectors pose major computational challenges in representing the stochastic solution, e.g., in terms of polynomial chaos or probabilistic collocation. In fact, the number of terms in polynomial chaos series expansions, or the number of collocation points in probabilistic collocation methods, grows exponentially fast with the number of dimensions (in tensor product discretizations).
2. *Low Stochastic Regularity*: The computational cost of resolving solutions with *low stochastic regularity* is also an issue. Parametric discontinuities can create Gibbs-type phenomena which can completely destroy the convergence numerical methods – just like in spectral methods [57, 102]. Parametric discontinuities are

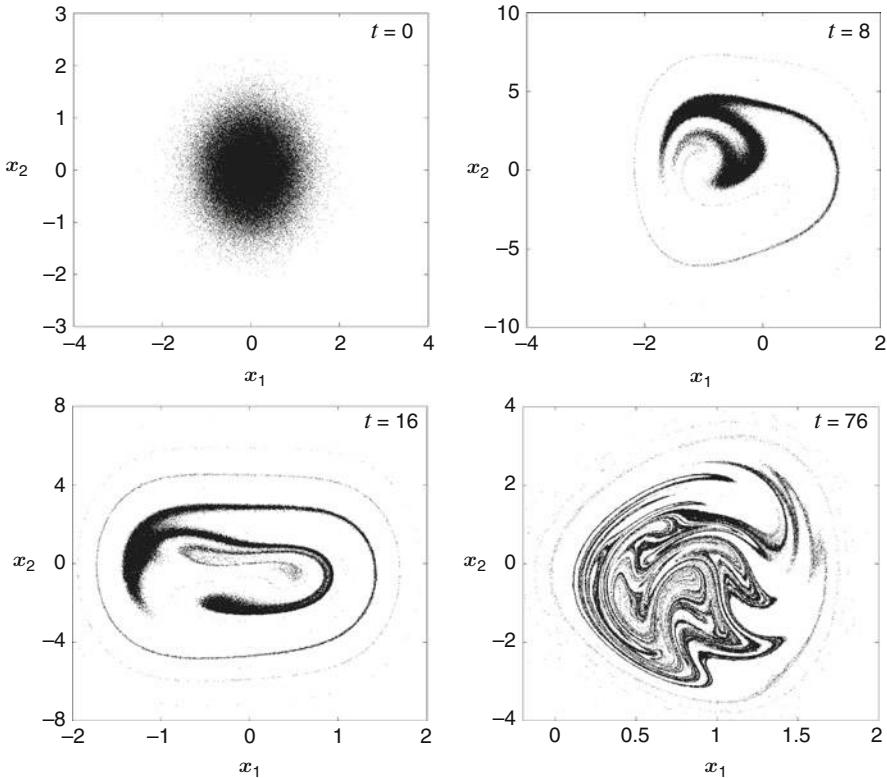

Fig. 29.1 Duffing equation. Poincaré sections of the phase space at different times obtained by evolving a zero-mean jointly Gaussian distribution with covariance $C_{11} = C_{22} = 1/4$, $C_{12} = 0$. Note that simple statistical properties such as the mean and variance are not sufficient to describe the stochastic dynamics of the system (29.5) (Adapted from [136])

unavoidable in nonlinear systems and they are often associated with interesting physics, e.g., around bifurcation points [138, 139]. By using adaptive methods, e.g., ME-gPC or ME-PCM, one can effectively resolve such discontinuities and restore convergence. This is where “ h -refinement” in parameter space is particularly important [43, 144].

3. *Multiple scales:* Stochastic systems can involve multiple scales in space, time, and phase space (see Fig. 29.1) which could be difficult to resolve by conventional numerical methods.
4. *Long-term integration:* The flow map defined by systems of differential equations can yield large deformations, stretching and folding of the phase space. As a consequence, methods that represent the parametric dependence of the solution on random input variables, e.g., in terms of polynomials chaos of fixed order or in terms of a fixed number of collocation points, will lose accuracy as time increases. This phenomenon can be mitigated, although not completely

overcome, by using multielement methods [43, 145], time-evolving bases [117], or a composition of short-term flow maps [80].

The Mori-Zwanzig and the effective propagator approaches have the potential of overcoming some of these limitations, in particular the curse of dimensionality and the lack of regularity.

1.1 Overcoming High Dimensions

The Mori-Zwanzig and the effective propagator approaches allow for a *systematic elimination* of the “irrelevant” degrees of freedom of the system, and they yield formally exact equations for quantities of interest, e.g., functionals of the solution to high-dimensional systems of stochastic ordinary differential equations (SODEs) and stochastic partial differential equations (SPDEs). This allows us to *avoid integrating the full (high-dimensional) stochastic dynamical system* and solve directly for the quantities of interest. In principle, this can break the curse of dimensionality in numerical simulations of SODEs and SPDEs at the price of solving complex integrodifferential PDEs – the Mori-Zwanzig equations. The computability of such PDEs relies on approximations. Over the years many methods have been proposed for this scope, for example, small correlation expansions [30, 46, 121], cumulant resummation methods [13, 17, 45, 78, 136], functional derivative techniques [51–53, 140], path integral methods [86, 108, 130, 153], decoupling approximations [54], and local linearization methods [35]. However, these techniques are not, in general, effective in eliminating degrees of freedom with the *same order of magnitude and dynamical properties* as the quantities of interest. Several attempts have been made to overcome these limitations and establish a computable framework for Mori-Zwanzig equations that goes beyond closures based on perturbation analysis. We will discuss some of these methods later in this chapter.

1.2 Overcoming Low Regularity

The PDF of low-dimensional quantities of interest depending on many phase variables is usually a *regular function*. This is due to a *homogenization effect* induced by multidimensional integration. In other words, the PDF of low-dimensional quantities of interest is often not just low-dimensional but also *smooth*, i.e., amenable to computation. As an example, consider the joint PDF of the Fourier coefficients of a turbulent flow. It is known that such joint PDF lies on an attractor with a possibly fractal structure [41, 42, 49]. However, the linear combination of the Fourier modes, i.e., the Fourier representation of the velocity field at a specific space-time location, turns out to be approximately Gaussian. This behavior is exhibited by other chaotic dynamical systems such as the Lorentz-96 system [79] evolving from a random initial state. In this case, it can be shown that the joint PDF of the phase variables approaches asymptotically in time a fractal attractor whose

dimension depends on the amplitude of the forcing term (see, e.g., [69]). However, the marginal distributions of such a complex joint PDF are approximately Gaussian (see Fig. 29.4).

2 Formulation

Let us consider the nonlinear dynamical system

$$\begin{cases} \frac{dx(t; \omega)}{dt} = f(x(t; \omega), \xi(\omega), t), \\ x(0; \omega) = x_0(\omega) \end{cases}, \quad (29.1)$$

where $x(t; \omega) \in \mathbb{R}^n$ is a multidimensional stochastic process, $f : \mathbb{R}^{n+m+1} \rightarrow \mathbb{R}^n$ is a deterministic nonlinear map assumed to be Lipschitz continuous in x , $\xi(\omega) \in \mathbb{R}^m$ is a random vector modeling input uncertainty, and $x_0(\omega) \in \mathbb{R}^n$ is a random initial state. The system (29.1) can be very large as it can arise, e.g., from a discretization of a nonlinear SPDE. We assume that the solution to (29.1) exists and is unique for each realization of $\xi(\omega)$ and $x_0(\omega)$. This allows us to consider $x(t; \omega)$ as a deterministic function of $\xi(\omega)$ and $x_0(\omega)$, i.e., we can define the parametrized *flow map* $\hat{x}(t; \xi(\omega), x_0(\omega))$. The joint PDF of $x(t; \omega)$ and $\xi(\omega)$ can be represented as

$$p(a, b, t) = \langle \delta(a - \hat{x}(t; \xi; x_0)) \delta(b - \xi) \rangle, \quad a \in \mathbb{R}^n, \quad b \in \mathbb{R}^m, \quad (29.2)$$

where $\langle \cdot \rangle$ denotes an integral with respect to the joint probability distribution of $\xi(\omega)$ and $x_0(\omega)$, while δ are multidimensional Dirac delta functions [68, 71]. Also, the vectors a and b represent the phase-space coordinates corresponding to $x_i(t; \omega)$ and $\xi(\omega)$, respectively. By differentiating (29.2) with respect to time and using well-known identities involving the Dirac delta function, it is straightforward to obtain the following exact hyperbolic conservation law:

$$\frac{\partial p(a, b, t)}{\partial t} = L(a, b, t) p(a, b, t), \quad L(a, b, t) = - \sum_{i=1}^n \left(\frac{\partial f_i(a, b, t)}{\partial a_i} + f_i \frac{\partial}{\partial a_i} \right). \quad (29.3)$$

In the sequel we will often set $p(t) \equiv p(a, b, t)$ and $L(t) \equiv L(a, b, t)$ for notational convenience. Equation (29.3) is equivalent to the Liouville equation of classical statistical mechanics (for non-Hamiltonian systems), with the remarkable difference that the phase variables we consider here can be rather general coordinates – not simply positions and momenta of particles. For instance, they could be the Galerkin or the collocation coefficients arising from a spatial discretization of a SPDE, e.g., if we represent the solution as

$$u(X, t; \omega) = \sum_{j=1}^n x_j(t; \omega) \phi_j(X), \quad (29.4)$$

where $\phi_j(X)$ are spatial basis functions. Early formulations in this direction were proposed by Edwards [33], Herring [56], and Montgomery [90] in the context of fluid turbulence.

2.1 Some Properties of the Solution to the Joint PDF Equation

Nonlinear systems in the form (29.1) can lead to all sorts of dynamics, including bifurcations, fractal attractors, multiple stable steady states, and transition scenarios. Consequently, the solution to the joint PDF equation (29.3) can be very complex as well, since it relates directly to the geometry of the phase space. For example, it is known that the time-asymptotic joint PDF associated with the Lorentz three-mode problem lies on a fractal attractor with Hausdorff dimension of about 2.06 (see [143]). Chaotic states and existence of strange attractors have been well documented for many other systems, such as the Lorenz-84 (see [14]) and the Lorenz-96 [69] models. Even in the much simpler case of the Duffing equation

$$\frac{dx_1}{dt} = x_2, \quad \frac{dx_2}{dt} = -x_1 - 5x_1^3 - \frac{x_2}{50} + 8 \cos\left(\frac{t}{2}\right) \quad (29.5)$$

we can have attractors with fractal structure and chaotic phase similarities [11]. This is clearly illustrated in Fig. 29.1 where we plot the Poincaré sections of the two-dimensional phase space at different times. Such sections are obtained by sampling 10^6 initial states from a zero-mean jointly Gaussian distribution and then evolving them by using (29.5). Since the joint PDF of the phase variables is, in general, a high-dimensional compactly supported distribution with a possibly fractal structure, its numerical approximation is a very challenging task, especially in longtime integration.

However, the statistical description of the system (29.1) in terms of the joint PDF equation (29.3) is often far beyond practical needs. For instance, we may be interested in the PDF of only one component, e.g., $x_1(t; \omega)$, or in the PDF of a phase space function $u = g(x)$ such as (29.4). These PDFs can be obtained either by integrating out several phase variables from the solution to Eq. (29.3), by constructing NARMAX (Nonlinear AutoRegressive Moving Average with exogenous input) models (see [7] §5.7) or by applying the projection operator or the effective propagator approaches discussed in this chapter. This may yield a *low-dimensional* PDF equation whose solution is *more regular* than the one obtained by solving directly Eq. (29.3) and therefore more amenable to computation. The regularization of the reduced-order PDF is due to multidimensional integration (marginalization) of the joint PDF.

3 Dimension Reduction: BBGKY Hierarchies

A family of reduced-order probability density functions can be obtained by integrating the solution to Eq. (29.3) with respect to the phase-space coordinates which are not of interest. This yields, for example,

$$p_i(a_i, t) = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} p(a, b, t) da_1 \cdots da_{i-1} da_{i+1} \cdots da_n db, \quad i = 1, \dots, n. \quad (29.6)$$

These reduced-order densities differ from those used in classical BBGKY theory [16], mainly in that they are not, in general, symmetric under interchanges of different phase-space coordinates. For instance, $p_i(a_i, t)$ is not the same function of a_i that $p_j(a_j, t)$ is of a_j , if i and j are different. In the classical BBGKY (Bogoliubov-Born-Green-Kirkwood-Yvon) framework, the phase coordinates of the systems are positions and momenta of identical particles. Therefore, the reduced-order multipoint densities are invariant under interchanges of phase-space coordinates of the same type, e.g., positions or momenta. Most of the added complexity to the classical BBGKY theory stems from this lack of symmetry. A related approach, due to Lundgren [81] and Monin [89], yields a hierarchy of PDF equations involving suitable limits of reduced density functions (see also [48, 59, 134, 135, 152]). The effective computability of both BBGKY-type and Lundgren-Monin hierarchies arising from Eq. (29.3) relies on appropriate closure schemes, e.g., a truncation based on a suitable decoupling approximation of the PDF. In particular, the mean-field approximation

$$p(t, a, b) = p_{\xi}(b) \prod_{i=1}^n p_i(a_i, t), \quad (29.7)$$

where $p_{\xi}(b)$ is the joint PDF of the random vector ξ , yields the system of conservation laws ($i = 1, \dots, n$):

$$\frac{\partial p_i(a_i, t)}{\partial t} = -\frac{\partial}{\partial a_i} \left[p_i(a_i, t) \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} f_i(a, b, t) p_{\xi}(b) \prod_{\substack{j=1 \\ j \neq i}}^n p_j(a_j, t) da_j db \right]. \quad (29.8)$$

These equations are coupled through the integrals appearing within the square bracket. As an example, consider the Lorentz-96 system [69]

$$\frac{dx_i}{dt} = (x_{i+1} - x_{i-2}) x_{i-1} - x_i + c, \quad i = 1, \dots, 40. \quad (29.9)$$

The first-order truncation of the BBGKY hierarchy is ($i = 1, \dots, 40$)

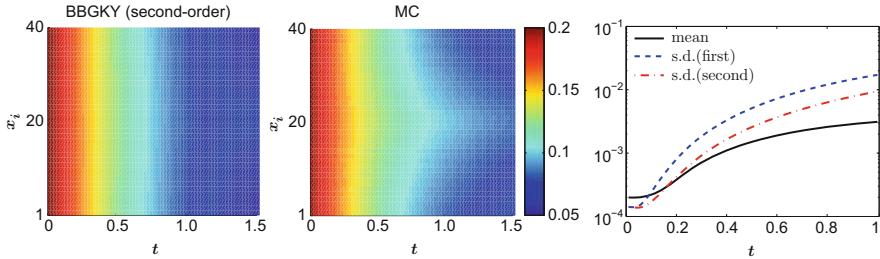

Fig. 29.2 Lorenz-96 system. Standard deviation of the phase variables versus time (left) and absolute errors of first- and second-order truncations of the BBGKY hierarchy relative to MC (Adapted from [22])

$$\frac{\partial p_i(a_i, t)}{\partial t} = -\frac{\partial}{\partial a_i} \left[(\langle x_{i+1} \rangle - \langle x_{i-2} \rangle) \langle x_{i-1} \rangle p_i(a_i, t) - (a_i - c) p_i(a_i, t) \right], \quad (29.10)$$

where $\langle \cdot \rangle$ denotes averaging with respect to the joint PDF of the system, assumed in the form (29.7). Higher-order truncations, i.e., truncations involving multipoint PDFs, can be obtained in a similar way (see [22, 90]). Clearly, higher truncation orders yield better accuracy, but at higher computational cost (see Fig. 29.2).

4 The Mori-Zwanzig Projection Operator Framework

The basic idea of the Mori-Zwanzig formalism is to reduce the dimensionality of the dynamical system (29.1) by splitting the phase variables into two categories: the *relevant* (or resolved) variables and the *irrelevant* (or unresolved) ones. These two sets can be easily classified by means of an orthogonal projection operator P that maps the state vector onto the set of resolved variables. By applying such orthogonal projection to Eq. (29.3), it is straightforward to obtain the following exact equation:

$$\frac{\partial P p(t)}{\partial t} = PL(t) P p(t) + PL(t) G(t, 0) Q p(0) + PL(t) \int_0^t G(t, s) QL(s) P p(s) ds, \quad (29.11)$$

first derived by Nakajima [96], Zwanzig [158, 159], and Mori [91]. Here we have set $p(t) \equiv p(a, b, t)$ and $L(t) \equiv L(a, b, t)$ for notational convenience and denoted by $Q = I - P$ the projection onto the unresolved variables. The operator $G(t, s)$ (forward propagator of the orthogonal dynamics) is formally defined as

$$G(t, s) = \overleftarrow{T} \exp \left[\int_s^t QL(\tau) d\tau \right], \quad (29.12)$$

where \overleftarrow{T} is the chronological time-ordering operator (latest times to the left). For a detailed derivation, see, e.g., [13, 17, 66, 136, 159]. From Eq. (29.11) we see that the

exact dynamics of the PDF of the relevant phase variables (projected PDF $Pp(t)$) depends on three terms: the *Markovian term* $PL(t)Pp(t)$, computable based on the current state $Pp(t)$, the *initial condition (or noise) term* $PL(t)G(t, 0)Qp(0)$, and the *memory term* (time convolution), both depending on the propagator $G(t, 0)$ of the orthogonal dynamics. The critical part of the MZ formulation is to find reliable and accurate approximations of the memory and the initial condition terms.

The nature of the projection operator P will be discussed extensively in subsequent sections. For now, it is sufficient to note that such projection basically extracts from the full joint PDF equation (29.3) only the part that describes (in an exact way) the dynamics of the relevant phase variables. A simple analysis of Eq. (29.11) immediately shows its irreversibility. Roughly speaking, the projected distribution function $Pp(t)$, initially in a certain subspace, leaks out of this subspace so that information is lost, hence the memory (time convolution) and the initial condition terms.

4.1 Coarse-Grained Dynamics in the Phase Space

The Mori-Zwanzig projection operator method just described can be also used to reduce the dimensionality of either deterministic or stochastic *systems of equations in the phase space*, yielding generalized Langevin equations [61, 118] for quantities of interest. One remarkable example of such equations is the one describing the *coarse-grained dynamics* of a particle system. Within this framework the phase variables $x_i(t)$ in (29.1) can represent either the position or the momentum of the particle “ i .” Coarse-graining is achieved by defining a new set of state variables:

$$u(t; \omega) = g(x(t; \omega), t) \quad (\text{quantities of interest}) \quad (29.13)$$

where $g : \mathbb{R}^{n+1} \rightarrow \mathbb{R}^q$ is a phase-space function and q is usually much smaller than n . These variables can represent the position or the momentum of entire *clusters of particles*, e.g., the big green particles shown in Fig. 29.3. The irrelevant phase variables in this case are the components of the full state vector x .

The generalized Langevin equation satisfied by (29.13) can be obtained by using standard methods [29, 61, 94, 118]. For example, if the system is autonomous, i.e., if the right-hand side of Eq. (29.1) reduces to $f(x)$, then we have the formally exact coarse-grained system (see [61, 92, 157]):

$$\frac{du_i(t)}{dt} = e^{tM} PM u_i(0) + \int_0^t e^{(t-s)M} PM R_i(s) ds + R_i(t), \quad i = 1, \dots, q \quad (29.14)$$

where P is an orthogonal projection operator and

$$M = \sum_{j=1}^n f_j(x_0) \frac{\partial}{\partial x_0}, \quad R_i(t) = e^{t(I-P)M}(I - P)Mu_i(t). \quad (29.15)$$

Particle System

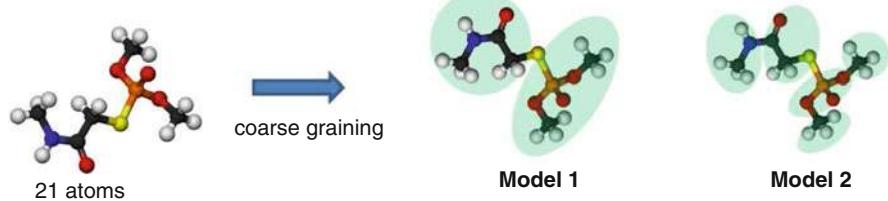

Fig. 29.3 Coarse-graining particle systems using the projection operator method. The microscopic degrees of freedom associated with each atom are condensed into a smaller number of degrees of freedom (those associated with the *big green particles*). Coarse-graining is not unique, and therefore fundamental questions regarding model inadequacy, selection, and validation have to be carefully addressed

The state-space reduced-order equations (29.14) are particularly useful if $u_i(t)$ is a complete set of slowly varying variables relative to the dynamics of the unresolved variables, i.e., the dynamics of $x(t; \omega)$. In this case, the fluctuating forces $R_i(t)$ are rapidly varying in time due to their modified propagator $\exp[t(I - P)M]$, and the memory kernel rapidly decays to zero. Effective approximations are possible in these cases [61, 65, 77, 157]. Based on the phase-space formulation, it is also possible to obtain the Mori-Zwanzig equation for the one-point or the multipoint PDF of the quantities of interest (29.13). To this end, it is sufficient to differentiate the distribution function

$$p_u(a, t) = \langle \delta(a - u(t; \omega)) \rangle, \quad (29.16)$$

with respect to time and substitute (29.14) within the average (see, e.g., [92, 118] for the derivation). If (29.1) represents the semi-discrete form of a SPDE and we are interested in the phase-space function (29.4), then the Mori-Zwanzig formulation yields the *exact PDF equation for the series expansion of the solution to the SPDE*. This overcomes the well-known *closure problem* arising in PDF equations corresponding to SPDEs with diffusion or higher-order terms [105, 110, 141]. On the other hand, if $u_i(t) = x_i(t)$ ($i = 1, \dots, q$) are the first q components of a Galerkin dynamical system, then the Mori-Zwanzig projection operator method allows us to construct a closure approximation in which the *unresolved dynamics* (modes from $q + 1$ to n) are injected in a *formally exact way* into the *resolved dynamics*. This use of projection operators has been investigated, e.g., by Chorin [24, 27], Stinis [119] and Chertok [20]. Early studies in this direction – not involving Mori-Zwanzig – employed *inertial manifolds* [40] and *nonlinear Galerkin projections* [83].

4.2 Projection Operators

The coarse-graining of the microscopic equations of motion can be performed by introducing a projection operator and applying it to the master equation (29.3) (coarse-graining in the PDF space – Eq. (29.11)) or to the dynamical system (29.1)

(coarse-graining in the phase space – Eq. (29.14)). Well-known choices are the Zwanzig projection [159], the Mori projection, projections defined in terms of Boltzmann-Gibbs measures [61, 118, 128], or projections defined by conditional expectations [25, 27, 29, 119]. If the relevant and the irrelevant phase variables (hereafter denoted by a and b , respectively) are statistically independent, i.e., if $p(0) = p_a(0)p_b(0)$, then a convenient projection is

$$Pp(t) = p_b(0) \int p(t)db \quad \Rightarrow \quad p_a(t) = \int Pp(t)db. \quad (29.17)$$

This projection takes the joint PDF $p(t)$ and basically sends it to a separated state. In this case we have that $p(0)$ is in the range of P , i.e., $Pp(0) = p(0)$, and therefore the initial condition term in the MZ-PDF equation drops out since $Qp(0) = (I - P)p(0) = 0$.

4.3 Time-Convolutionless Form of the Mori-Zwanzig Equation

The Mori-Zwanzig PDF (MZ-PDF) equation (29.11) can be transformed into a Markovian (time-convolutionless) form. To this end, we simply consider the formal solution to the orthogonal dynamics equation

$$Qp(t) = G(t, 0)Qp(0) + \int_0^t G(t, s)QL(s)Pp(s)ds, \quad (29.18)$$

and replace $p(s)$ with the solution to Eq. (29.3), propagated backward from time t to time $s < t$, i.e.,

$$p(s) = Z(t, s)p(t), \quad \text{where} \quad Z(t, s) = \overrightarrow{T} \exp \left[- \int_s^t L(\tau)d\tau \right]. \quad (29.19)$$

In the latter definition \overrightarrow{T} is the anti-chronological ordering operator (latest times to the right). Substituting (29.19) into (29.18) yields

$$Qp(t) = [I - \Sigma(t)]^{-1} G(t, 0)Qp(0) + [I - \Sigma(t)]^{-1} \Sigma(t)Pp(t), \quad (29.20)$$

where

$$\Sigma(t) = \int_0^t G(t, s)QL(s)PZ(t, s)ds. \quad (29.21)$$

Equation (29.20) states that the “irrelevant” part of the PDF $Qp(t)$ can, in principle, be determined from the knowledge of the “relevant” part $Pp(t)$ at time t and from the initial condition $Qp(0)$. Thus, the dependence on the history of the relevant part which occurs in the classical Mori-Zwanzig equation has been removed by

the introduction of the backward propagator (29.19). By using the orthogonal dynamics equation (29.20), we obtain the Markovian (time-convolutionless) MZ-PDF equation

$$\frac{\partial Pp(t)}{\partial t} = K(t)Pp(t) + H(t)Qp(0), \quad (29.22)$$

where

$$K(t) = PL(t)[I - \Sigma(t)]^{-1}, \quad H(t) = PL(t)[I - \Sigma(t)]^{-1}G(t, 0). \quad (29.23)$$

Many other equivalent forms of the Mori-Zwanzig equation can be constructed (see the Appendix in [136]), exactly for the same reason as why it is possible to represent an effective propagator of reduced-order dynamics in terms of generalized operator cumulants [55, 73, 74, 97]. So far, everything that has been said is exact, and it led us to the equation of motion (29.22), which is linear and local in time. Unfortunately, such an equation is still of little practical use, because the exact determination of the operators K and H is as complicated as the solution of Eq.(29.3). However, the time-convolutionless form (29.22) is a convenient starting point to construct *systematic approximation schemes*, e.g., by expanding K and H in terms of cumulant operators relative to suitable coupling constants [13, 17, 64, 66, 74, 97, 107, 115].

4.4 Multilevel Coarse-Graining in Probability and Phase Spaces

In [136] we recently proposed a multilevel coarse-graining technique in which the evolution equation for the orthogonal PDF dynamics $Qp(t)$

$$\frac{\partial Qp(t)}{\partial t} = QL(t)[Pp(t) + Qp(t)], \quad (29.24)$$

is decomposed further by introducing a new pair of orthogonal projections P_1 and Q_1 such that $P_1 + Q_1 = I$. This yields the coupled system

$$\frac{\partial P_1 Qp(t)}{\partial t} = P_1 QL(t)[Pp(t) + P_1 Qp(t) + Q_1 Qp(t)], \quad (29.25)$$

$$\frac{\partial Q_1 Qp(t)}{\partial t} = Q_1 QL(t)[Pp(t) + P_1 Qp(t) + Q_1 Qp(t)]. \quad (29.26)$$

Proceeding similarly, we can split the equation for $Q_1 Qp(t)$ by using a new pair of orthogonal projections P_2 and Q_2 satisfying $P_2 + Q_2 = I$. This yields two additional evolution equations for $P_2 Q_1 Qp(t)$ and $Q_2 Q_1 Qp(t)$, respectively. Obviously, one can repeat this process indefinitely to obtain a hierarchy of equations which *generalizes* both the Mori-Zwanzig as well as the BBGKY frameworks. The

advantage of this formulation with respect to the classical approach relies on the fact that the joint PDF $p(t)$ is not simply split into the “relevant” and the “irrelevant” parts by using P and Q . Indeed, the dynamics of the irrelevant part $Qp(t)$ are decomposed further in terms of a new set of projections.

This allows us to coarse-grain relevant features of the orthogonal dynamics further in terms of lower-dimensional quantities. In other words, the *multilevel projection operator method* allows us to *seemingly interface dynamical systems at different scales in a mathematically rigorous way*. This is particularly useful when coarse-graining (in state space) high-dimensional systems in the form (29.1). To this end, we simply have to define a set of quantities of interest $u^{(1)} = g^{(1)}(x, t)$, $u^{(2)} = g^{(2)}(x, t)$, etc. (see (29.13)), e.g., representing clusters of particles of different sizes and corresponding projection operators P_1 , P_2 , etc. This yields a coupled set of equations resembling (29.14) in which relevant features of the microscopic dynamics are interacting at different scales defined by different projection operators.

5 The Closure Problem

Most schemes that attempt to compute the solution of MZ equations or BBGKY-type hierarchies rely on the identification of some small quantity that serves as the basis for a perturbation expansion, e.g., the density for Boltzmann equations [16], the coupling constant or correlation time for Fokker-Planck-type equations [30, 46, 93, 121], or the Kraichnan absolute equilibrium distribution for turbulent inviscid flows [72, 90]. One of the most stubborn impediments for the development of a general theory of reduced-order PDF equations has been the lack of such readily identifiable small parameters. Most of the work that has been done so far refers to the situation in which such small parameters exist, e.g., when the operator L in Eq. (29.3) can be decomposed as

$$L = L_0 + \sigma L_1. \quad (29.27)$$

Here L_0 depends only on the relevant variables of the system, σ is a positive real number (coupling constant in time-dependent quantum perturbation theory), and the norm $\sigma \|L_1\|$ is somehow *small* (see, e.g., [13, 17, 93]). By using the interaction representation of quantum mechanics [9, 149], then it is quite straightforward to obtain from (29.22) and (29.27) an effective approximation (see [136]). One way to do so is to expand the operators (29.23) in a cumulant series, e.g., in terms of Kubo-Van Kampen operator cumulants [55, 64, 74, 97], involving increasing powers of σ (coupling parameter). Any finite-order truncation of such series then represents an *approximation* to the exact MZ-PDF equation. In particular, the approximation obtained by retaining only the first two cumulants is known as *Born approximation* in quantum field theory [17]. We remark that from the point of view of perturbation theory, the convolutionless form (29.22) has distinctive advantages over the usual convolution form (29.11). In particular, in the latter case, a certain amount of

rearrangement is necessary to obtain an expression which is correct up to a certain order in the coupling parameter [126].

5.1 Beyond Perturbation

Several attempts have been made to approximate MZ equations beyond closures based on perturbation analysis. For example, Chorin [24, 25, 27], Stinis [119, 120], and Chertok [20] proposed various models – such as the t -model or the modified t -model – for dimension reduction of autonomous dynamical systems in situations where there is no clear separation of scales between the resolved and the unresolved dynamics.

Another widely used closure approximation is based on the assumption that the distribution of the quantity of interest has a specific form, e.g., approximately Gaussian. This assumption can be justified in some cases on the basis of mixing, high dimensionality, and chaos. For example, the marginal densities of the Lorenz-96 system (29.9) are approximately Gaussian (see Fig. 29.4). In these cases, a Gaussian closure can be used to represent the PDF of the quantity of interest. Alternative methods rely, e.g., on maximum entropy closures [60, 62, 99, 128], functional renormalization [5, 120], and *renormalized perturbation series* ([87], Ch. 5). The key idea is to use methods of many body-theory to generalize traditional perturbation series to the case of strong interactions [85]. These approaches have been used extensively in turbulence theory [49, 87].

A different technique to compute the memory and the initial condition terms appearing in the Mori-Zwanzig equation relies on sampling, e.g., few realizations of the full dynamical system (29.1). In particular, one can leverage implicit sampling

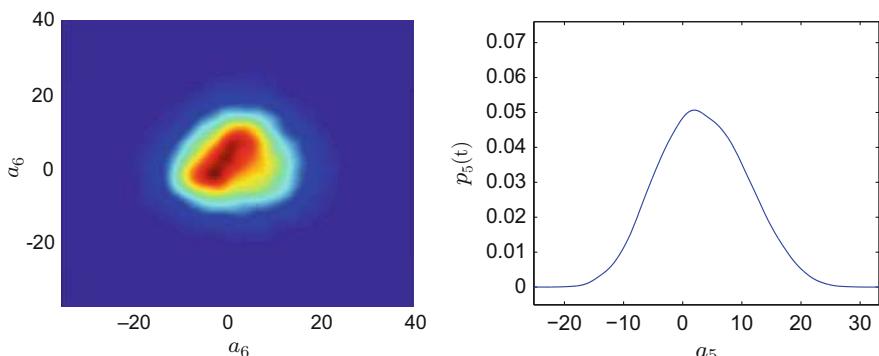

Fig. 29.4 Lorenz-96 system. Joint PDFs of different phase variables at time $t = 100$. Setting $c = 20$ in (29.9) yields a chaotic dynamics. In this case it can be shown that the joint PDF that solves Eq. (29.3) goes to a fractal attractor with Hausdorff dimension 34.5 [69]. However, the reduced-order PDFs are approximately Gaussian. This can be justified on the basis of chaos and multidimensional integration (29.6)

techniques [26] and PDF estimates to construct a hybrid approach in which the memory and the initial condition terms in the MZ equation are computed on the fly based on samples. In this way, one can compensate for the loss of accuracy associated with the approximation of the full MZ equation with few samples of the full dynamical system. A closely related approach is to estimate the expansion coefficients of the effective propagator (subsequent section) by using samples of the full dynamical system (29.1) and retain only the coefficients larger than a certain threshold.

5.2 Effective Propagators

Let us consider a dynamical system in the form (29.1) with time-independent f , i.e., an autonomous system. The formal solution to the joint PDF equation (29.3) in this case can be expressed as

$$p(t) = e^{tL} p(0). \quad (29.28)$$

If the initial state $p(0)$ is separable, i.e., if $p(0) = p_a(0)p_b(0)$ (where a and b are the relevant and irrelevant phase-space coordinates), then the exact evolution of the relevant part of the PDF is given by

$$p_a(t) = \langle e^{tL} \rangle p_a(0), \quad (29.29)$$

where $\langle \cdot \rangle$ is an average with respect to the PDF $p_b(0)$. For example, the exact evolution of the PDF of the first component of the Lorenz-96 system (29.9) is given by

$$p_1(a_1, t) = \left(\int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} e^{tL} p_2(a_2, 0) \cdots p_n(a_n, 0) da_2 \cdots da_n \right) p_1(a_1, 0), \quad (29.30)$$

where L , in this case, is

$$L = -nI - \sum_{i=1}^n [(a_{i+1} - a_{i-2}) a_{i-1} + a_i + c] \frac{\partial}{\partial a_i}. \quad (29.31)$$

The linear operator $\langle e^{tL} \rangle$ appearing in (29.29) is known as *relaxation operator* [74] or *effective propagator* [63, 87] of the reduced-order dynamics. Such a propagator is no longer a semigroup as $\langle e^{(t+s)L} \rangle \neq \langle e^{tL} \rangle \langle e^{sL} \rangle$, i.e., the evolution of $p_a(t)$ is non-Markovian. This reflects the memory effect induced in the reduced-order dynamics when we integrate out the phase variables b . To compute the effective propagator, we need to resort to approximations. For example, we could expand it in a power series [34, 70] as

$$\langle e^{tL} \rangle = I + \sum_{k=1}^{\infty} \frac{t^k}{k!} \langle L^k \rangle. \quad (29.32)$$

This expression shows that the dynamics of the PDF $p_a(t)$ is fully determined by the moments of the operator L relative to the joint distribution of the irrelevant phase variables. In particular, the k th-order moment $\langle L^k \rangle$ governing the dynamics of $p_1(a_1, t)$ in the Lorenz-96 system (29.30) is a linear differential operator in a_1 involving derivatives up to order k , i.e.,

$$\langle L^k \rangle = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} \underbrace{L \cdots L}_{k \text{ times}} p_2(a_2, 0) \cdots p_n(a_n, 0) da_2 \cdots da_n \quad (29.33)$$

$$= \sum_{j=0}^k \alpha_j^{(k)}(a_1) \frac{\partial^j}{\partial a_1^j}. \quad (29.34)$$

The coefficients $\alpha_j^{(k)}$ can be calculated by substituting (29.31) into (29.33) and performing all integrations. This is a cumbersome calculation, but in principle it can be carried out and yields exact results. The problem is that truncating moment expansions such as (29.32) to any finite order usually yields results of poor accuracy. This is because we may be discarding terms growing like t^k , if the norm of $\langle L^k \rangle$ does not decay rapidly enough. A classical approach to overcome these limitations is to use operator cumulants [55, 64, 66, 73, 74]. For autonomous dynamical systems, we have the exact formula (see, e.g., [4])

$$\langle e^{tL} \rangle = e^{\langle e^{tL} - I \rangle_c}, \quad (29.35)$$

where $\langle \cdot \rangle_c$ here denotes a cumulant average, e.g.,

$$\langle L \rangle_c = \langle L \rangle, \quad \langle L^2 \rangle_c = \langle L^2 \rangle - \langle L \rangle^2, \quad \dots. \quad (29.36)$$

Following Kubo [73, 74], we emphasize that many different types of operator cumulants can be defined. Disregarding, for the moment, the specific *prescription* we use to construct such operator cumulants (see [55, 74]), let us differentiate (29.29) with respect to time and take (29.35) into account. This yields the following exact reduced-order PDF equation

$$\frac{\partial p_a(t)}{\partial t} = \left(\langle L \rangle_c + \sum_{k=2}^{\infty} \frac{t^{k-1}}{(k-1)!} \langle L^k \rangle_c \right) p_a(t), \quad (29.37)$$

which is completely equivalent to the MZ-PDF equation (29.22). Any truncation of the series expansion in (29.37) yields an approximated equation whose specific form depends on the way we define the cumulant average $\langle \cdot \rangle_c$. For example,

we can get expansions in terms of *Kubo-Van Kampen*, *Waldenfels*, or *Speicher* operator cumulants (see the Appendix of [136] or [55, 97]). The choice of the most appropriate operator cumulant expansion is problem dependent.

Other methods to compute approximations to the effective propagator $\langle e^{tL} \rangle$ rely on functional renormalization, in particular on *renormalized perturbation series* ([87], Ch. 5). The key idea of these approaches is to use methods of many body-theory to generalize traditional perturbation series to the case of strong interactions. Formal treatment of this subject, along with the introduction of diagrammatic representations, can be found in [5, 87]. If $p_a(t)$ involves q phase variables (a_1, \dots, a_q) , then each $\langle L^k \rangle_c$ is a linear operator of order k involving a linear combination of generators $\partial^j / \partial a_k^j$ in the form

$$\langle L^k \rangle_c = \sum_{i_1, \dots, i_q=0}^k \beta_{i_1 \dots i_q}^{(k)}(a_1, \dots, a_q) \frac{\partial^{i_1 + \dots + i_q}}{\partial a_1^{i_1} \dots \partial a_q^{i_q}}. \quad (29.38)$$

A substitution of this series expansion into Eq. (29.37) immediately suggests that the exact evolution of the reduced-order PDF $p_a(t)$ is governed, in general, by a linear PDE involving derivatives of *infinite order* in the phase variables (a_1, \dots, a_q) . All coefficients $\beta_{i_1 \dots i_q}^{(k)}(a_1, \dots, a_q)$ appearing in (29.38) can be expressed in terms of integrals of polynomial functions of f_i (see Eq. (29.1)). However, computing such coefficients at all orders is neither trivial nor practical. On the other hand, determining an approximated advection-diffusion form of (29.37) is possible, simply by taking into account those coefficients leading to second-order derivatives in the phase variables. This can be achieved in a systematic way by truncating the series (29.38) to derivatives of second order and computing the corresponding coefficients.

5.2.1 Operator Splitting and Series Expansions

Let us consider an autonomous dynamical system evolving from a random initial state. The propagator $U(t, t_0) = e^{(t-t_0)L}$ forms a semigroup and therefore it can be split as

$$U(t_n, t_0) = U(t_n, t_{n-1}) \cdots U(t_2, t_1) U(t_1, t_0). \quad (29.39)$$

Each operator $U(t_i, t_{i-1})$ (short-time propagator) can be then approximated according to an appropriate decomposition formula [10, 122, 123, 150]. In particular, if L is given by (29.3) and if $\Delta t = |t_i - t_{i-1}|$ is small, then one can use the following first-order approximation

$$\exp \left[-\Delta t \left(\sum_{i=1}^n \frac{\partial f_i}{\partial a_i} + f_i \frac{\partial}{\partial a_i} \right) \right] \simeq \exp \left[-\Delta t \sum_{i=1}^n \frac{\partial f_i}{\partial a_i} \right] \prod_{k=1}^n \exp \left[-\Delta t f_k \frac{\partial}{\partial a_k} \right]. \quad (29.40)$$

This allows us to split the joint PDF equation (29.3) into a system of PDF equations. This approach is quite standard in numerical methods to solve linear PDEs in which the generator of the semigroup can be represented as a superimposition of linear operators. The error estimate for the decomposition formula (29.40) is given in [122, 124]. Higher-order formulas such as Lie-Trotter, Suzuki, and related Backer-Campbell-Hausdorff formulas can be constructed as well. The literature on this subject is very rich e.g., [9, 15, 122, 127, 148, 151].

A somewhat related approach relies on approximating the exponential semigroup e^{tL} in terms of operator polynomials, e.g., the *Faber polynomials* F_k [103]. In this case, the exact evolution of the PDF can be expressed as

$$p_a(t) = \sum_{k=0}^N \psi_k(t) \Phi_k(a), \quad \text{where} \quad \Phi_k(a) = \langle F_k(L) \rangle p_a(0). \quad (29.41)$$

In particular, if F_k are generated by elliptic conformal mappings, then they satisfy a three-term recurrence in the form

$$F_{k+1}(L) = (L - c_0) F_k(L) - c_1 F_{k-1}(L), \quad F_0(L) = I, \quad (29.42)$$

which yields an *unclosed* three-term recurrence for the *modes* Φ_k

$$\Phi_{k+1}(a) = \langle L F_k(L) \rangle p_a(0) - c_0 \Phi_k(a) - c_1 \Phi_{k-1}(a), \quad \Phi_0(a) = 1. \quad (29.43)$$

In some cases, the operator averages $\langle L^n \rangle$ appearing in $\langle L F_k(L) \rangle$ can be reduced to one-dimensional integrals. This happens, in particular, if the initial $p(0)$ is separable and if the functions f_k appearing in (29.1) are separable as well. Although this might seem a severe restriction, it is actually satisfied by many systems including Lorentz-96 [79], Kraichnan-Orszag [106], and the semi-discrete form of SPDEs with polynomial-type nonlinearities (e.g., viscous Burgers and Navier-Stokes equations).

5.3 Algorithms and Solvers

MZ-PDF equations are a particular class of probability density function equations involving memory and initial condition terms. Computing the numerical solution to a probability density function equation is, in general, a very challenging task that involves several problems of different nature. In particular,

High dimensionality: PDF equations describing realistic physical systems usually involve many phase variables. For example, the Fokker-Planck equation of classical statistical mechanics yields a joint probability density function in n phase variables, where n is the dimension of the underlying dynamical system, plus time.

Multiple scales: PDF equations may involve multiple scales in space and time, which could be hardly accessible by conventional numerical methods. For

example, the joint PDF equation (29.3) is a hyperbolic conservation law whose solution is purely advected (with no diffusion) by the compressible flow G . This can easily yield mixing, fractal attractors, and all sorts of complex dynamics (see Fig. 29.1).

Lack of regularity: The solution to a PDF equation is, in general, a distribution [68]. For example, it could be a multivariate Dirac delta function, a function with shock-type discontinuities [23], or even a fractal object. From a numerical viewpoint, resolving such distributions is not trivial although in some cases it can be done by taking integral transformations or projections [156]. An additional numerical difficulty inherent to the simulation of PDF equations arises due to the fact that the solution could be compactly supported over disjoint domains. This obviously requires the development of appropriate numerical techniques such as adaptive discontinuous Galerkin methods [21, 28, 113].

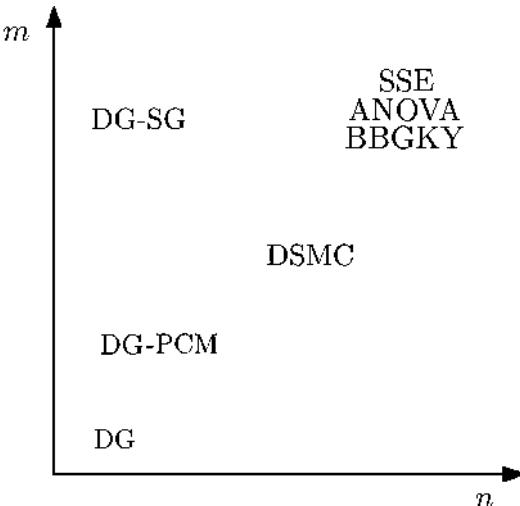

Conservation properties: There are several properties of the solution to a PDF equation that must be preserved in time. The most obvious one is mass, i.e., the solution always integrates to one. Other properties that must be preserved are the positivity of the joint PDF and the fact that a partial marginalization of a joint PDF still yields a PDF.

Long-term integration: The flow map defined by nonlinear dynamical systems can yield large deformations, stretching and folding of the phase space. As a consequence, numerical schemes for kinetic equations associated with such systems will generally loose accuracy in time.

Over the years, many different methods have been proposed to address these issues, with the most efficient ones being problem dependent. For example, a widely used method in statistical fluid mechanics is the particle/mesh method [95, 109–111], which is based directly on stochastic Lagrangian models. Other methods make use of stochastic fields [129] or direct quadrature of moments [47]. In the case of Boltzmann equation, there is a very rich literature. Both probabilistic approaches such as direct simulation Monte Carlo [8, 116] and deterministic methods, e.g., discontinuous Galerkin and spectral methods [18, 19, 39], have been proposed to compute the solution. Probabilistic methods such as direct simulation Monte Carlo are extensively used because of their very low computational cost compared to finite volumes, finite differences, or spectral methods, especially in the multidimensional case. However, Monte Carlo usually yields poorly accurate and fluctuating solutions, which need to be post-processed appropriately, for example, through variance reduction techniques. We refer to Dimarco and Pareschi [31] for a recent review.

In our previous work [21], we addressed the lack of regularity and high dimensionality (in the space of parameters) of kinetic equations by using adaptive discontinuous Galerkin methods [28, 114] combined with sparse probabilistic collocation. Specifically, the phase variables of the system were discretized by using spectral elements on an adaptive nonconforming grid that tracks the support of the PDF in time, while the parametric dependence of the solution was handled by using sparse grids. More recently, we proposed and validated new classes of algorithms

Fig. 29.5 Range of applicability of numerical methods for solving PDF equations as a function of the number of phase variables n and the number parameters m appearing in the equation. Shown are: Separated series expansion methods (SSE), BBGKY closures, high-dimensional model representations (ANOVA), adaptive discontinuous Galerkin methods (DG) combined with sparse grids (SG) or tensor product probabilistic collocation (PCM), direct simulation Monte Carlo (DSMC)

addressing the high-dimensional challenge in PDF equations [22]. These algorithms rely on separated series expansions, high-dimensional model representations, and BBGKY hierarchies. Their range of applicability is sketched in Fig. 29.5 as a function of the number of phase variables n and the number of parameters m appearing in the PDF equation (see also Eq. (29.1)).

The numerical treatment of MZ-PDF equations is even more challenging than classical PDF equations, due to the complexity of the memory and the initial condition terms. Such terms involve the projected part of the full orthogonal dynamics, which is represented by an exponential operator of very high dimension. Computing the solution to MZ-PDF equations, therefore, heavily relies on the approximation of memory and initial condition terms, e.g., in terms of operator cumulants [23, 136], approximate exponential matrices [2, 3, 88], or samples of the full dynamical system [24]. Developing new algorithms to compute the solution to MZ-PDF equations is a matter for future research.

6 Applications

In this section we illustrate the application of the the Mori-Zwanzig formulation to some well-known stochastic systems.

6.1 Stochastic Resonance Driven by Colored Noise

Let us consider a nonlinear dynamical system subject to a weak deterministic periodic signal and additive colored random noise. As is well known, in some cases, e.g., in bistable systems, the cooperation between noise and signal can yield

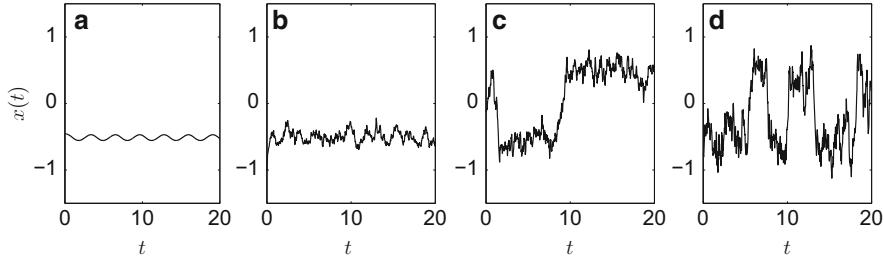

Fig. 29.6 Stochastic resonance. We study the system (29.44) with parameters $\mu = 10$, $\nu = 3$, $\Omega = 2$, $\epsilon = 0.2$ subject to weakly colored random noise ($\tau = 0.01$) of different amplitudes: (a) $\sigma = 0$; (b) $\sigma = 0.2$; (c) $\sigma = 0.4$; (d) $\sigma = 0.8$. Each figure shows only one solution sample. At low noise levels, the average residence time in the two states is much longer than the driving period. However, if we increase the noise level to $\sigma = 0.8$ (d), then we observe almost periodic transitions between the two metastable states. In most cases, we have a jump from one state to the other and back again approximately once per modulation period (Adapted from [136])

a phenomenon known as *stochastic resonance* [6, 82, 104, 147], namely, random noise can enhance significantly the transmission of the weak periodic signal. The mechanism that makes this possible is explained in Fig. 29.6, with reference to the system

$$\begin{cases} \frac{dx(t)}{dt} = \frac{2\mu x - 2\nu x^3 - \nu x^5}{2(1+x^2)^2} + \sigma f(t; \xi) + \epsilon \cos(\Omega t) \\ x(0) = x_0(\omega) \end{cases}. \quad (29.44)$$

Here $\xi \in \mathbb{R}^m$ is a vector of uncorrelated Gaussian random variables, while $x_0 \in \mathbb{R}$ is a Gaussian initial state. Also, the random noise $f(t; \xi)$ is assumed to be a zero-mean Gaussian process with exponential covariance function

$$C(t, s) = \frac{1}{2\tau} e^{-|t-s|/\tau} \quad (29.45)$$

and finite correlation time τ .

6.2 Mori-Zwanzig Equation

The exact evolution equation for the PDF of $x(t)$ can be obtained by applying the convolutionless projection operator method described in previous sections. Such an equation is a linear partial differential equation of *infinite order* in the phase variable a . If we consider a second-order approximation, i.e., if we expand the propagator of p_x in terms of cumulant operators and truncate the expansion at the second order, then we obtain

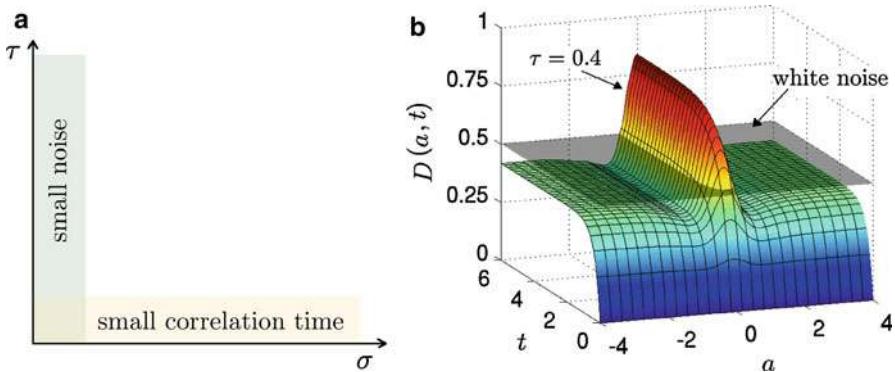

Fig. 29.7 Stochastic resonance. Range of validity of the MZ-PDF equation (29.46) as a function of the noise amplitude σ and correlation time τ (a). Effective diffusion coefficient $D(a, t)$ (see Eq. (29.48)) corresponding to exponentially correlated Gaussian noises (b) (Adapted from [136])

$$\begin{aligned} \frac{\partial p_x}{\partial t} &= L_0 p_x - \epsilon \cos(\Omega t) \frac{\partial p_x}{\partial a} \\ &\quad + \sigma^2 \left[\int_0^t C(t, s) \frac{\partial}{\partial a} e^{(t-s)L_0} \frac{\partial}{\partial a} e^{(s-t)L_0} ds \right] p_x, \end{aligned} \quad (29.46)$$

where

$$L_0 = \frac{\partial}{\partial a} \left(\frac{2\mu a - 2\nu a^3 - \nu a^5}{2(1+a^2)^2} \right) I + \left(\frac{2\mu a - 2\nu a^3 - \nu a^5}{2(1+a^2)^2} \right) \frac{\partial}{\partial a}. \quad (29.47)$$

The rationale behind this approximation is that higher-order cumulants can be neglected [36,37]. This happens, in particular, if both ϵ and σ are small. Faetti et al. [36,37] have shown that for $\epsilon = 0$, the correction due to the fourth-order cumulants is of order $\sigma \tau^2$ for Gaussian noise and order $\sigma \tau$ for other noises. Thus, (29.46) holds true either for small ϵ and σ and arbitrary correlation time τ or for small ϵ and τ and arbitrary noise amplitude σ (see Fig. 29.7). It can be shown (see, e.g., [93,136]) that (29.46) is equivalent to the following *advection-diffusion equation*

$$\frac{\partial p_x}{\partial t} = L_0 p_x - \varepsilon \cos(\Omega t) \frac{\partial p_x}{\partial a} + \sigma^2 \frac{\partial^2}{\partial a^2} (D(a, t) p_x), \quad (29.48)$$

where the effective diffusion coefficient $D(a, t)$ depends on the type of noise. Note that if the correlation time τ goes to zero (white-noise limit), then Eq. (29.46), with $C(t, s)$ defined in (29.45), consistently reduces to the classical Fokker-Planck equation. The proof is simple, and it relies on the limits

$$\lim_{\tau \rightarrow 0} \int_0^t \frac{1}{2\tau} e^{-s/\tau} ds = \frac{1}{2}, \quad \lim_{\tau \rightarrow 0} \int_0^t \frac{1}{2\tau} e^{-s/\tau} s^k ds = 0, \quad k \in \mathbb{N}. \quad (29.49)$$

These equations allow us to conclude that

$$\lim_{\tau \rightarrow 0} \int_0^t \frac{1}{2\tau} e^{-s/\tau} \frac{\partial}{\partial a} e^{sL_0} \frac{\partial}{\partial a} e^{-sL_0} ds = \lim_{\tau \rightarrow 0} \left[\int_0^t \frac{1}{2\tau} e^{-s/\tau} ds \right] \frac{\partial^2}{\partial a^2} = \frac{1}{2} \frac{\partial^2}{\partial a^2}, \quad (29.50)$$

i.e., for $\tau \rightarrow 0$ Eq. (29.46) reduces to the Fokker-Planck equation

$$\frac{\partial p_x}{\partial t} = L_0 p_x - \epsilon \cos(\Omega t) \frac{\partial p_x}{\partial a} + \frac{\sigma^2}{2} \frac{\partial^2 p_x}{\partial a^2}. \quad (29.51)$$

Next, we study the transient dynamics of the one-time PDF of the solution $x(t)$ within the period $T = 3$. To this end, we consider the following set of parameters $\mu = 1$, $\nu = 1$, $\Omega = 10$, $\epsilon = 0.5$, leading to a slow relaxation to statistical equilibrium. This allows us to study the transient of the PDF more carefully and compare the results with Monte Carlo (MC). This is shown in Fig. 29.8, where it is seen that for small σ the random forcing term in (29.44) does not influence significantly the dynamics and therefore the PDF of $x(t)$ is mainly advected by the operator L_0 . Note that the PDF tends to accumulate around the metastable equilibrium states $\pm \sqrt{\sqrt{3} - 1}$. For larger σ the probability of switching between the metastable states increases and therefore the strong bimodality observed in Fig. 29.8 (left) is attenuated.

6.3 Fractional Brownian Motion, Levy, and Other Noises

There exists a close connection between the statistical properties of the random noise and the structure of the MZ-PDF equation for the response variables of the system. In particular, it has been recently shown, e.g., in [75], that the PDF of the solution to the Langevin equation driven by Levy flights satisfies a *fractional* Fokker-Plank equation. Such an equation can be easily derived by using the Mori-Zwanzig projection operator framework, which represents therefore a very general tool to exploit the relation between noise and reduced-order PDF equations. For example, let us consider the non-stationary covariance function of *fractional Brownian motion*

$$C(t, s) = \frac{1}{2} (|t|^{2h} + |s|^{2h} - |t - s|^{2h}), \quad 0 < h < 1, \quad t, s > 0 \quad (29.52)$$

which reduces to the covariance function of standard Levy noise for $h = 1/2$, i.e., $C_{Levy}(t, s) = \min\{t, s\}$. A substitution of (29.52) into (29.46) yields an equation for the PDF of the solution to the system (29.1) driven by fractional Brownian motion of *small amplitude*. As is well known, such noise can trigger either sub-diffusion or super-diffusion in the PDF dynamics.

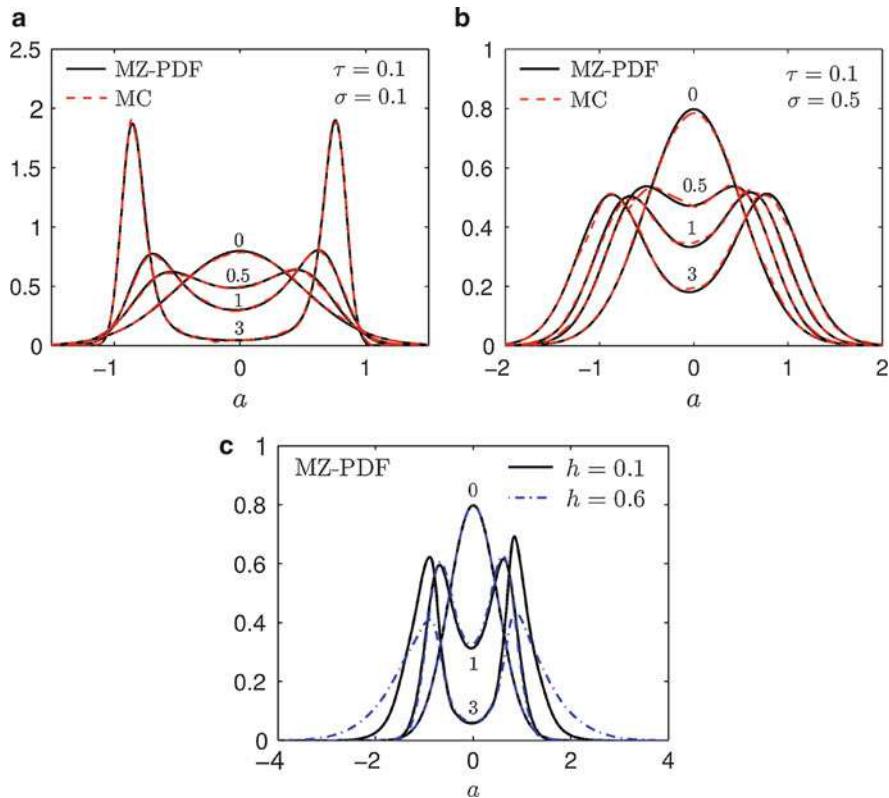

Fig. 29.8 Stochastic resonance. Time snapshots of the PDF of $x(t)$ as predicted by Eq. (29.46) (continuous lines) and MC simulation (10^5 samples) (dashed lines). The Gaussian process $f(t; \xi)$ in (29.44) is exponentially correlated with small correlation time τ ((a) and (b)). Note that the Karhunen-Lo  e expansion of such noise requires 280 Gaussian random variables to achieve 99% of the correlation energy in the time interval $[0, 3]$. We also show the PDF dynamics corresponding to fractional Brownian motion of small amplitude and different Hurst indices (c) (Adapted from [136])

6.4 Stochastic Advection-Reaction

Let us consider the advection-reaction equation for a scalar concentration field

$$\frac{\partial u}{\partial t} + V(x) \cdot \nabla u = [\kappa_0(x) + \sigma \kappa_1(x; \xi)] R(u), \quad \xi \in \mathbb{R}^m, \quad (29.53)$$

where $V(x)$ is a divergence-free (deterministic) advection velocity field, $R(u)$ is a nonlinear reaction term, and $\kappa_1(x; \xi)$ is a zero-mean random perturbation in the reaction rate $\kappa_0(x)$. In Fig. 29.9 we plot a few samples of the concentration field solving (29.53) in one spatial dimension, for different realizations of the random reaction rate and the random initial condition.

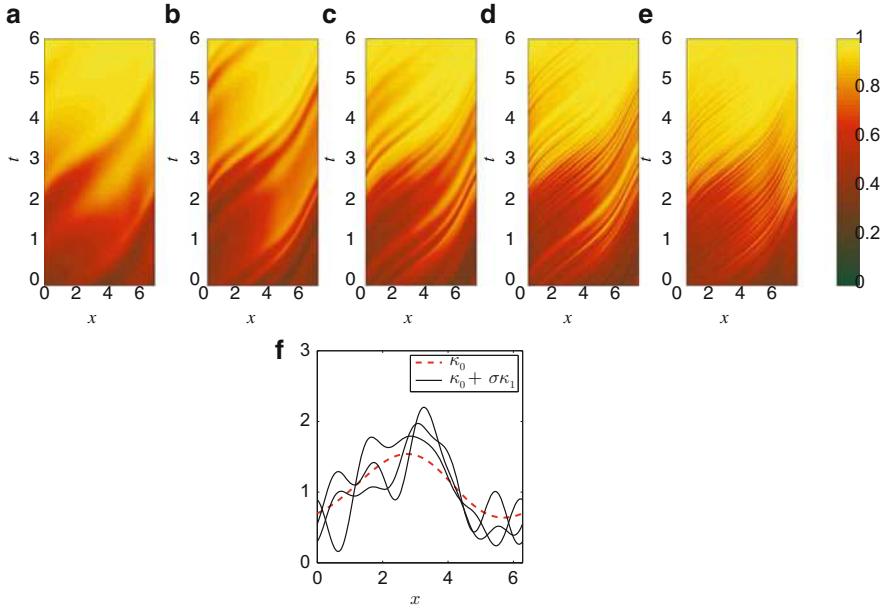

Fig. 29.9 Stochastic advection-reaction. Samples of the concentration field solving (29.53) in one spatial dimension for periodic boundary conditions and different realizations of the random initial condition and the random reaction rate. The correlation length of the random initial condition decreases from (a) to (e). In (f) we plot a few realizations of the random reaction rate ($\sigma = 0.3$) (Adapted from [136])

In [135, 141] we have studied Eq. (29.53) by using the response-excitation PDF method as well as the large-eddy-diffusivity (LED) closure [125]. Here we consider a different approach based on the MZ-PDF equation [136]. To this end, we assume that σ is reasonably small and that the concentration field u is independent of ξ at initial time, i.e., that the initial joint PDF of the system has the form $p(0) = p_u(0)p_\xi$. In these hypotheses, we obtain the following second-order approximation to the MZ-PDF equation

$$\frac{\partial p_u(t)}{\partial t} = L_0 p_u(t) + \sigma^2 \left[\int_0^t \langle \kappa_1 e^{sL_0} \kappa_1 \rangle e^{-sL_0} ds \right] F^2 p_u(t), \quad (29.54)$$

where the average $\langle \cdot \rangle$ is relative to the joint PDF of ξ and

$$L_0 = -\kappa_0(x)F - V(x) \cdot \nabla, \quad F = \frac{\partial R(a)}{\partial a} + R(a) \frac{\partial}{\partial a}. \quad (29.55)$$

Equation (29.54) is linear, but it involves derivatives of infinite order in both variables x and a . Such derivatives come from the exponential operators e^{sL_0} within the time convolution term. Note that such convolution can be also expressed as

a functional derivative [133] of the exponential operator along $\kappa_1(x)$, by using an identity of Feynman (see [38], Eq. (6) or [151]). In a finite-dimensional setting, these quantities can be computed by using efficient numerical algorithms, e.g., based on scaling-squaring methods and Padé approximants [2,3,88]. In Fig. 29.10 we plot the time snapshots of the PDF of the concentration field as predicted by the MZ-PDF equation (29.54). The comparison between such PDF and a Monte Carlo solution is done in Fig. 29.11. It is seen that in this case the second-order operator cumulant approximation provides accurate results for a quite large degree of perturbation (see Fig. 29.9f).

6.5 Stochastic Burgers Equation

The Mori-Zwanzig formulation can be applied also to the Burgers equation

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} = \sigma f(x, t; \omega) \quad (29.56)$$

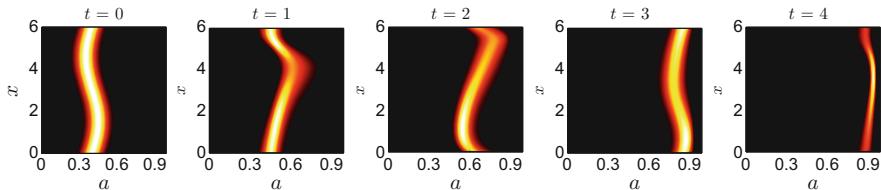

Fig. 29.10 Stochastic advection-reaction. Time snapshots of the concentration PDF predicted by the MZ-PDF equation (29.54) (Adapted from [136])

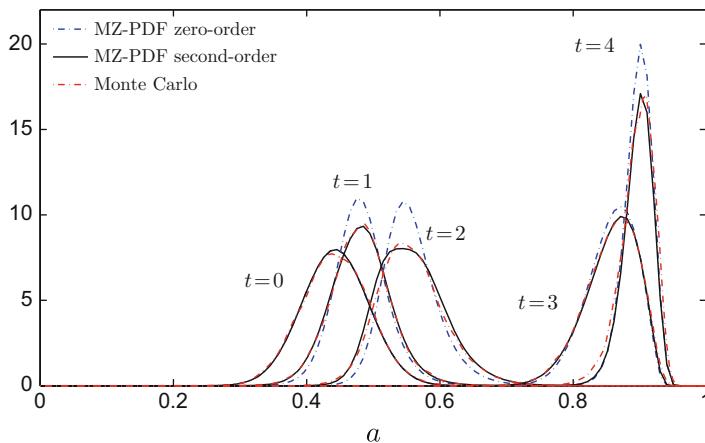

Fig. 29.11 Stochastic advection-reaction. Comparison between the MZ-PDF solution at $x = 1$ and a nonparametric kernel density estimation [12] of the PDF based on 10000 MC solution samples. The zero-order approximation is obtained by neglecting the second-order term in σ in Eq. (29.54) (Adapted from [136])

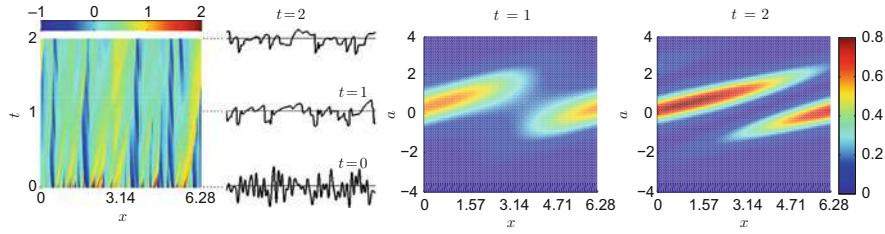

Fig. 29.12 Stochastic Burgers equation. One realization of the velocity field computed by using adaptive discontinuous Galerkin methods (left). Time snapshots of the one-point PDF obtained by solving the MZ-PDF equation (29.57) (Adapted from [23])

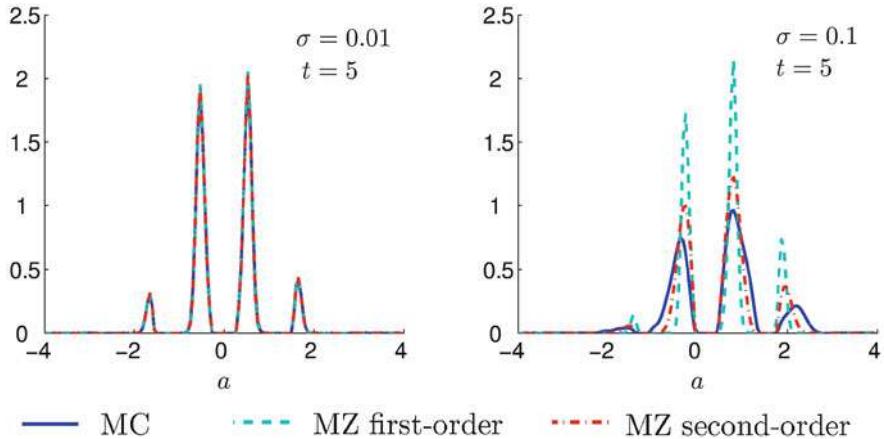

Fig. 29.13 Stochastic Burgers equation. One-point PDF of the velocity field at $x = \pi$ for exponentially correlated, homogeneous (in space) random forcing processes with correlation time 0.01 and amplitude $\sigma = 0.01$ and $\sigma = 0.1$ (second row). Shown are results obtained from MC and from two different truncations of the MZ-PDF equation (29.57) (Adapted from [23])

to formally integrate out the random forcing term. This yields the following equation (second-order approximation) for the one-point one-time PDF of the velocity field (see Fig. 29.12 and [23])

$$\frac{\partial p_u(t)}{\partial t} = L_0 p_u(t) + \sigma \langle f(x, t) \rangle \frac{\partial p_u(t)}{\partial a} + \sigma^2 \left[\int_0^t \left\langle f(x, t) \frac{\partial}{\partial a} e^{(t-s)L_0} f(x, s) \right\rangle \frac{\partial}{\partial a} e^{-(t-s)L_0} ds \right] p_u(t), \quad (29.57)$$

where L_0 is given by

$$L_0 = - \int_{-\infty}^a da \frac{\partial}{\partial x} - a \frac{\partial}{\partial x}. \quad (29.58)$$

In Fig. 29.13 we compare the PDF dynamics obtained by solving Eq. (29.57) with Monte Carlo simulation. It is seen that, as we increase the amplitude σ of the forcing, the second-order approximation (29.57) loses accuracy and higher-order corrections have to be included.

6.6 Coarse-Grained Models of Particle Systems

Particle systems are often used in models of system biology and soft matter physics to simulate and understand large-scale effects based on microscopic first principles. The computability of such systems depends critically on the number of particles and the interaction potentials. Full molecular dynamics (MD) simulations can be performed for particle systems with $\mathcal{O}(10^{13})$ particles. However, such “hero” simulations require hundred of thousands of computer cores and significant time and data processing to be successfully completed. This motivates the use of coarse-graining techniques, such as dissipative particle dynamics (DPD) [98], for particle systems to compute macroscopic/mesoscopic observables at a reasonable computational cost. Among different approaches, the Mori-Zwanzig formulation [61, 118] has proved to be effective in achieving this goal [1, 58, 77]. The key idea is shown in Fig. 29.14, where a star polymer described atomistically is coarse-grained to bigger particles – the MZ-DPD particles – by following the procedure sketched in Fig. 29.3 for a star polymer. The calculation of the solution to the MZ-DPD system, e.g., Eq. (29.14), relies on approximations. In particular, the memory term plays an important role in the dynamics of the coarse-grained system, and this role becomes more relevant as we increase the coarse-graining level [77, 157]. In Fig. 29.14 we compare the velocity autocorrelation function obtained from molecular dynamics simulations (MD) and the coarse-grained MZ-DPD system.

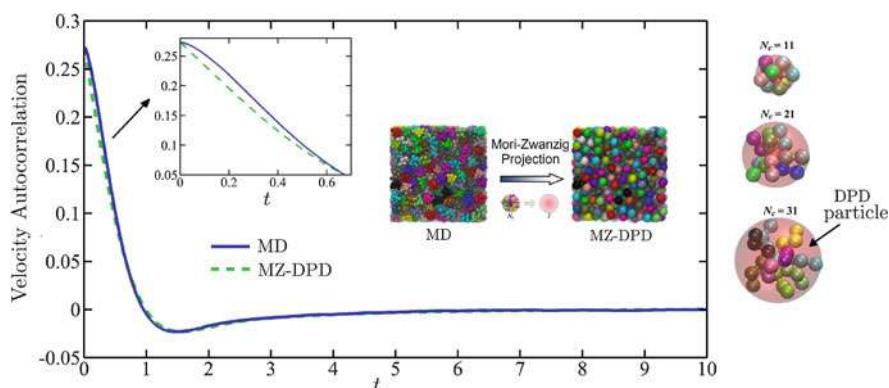

Fig. 29.14 Coarse-grained model of a particle system. Comparison between the velocity autocorrelation function obtained from molecular dynamics simulation (MD) and Mori-Zwanzig dissipative particle-dynamics (MZ-DPD) (Courtesy of Dr. Zhen Li, Brown University (unpublished))

7 Conclusions

In this chapter we discussed how to perform the contraction of state variables in nonequilibrium stochastic dynamical systems by using the Mori-Zwanzig projection operator method and the effective propagator approaches. Both techniques yield exact equations of motion for quantities of interest in high-dimensional systems, e.g., functionals of the solution to systems of stochastic ordinary and partial differential equations. Examples of such functionals are the position and momentum of clusters of particles (MZ-DPD methods), the series expansion of the solution to a SPDE, or the turbulent viscosity in the inertial range of fully developed turbulence. One of the main advantages of developing such exact equations is that they allow us to avoid integrating the full (high-dimensional) stochastic dynamical system and solve directly for the quantities of interest, thus reducing the computational cost significantly. In principle, this can break the curse of dimensionality in numerical simulations of SODEs and SPDEs at the price of solving complex integrodifferential equations. Computing the solution to the Mori-Zwanzig equations relies on approximations and appropriate numerical schemes. Over the years many different techniques have been proposed for this scope, with the most efficient ones being problem dependent. We discussed classical perturbation methods such as truncated operator cumulant expansions, as well as more recent approaches, e.g., based on orthogonal expansions of memory kernels, renormalized perturbation theory, sampling techniques, and maximum entropy principles. There is no general recipe to effectively approximate the Mori-Zwanzig equations for systems in which the relevant and the irrelevant phase variables have similar dynamical properties and order of magnitude. This situation arises very often when dealing with the problem of eliminating macroscopic phase variables, and it should be approached on a case-by-case basis.

Abstract

Rare events are events that are expected to occur infrequently or, more technically, those that have low probabilities (say, order of 10^{-3} or less) of occurring according to a probability model. In the context of uncertainty quantification, the rare events often correspond to failure of systems designed for high reliability, meaning that the system performance fails to meet some design or operation specifications. As reviewed in this section, computation of such rare-event probabilities is challenging. Analytical solutions are usually not available for nontrivial problems, and standard Monte Carlo simulation is computationally inefficient. Therefore, much research effort has focused on developing advanced stochastic simulation methods that are more efficient. In this section, we address the problem of estimating rare-event probabilities by Monte Carlo simulation, importance sampling, and subset simulation for highly reliable dynamic systems.

1 Introduction

We focus on rare-event simulation for addressing reliability problems corresponding to dynamic systems. To compute the rare-event (failure) probability for a dynamic system, both input (excitation) and modeling uncertainties should be quantified and propagated. Therefore, a probability model must be chosen to describe the uncertainty in the future input for the system, and then a chosen deterministic or stochastic system model is used, preferably in conjunction with a probability model describing the associated modeling uncertainties, to propagate these uncertainties. These input and system models define a probabilistic description of the system output (response). For example, the problem of interest might be to compute the small failure probability for a highly reliable dynamic system such as a bridge or building under uncertain future earthquake excitation, or for an aircraft under uncertain excitation by turbulence, using a finite-element structural model to approximate the dynamics of the system. This model will usually be subject to both parametric uncertainty (what values of the model parameters best represent the behavior of the system?) and nonparametric modeling uncertainty (what are the effects of the aspects of the system behavior not captured by the dynamic model?). The treatment of input uncertainty has a long history in dynamic reliability theory and random vibrations, now more commonly called stochastic dynamics, but the treatment of modeling uncertainty is more recent.

Usually the dynamic model of the system is represented by a time-dependent BVP (boundary-value problem) involving PDEs (partial differential equations) or by a set of coupled ODEs (ordinary differential equations). Typically the failure event is defined as any one of a set of performance quantities of interest exceeding its specified threshold over some time interval. This is the so-called first-passage problem. This challenging problem is characterized by a lack of analytical solutions, even for the simplest case of a single-degree-of-freedom linear oscillator subject to excitation that is modeled as a Gaussian process. Approximate analytical methods exist that are usually limited in scope, and their accuracy is difficult to assess in a given application [43, 51]. Semi-analytical methods from structural reliability theory such as FORM and SORM (first- and second-order reliability methods) [20, 43] cannot be applied directly to the first-passage problem and are inapplicable, anyway, because of the high-dimensional nature of the discrete-time input history [32, 53]. Standard Monte Carlo simulation has general applicability, but it is computationally very inefficient because of the low failure probabilities. As a consequence, advanced stochastic simulation schemes are needed.

1.1 Mathematical Formulation of Problem

We assume that initially there is a continuous-time deterministic model of the real dynamic system that consists of a state-space model with a finite-dimensional state $X(t) \in \mathbb{R}^n$ at time t , and this is converted to a discrete-time state-space model using a numerical time-stepping method to give

$$X(t+1) = f(X(t), U(t), t), \quad X(t) \in \mathbb{R}^n, \quad U(t) \in \mathbb{R}^m, \quad t = 0, \dots, T \quad (30.1)$$

where $U(t) \in \mathbb{R}^m$ is the input at discrete time t .

If the original model consists of a BVP with PDEs describing a response $u(x, t)$ where $x \in \mathbb{R}^d$, then we assume that a finite set of basis functions $\{\phi_1(x), \dots, \phi_n(x)\}$ is chosen (e.g., global bases such as Fourier and Hermite polynomials or localized ones such as finite-element interpolation functions) so that the solution is well approximated by

$$u(x, t) \approx \sum_{i=1}^n X_i(t) \phi_i(x) \quad (30.2)$$

Then a numerical method is applied to the BVP PDEs to establish time-dependent equations for the vector of coefficients $X(t) = [X_1(t), \dots, X_n(t)]$ so that the standard state-space equation in (30.1) still applies. For example, for a finite-element model of a structural system, $\{\phi_1(x), \dots, \phi_n(x)\}$ would be local interpolation functions over the elements. Then, expressing the BVP in weak form, a weighted residual or Galerkin method could be applied to give a state-space equation for the vector of coefficients $X(t)$ [27].

Suppose that a positive scalar performance function $g(X(t))$ is a quantity of interest and that the rare-event \mathcal{E} of concern is that $g(X(t))$ exceeds a threshold b over some discrete-time interval $t = 0, \dots, T$:

$$\mathcal{E} = \left\{ U = (U(0), \dots, U(T)) : \max_{t=0, \dots, T} g(X(t)) > b \right\} \subset \mathbb{R}^{m \times (T+1)} \quad (30.3)$$

where $X(t)$ satisfies (30.1). The performance function $g(X(t))$ may involve exceedance of multiple performance quantities of interest $\{g_k(X(t)) : k = 1, \dots, K\}$ above their corresponding thresholds $\{a_k\}$. This can be accomplished by aggregating them using the *max* and *min* operators in an appropriate combination on the set of g_k 's; for example, for a *pure series* failure criterion, where the threshold exceedance of *any* a_k represents failure, one takes the aggregate performance failure criterion as $g(X(t)) = \max\{g_k(X(t))/a_k : k = 1, \dots, K\} > 1$, while for a *pure parallel* failure criterion, where *all* of the g_k must exceed their thresholds before failure is considered to have occurred, one takes the aggregate performance failure criterion as $g(X(t)) = \min\{g_k(X(t))/a_k : k = 1, \dots, K\} > 1$.

If the uncertainty in the input time history vector $U = [U(0), \dots, U(T)] \in \mathbb{R}^D$ ($D = m \times (T + 1)$) is quantified by a probability distribution for U that has a PDF (probability density function) $p(u)$ with respect to Lebesgue integration over \mathbb{R}^D , then the rare-event probability is given by

$$p_{\mathcal{E}} = \mathbb{P}(U \in \mathcal{E}) = \int_{\mathcal{E}} p(u) du \quad (30.4)$$

The PDF $p(u)$ is assumed to be readily sampled. Although *direct sampling* from a high-dimensional PDF is not possible in most cases, multidimensional Gaussians

are an exception because the Gaussian vector can be readily transformed so that the components are independent and the PDF is a product of one-dimensional Gaussian PDFs. In many applications, the discrete-time stochastic input history is modeled by running discrete-time Gaussian white noise through a digital filter to shape its spectrum in the frequency domain and then multiplying the filtered sequence by an envelope function to shape it in the time domain, if it is nonstationary.

The model in (30.1) may also depend on uncertain parameters $\theta \in \Theta \subset \mathbb{R}^p$ which includes the initial values $X(0)$ if they are uncertain. Then a prior PDF $p(\theta)$ may be chosen to quantify the uncertainty in the value of vector θ . Some of the parameters may characterize the PDF for input U which can then be denoted $p(u|\theta)$. It is convenient to redefine vector U to also include θ ; then the new PDF $p(u)$ is $p(u|\theta)p(\theta)$ in terms of the previous PDFs. We assume that model parameter uncertainty is incorporated in this way, so the basic equations remain the same as (30.1), (30.3), and (30.4). When model uncertainty is incorporated, the calculated $p_{\mathcal{E}}$ has been referred to as the robust rare-event probability [10, 40], meaning robust to model uncertainty, as in robust control theory.

2 Standard Monte Carlo Simulation

The standard *Monte Carlo simulation* method (MCS) is one of the most robust and straightforward ways to simulate rare events and estimate their probabilities. The method was originally developed in [37] for solving problems in mathematical physics. Since then MCS has been used in many applications in physics, statistics, computer science, and engineering, and currently it lays at the heart of all random sampling-based techniques [35, 44].

The basic idea behind MCS is to observe that the probability in (30.4) can be written as an expectation:

$$p_{\mathcal{E}} = \int_{\mathbb{R}^D} I_{\mathcal{E}}(u) p(u) du = \mathbb{E}_p[I_{\mathcal{E}}] \quad (30.5)$$

where $I_{\mathcal{E}}$ is the indicator function of \mathcal{E} , that is, $I_{\mathcal{E}}(u) = 1$ if $u \in \mathcal{E}$ and $I_{\mathcal{E}}(u) = 0$ otherwise, and $D = m \times (T + 1)$ is the dimension of the integral. Recall that the strong law of large numbers [45] states that if U_1, \dots, U_N are independent and identically distributed (i.i.d.) samples of vector U drawn from the distribution $p(u)$, then for any function $h(u)$ with finite mean $\mathbb{E}_p[h(u)]$, the sample average $\frac{1}{N} \sum_{i=1}^N h(U_i)$ converges to the true value $\mathbb{E}_p[h(u)]$ as $N \rightarrow \infty$ almost surely (i.e., with probability 1). Therefore, setting $h(u) = I_{\mathcal{E}}(u)$, the probability in (30.5) can be estimated as follows:

$$p_{\mathcal{E}} \approx p_{\mathcal{E}}^{MCS} = \frac{1}{N} \sum_{i=1}^N I_{\mathcal{E}}(U_i) \quad (30.6)$$

It is straightforward to show that $p_{\mathcal{E}}^{MCS}$ is an *unbiased* estimator of $p_{\mathcal{E}}$ with mean and variance:

$$\begin{aligned}\mathbb{E}_p[p_{\mathcal{E}}^{MCS}] &= \mathbb{E}_p \left[\frac{1}{N} \sum_{i=1}^N I_{\mathcal{E}}(U_i) \right] = \frac{1}{N} \sum_{i=1}^N \mathbb{E}_p[I_{\mathcal{E}}] = p_{\mathcal{E}} \\ \text{Var}_p[p_{\mathcal{E}}^{MCS}] &= \text{Var}_p \left[\frac{1}{N} \sum_{i=1}^N I_{\mathcal{E}}(U_i) \right] = \frac{1}{N^2} \sum_{i=1}^N \text{Var}_p[I_{\mathcal{E}}] = \frac{p_{\mathcal{E}}(1-p_{\mathcal{E}})}{N}\end{aligned}\tag{30.7}$$

Furthermore, by the central limit theorem [45], as $N \rightarrow \infty$, $p_{\mathcal{E}}^{MCS}$ is distributed asymptotically as Gaussian with this mean and variance.

Frequentist interpretation of MCS: The frequentist interpretation of MCS focuses on the forward problem, arguing that if N is large so that the variance of $p_{\mathcal{E}}^{MCS}$ is relatively small, then the value $\hat{p}_{\mathcal{E}}^{MCS}$ based on (30.6) for a specific set of N samples $\{\hat{U}_1, \dots, \hat{U}_N\}$ drawn from $p(u)$ should be close to the mean $p_{\mathcal{E}}$ of $p_{\mathcal{E}}^{MCS}$. The sample mean estimate $\hat{p}_{\mathcal{E}}^{MCS}$ is very intuitive and, in fact, simply reflects the frequentist definition of probability: $\hat{p}_{\mathcal{E}}^{MCS}$ is the ratio between the number of trials where the event \mathcal{E} occurred, $\hat{N}_{\mathcal{E}} = \sum_{i=1}^N I_{\mathcal{E}}(\hat{U}_i)$, and the total number of trials N .

Bayesian interpretation of MCS: The same MCS estimate $\hat{p}_{\mathcal{E}}^{MCS}$ has a simple Bayesian interpretation (e.g., [56]), which focuses on the inverse problem for the specific set of N samples $\{\hat{U}_1, \dots, \hat{U}_N\}$ drawn from $p(u)$. Following the Bayesian approach [26], the unknown probability $p_{\mathcal{E}}$ is considered as a stochastic variable whose value in $[0, 1]$ is uncertain. The *Principle of Maximum Entropy* [25] leads to the uniform prior distribution for $p_{\mathcal{E}}$, $p(p_{\mathcal{E}}) = 1$, $0 \leq p_{\mathcal{E}} \leq 1$, which implies that all values are taken as equally plausible a priori. Since samples U_1, \dots, U_N are i.i.d., the binary sequence $I_{\mathcal{E}}(U_1), \dots, I_{\mathcal{E}}(U_N)$ is a sequence of Bernoulli trials, and so for the forward problem, $N_{\mathcal{E}}$ is distributed according to the binomial distribution with parameters N and $p_{\mathcal{E}}$, $N_{\mathcal{E}} \sim \text{Bin}(N, p_{\mathcal{E}})$. Therefore, for the set of N samples, the likelihood function is $p(\hat{N}_{\mathcal{E}}|p_{\mathcal{E}}, N) = \binom{N}{\hat{N}_{\mathcal{E}}} p_{\mathcal{E}}^{\hat{N}_{\mathcal{E}}} (1-p_{\mathcal{E}})^{N-\hat{N}_{\mathcal{E}}}$. Using *Bayes' theorem*, the posterior distribution for $p_{\mathcal{E}}$, $p(p_{\mathcal{E}}|\hat{N}_{\mathcal{E}}, N) \propto p(p_{\mathcal{E}})p(\hat{N}_{\mathcal{E}}|p_{\mathcal{E}}, N)$, is therefore the beta distribution $\text{Beta}(\hat{N}_{\mathcal{E}} + 1, N - \hat{N}_{\mathcal{E}} + 1)$, i.e.,

$$p(p_{\mathcal{E}}|\hat{N}_{\mathcal{E}}, N) = \frac{p_{\mathcal{E}}^{\hat{N}_{\mathcal{E}}} (1-p_{\mathcal{E}})^{N-\hat{N}_{\mathcal{E}}}}{B(\hat{N}_{\mathcal{E}} + 1, N - \hat{N}_{\mathcal{E}} + 1)}\tag{30.8}$$

where the beta function B is the normalizing constant that equals $(N + 1)! / (\hat{N}_{\mathcal{E}}!(N - \hat{N}_{\mathcal{E}})!)$ here. The MCS estimate is the *maximum a posteriori (MAP) estimate*, which is the mode of the posterior distribution (30.8) and therefore the most probable value of $p_{\mathcal{E}}$ a posteriori:

$$\hat{p}_{\mathcal{E}}^{MCS} = \frac{\hat{N}_{\mathcal{E}}}{N}\tag{30.9}$$

Notice that the posterior PDF in (30.8) gives a complete description of the uncertainty in the value of $p_{\mathcal{E}}$ based on the specific set of N samples of U drawn from $p(u)$. The posterior distribution in (30.8) is in fact the original Bayes' result [9], although Bayes' theorem was developed in full generality by Laplace [34].

The standard MCS method for estimating the probability in (30.4) is summarized in the following pseudo-code.

Monte Carlo Simulation

Input:

▷ N , total number of samples.

Algorithm:

Set $N_{\mathcal{E}} = 0$, number of trials where the event \mathcal{E} occurred.

for $i = 1, \dots, N$ **do**

 Sample the input excitation $U_i = (U_i(0), \dots, U_i(T)) \sim p(u)$.

 Compute the system trajectory $X_i = (X_i(0), \dots, X_i(T))$
 using the system model (30.1) with $U(t) = U_i(t)$.

if $\max_{t=0, \dots, T} g(X_i(t)) > b$

$N_{\mathcal{E}} \leftarrow N_{\mathcal{E}} + 1$

end if

end for

Output:

► $\hat{p}_{\mathcal{E}}^{MCS} = \frac{N_{\mathcal{E}}}{N}$, MCS estimate of $p_{\mathcal{E}}$

► $p(p_{\mathcal{E}}|N_{\mathcal{E}}, N) = \frac{p_{\mathcal{E}}^{N_{\mathcal{E}}} (1-p_{\mathcal{E}})^{N-N_{\mathcal{E}}}}{B(N_{\mathcal{E}}+1, N-N_{\mathcal{E}}+1)}$, posterior PDF of $p_{\mathcal{E}}$

Assessment of accuracy of MCS estimate: For the frequentist interpretation, the coefficient of variation (c.o.v.) for the estimator $\hat{p}_{\mathcal{E}}^{MCS}$ given by (30.6), conditional on $p_{\mathcal{E}}$ and N , is given by (30.7):

$$\delta(\hat{p}_{\mathcal{E}}^{MCS}|p_{\mathcal{E}}, N) = \sqrt{\frac{\text{Var}_p[\hat{p}_{\mathcal{E}}^{MCS}]}{\mathbb{E}_p[\hat{p}_{\mathcal{E}}^{MCS}]}} = \sqrt{\frac{1-p_{\mathcal{E}}}{Np_{\mathcal{E}}}} \quad (30.10)$$

This can be approximated by replacing $p_{\mathcal{E}}$ by the estimate $\hat{p}_{\mathcal{E}}^{MCS} = \hat{N}_{\mathcal{E}}/N$ for a given set of N samples $\{\hat{U}_1, \dots, \hat{U}_N\}$:

$$\delta(\hat{p}_{\mathcal{E}}^{MCS}|p_{\mathcal{E}}, N) \approx \sqrt{\frac{1-\hat{p}_{\mathcal{E}}^{MCS}}{N\hat{p}_{\mathcal{E}}^{MCS}}} \triangleq \hat{\delta}_N^{MCS} \quad (30.11)$$

For the Bayesian interpretation, the posterior c.o.v. for the stochastic variable $p_{\mathcal{E}}$, conditional on the set of N samples, follows from (30.8):

$$\delta(p_{\mathcal{E}}|\widehat{N}_{\mathcal{E}}, N) = \frac{\sqrt{\text{Var}[p_{\mathcal{E}}|\widehat{N}_{\mathcal{E}}, N]}}{\mathbb{E}[p_{\mathcal{E}}|\widehat{N}_{\mathcal{E}}, N]} = \frac{\sqrt{1 - \frac{\widehat{N}_{\mathcal{E}}+1}{N+2}}}{\sqrt{(N+3)\left(\frac{\widehat{N}_{\mathcal{E}}+1}{N+2}\right)}} \xrightarrow{\text{as } N \rightarrow \infty} \sqrt{\frac{1 - \hat{p}_{\mathcal{E}}^{MCS}}{N \hat{p}_{\mathcal{E}}^{MCS}}} = \hat{\delta}_N^{MCS}$$
(30.12)

as $N \rightarrow \infty$. Therefore, the same expression $\hat{\delta}_N^{MCS}$ can be used to assess the accuracy of the MCS estimate, even though the two c.o.v.s have distinct interpretations.

The approximation $\hat{\delta}_N^{MCS}$ for the two c.o.v.s reveals both the main advantage of the standard MCS method and its main drawback. The main strength of MCS, which makes it very robust, is that its accuracy does not depend on the geometry of the domain $\mathcal{E} \subset \mathbb{R}^D$ and its dimension D . As long as an algorithm for generating i.i.d. samples from $p(u)$ is available, MCS, unlike many other methods (e.g., numerical integration), does not suffer from the “curse of dimensionality.” Moreover, an irregular, or even fractal-like, shape of \mathcal{E} will not affect the accuracy of MCS.

On the other hand, the serious drawback of MCS is that this method is not computationally efficient in estimating the *small probabilities* $p_{\mathcal{E}}$ corresponding to *rare events*, where from (30.10),

$$\delta(p_{\mathcal{E}}^{MCS}|p_{\mathcal{E}}, N) \approx \frac{1}{\sqrt{N p_{\mathcal{E}}}} \quad (30.13)$$

Therefore, to achieve a prescribed level of accuracy $\delta < 1$, the required total number of samples is $N = (p_{\mathcal{E}}\delta^2)^{-1} \gg 1$. For each sampled excitation U_i , a system analysis – usually computationally very intensive – is required to compute the corresponding system trajectory X_i and to check whether U_i belongs to \mathcal{E} . This makes MCS excessively costly and inapplicable for generating rare events and estimating their small probabilities. Nevertheless, essentially all sampling-based methods for estimation of rare-event probability are either based on MCS (e.g., importance sampling) or have it as a part of the algorithm (e.g., subset simulation).

3 Importance Sampling

The *importance sampling* (IS) method belongs to the class of *variance reduction techniques* that aim to increase the accuracy of the estimates by constructing (sometimes biased) estimators with a smaller variance [1, 22]. It seems it was first proposed in [29], soon after the standard MCS method appeared.

The inefficiency of MCS for rare-event estimation stems from the fact that most of the generated samples $U_i \sim p(u)$ do not belong to \mathcal{E} so that the vast majority of the terms in the sum (30.6) are zero and only very few (if any) are equal to one. The basic idea of IS is to make use of the information available about the rare-event \mathcal{E} to generate samples that lie more frequently in \mathcal{E} or in the *important region* $\tilde{\mathcal{E}} \subset \mathcal{E}$ that accounts for most of the probability content in (30.4). Rather than estimating $p_{\mathcal{E}}$ as an average of many 0's and very few 1's like in $\hat{p}_{\mathcal{E}}^{MCS}$, IS seeks to reduce the

variance by constructing an estimator of the form $p_{\mathcal{E}}^{IS} = \frac{1}{N} \sum_{i=1}^{N'} w_i$, where N' is an appreciable fraction of N and the w_i are small but not zero, ideally of the same order as the target probability, $w_i \approx p_{\mathcal{E}}$.

Specifically, for an appropriate PDF $q(u)$ on the excitation space \mathbb{R}^D , the integral in (30.5) can be rewritten as follows:

$$p_{\mathcal{E}} = \int_{\mathbb{R}^D} I_{\mathcal{E}}(u) p(u) du = \int_{\mathbb{R}^D} \frac{I_{\mathcal{E}}(u) p(u)}{q(u)} q(u) du = \mathbb{E}_q \left[\frac{I_{\mathcal{E}} p}{q} \right] \quad (30.14)$$

The IS estimator is now constructed similarly to (30.6) by utilizing the law of large numbers:

$$p_{\mathcal{E}} \approx p_{\mathcal{E}}^{IS} = \frac{1}{N} \sum_{i=1}^N \frac{I_{\mathcal{E}}(U_i) p(U_i)}{q(U_i)} = \frac{1}{N} \sum_{i=1}^N I_{\mathcal{E}}(U_i) w(U_i) \quad (30.15)$$

where U_1, \dots, U_N are i.i.d. samples from $q(u)$, called the *importance sampling density* (ISD), and $w(U_i) = \frac{p(U_i)}{q(U_i)}$ is the *importance weight* of sample U_i .

The IS estimator $p_{\mathcal{E}}^{IS}$ converges almost surely as $N \rightarrow \infty$ to $p_{\mathcal{E}}$ by the strong law of large numbers, provided that the support of $q(u)$, i.e., the domain in \mathbb{R}^D where $q(u) > 0$, contains the support of $I_{\mathcal{E}}(u)p(u)$. Intuitively, the latter condition guarantees that all points of \mathcal{E} that can be generated by sampling from the original PDF $p(u)$ can also be generated by sampling from the ISD $q(u)$. Note that if $q(u) = p(u)$, then $w(U_i) = 1$ and IS simply reduces to MCS, $p_{\mathcal{E}}^{MCS} = p_{\mathcal{E}}^{IS}$. By choosing the ISD $q(u)$ appropriately, IS aims to obtain an estimator with a smaller variance.

The IS estimator $p_{\mathcal{E}}^{IS}$ is also *unbiased* with mean and variance:

$$\begin{aligned} \mathbb{E}_q[p_{\mathcal{E}}^{IS}] &= \mathbb{E}_q \left[\frac{1}{N} \sum_{i=1}^N I_{\mathcal{E}}(U_i) w(U_i) \right] = \frac{1}{N} \sum_{i=1}^N \mathbb{E}_q \left[\frac{I_{\mathcal{E}} p}{q} \right] = p_{\mathcal{E}} \\ \text{Var}_q[p_{\mathcal{E}}^{IS}] &= \frac{1}{N^2} \sum_{i=1}^N \text{Var}_q \left[\frac{I_{\mathcal{E}} p}{q} \right] = \frac{1}{N} \left(\mathbb{E}_q \left[\frac{I_{\mathcal{E}} p^2}{q^2} \right] - p_{\mathcal{E}}^2 \right) \end{aligned} \quad (30.16)$$

The IS method is summarized in the following pseudo-code.

The most important task in applying IS for estimating small probabilities of rare events is the construction of the ISD, since the accuracy of $\hat{p}_{\mathcal{E}}^{IS}$ depends critically on $q(u)$. If the ISD is “good,” then one can get great improvement in efficiency over standard MCS. If, however, the ISD is chosen inappropriately so that, for instance, $N_{\mathcal{E}} = 0$ or the importance weights have a large variation, then IS will yield a very poor estimate. Both scenarios are demonstrated below in Sect. 6.

It is straightforward to show that the *optimal* ISD, which minimizes the variance in (30.16), is simply the original PDF $p(u)$ conditional on the domain \mathcal{E} :

Importance Sampling

Input:

- ▷ N , total number of samples.
- ▷ $q(u)$, importance sampling density.

Algorithm:

```

Set  $j = 0$ , counter for the number of samples in  $\mathcal{E}$ .
for  $i = 1, \dots, N$  do
    Sample the input excitation  $U_i = (U_i(0), \dots, U_i(T)) \sim q(u)$ .
    Compute the system trajectory  $X_i = (X_i(0), \dots, X_i(T))$ 
    using the system model (30.1) with  $U(t) = U_i(t)$ .
    if  $\max_{t=0,\dots,T} g(X_i(t)) > b$ 
         $j \leftarrow j + 1$ 
        Compute the importance weight of the  $j^{th}$  sample in  $\mathcal{E}$ ,  $w_j = \frac{p(U_i)}{q(U_i)}$ .
    end if
end for

```

$N_{\mathcal{E}} = j$, the total number of trials where the event \mathcal{E} occurred.

Output:

► $\hat{p}_{\mathcal{E}}^{IS} = \frac{\sum_{j=1}^{N_{\mathcal{E}}} w_j}{N}$, IS estimate of $p_{\mathcal{E}}$

$$q_0(u) = p(u|\mathcal{E}) = \frac{I_{\mathcal{E}}(u)p(u)}{p_{\mathcal{E}}} \quad (30.17)$$

Indeed, in this case, all generated sample excitations satisfy $U_i \in \mathcal{E}$, so their importance weights $w(U_i) = p_{\mathcal{E}}$, and the IS estimate $\hat{p}_{\mathcal{E}}^{IS} = p_{\mathcal{E}}$. Moreover, just one sample ($N = 1$) generated from $q_0(u)$ is enough to find the probability $p_{\mathcal{E}}$ exactly. Note, however, that this is a purely theoretical result since in practice sampling from the conditional distribution $p(u|\mathcal{E})$ is challenging, and, most importantly, it is impossible to compute $q_0(u)$: this would require the knowledge of $p_{\mathcal{E}}$, which is unknown. Nevertheless, this result indicates that the ISD $q(u)$ should be chosen as close to $q_0(u)$ as possible. In particular, most of the probability mass of $q(u)$ should be concentrated on \mathcal{E} . Based on these considerations, several ad hoc techniques for constructing ISDs have been developed, e.g., variance scaling and mean shifting [15].

In the special case of linear dynamics and Gaussian excitation, an extremely efficient algorithm for estimating the rare-event probability $p_{\mathcal{E}}$ in (30.4), referred to as ISEE (*importance sampling using elementary events*), has been presented [3]. The choice of the ISD exploits known information about each elementary event, defined as an outcrossing of the performance threshold b in (30.3) at a specific time $t \in \{0, \dots, T\}$. The c.o.v. of the ISEE estimator for N samples of U from $p(u)$ is given by

$$\delta_N^{ISEE} = \frac{\alpha}{\sqrt{N}} \quad (30.18)$$

where the proportionality constant α is close to 1, regardless of how small the value of $p_{\mathcal{E}}$. In fact, α decreases slightly as $p_{\mathcal{E}}$ decreases, exhibiting the opposite behavior to MCS.

In general, it is known that in many practical cases of rare-event estimation, it is difficult to construct a good ISD that leads to a low-variance IS estimator, especially if the dimension of the uncertain excitation space \mathbb{R}^D is large, as it is in dynamic reliability problems [5]. A geometric explanation as to why IS is often inefficient in high dimensions is given in [32]. Au [2] has presented an efficient IS method for estimating $p_{\mathcal{E}}$ in (30.4) for elastoplastic systems subject to Gaussian excitation. In recent years, substantial progress has been made by tailoring the *sequential importance sampling* (SIS) methods [35], where the ISD is iteratively refined, to rare-event problems. SIS and its modifications have been successfully used for estimating rare events in dynamic portfolio credit risk [19], structural reliability [33], and other areas.

4 Subset Simulation

The *subset simulation* (SS) method [4] is an advanced stochastic simulation method for estimating rare events which is based on *Markov chain Monte Carlo* (MCMC) [35, 44]. The basic idea behind SS is to represent a very small probability $p_{\mathcal{E}}$ of the rare-event \mathcal{E} as a product of larger probabilities of “more-frequent” events and then estimate these larger probabilities separately. To implement this idea, let

$$\mathbb{R}^D \equiv \mathcal{E}_0 \supset \mathcal{E}_1 \dots \supset \mathcal{E}_L \equiv \mathcal{E} \quad (30.19)$$

be a sequence of nested subsets of the uncertain excitation space starting from the entire space $\mathcal{E}_0 = \mathbb{R}^D$ and shrinking to the target rare-event $\mathcal{E}_L = \mathcal{E}$. By analogy with (30.3), subsets \mathcal{E}_i can be defined by relaxing the value of the critical threshold b :

$$\mathcal{E}_i = \left\{ U \in \mathbb{R}^D : \max_{t=0, \dots, T} g(X(t)) > b_i \right\} \quad (30.20)$$

where $b_1 < \dots < b_L = b$. In the actual implementation of SS, the number of subsets L and the values of intermediate thresholds $\{b_i\}$ are chosen adaptively.

Using the notion of conditional probability and exploiting the nesting of the subsets, the target probability $p_{\mathcal{E}}$ can be factorized as follows:

$$p_{\mathcal{E}} = \prod_{i=1}^L \mathbb{P}(\mathcal{E}_i | \mathcal{E}_{i-1}) \quad (30.21)$$

An important observation is that by choosing the intermediate thresholds $\{b_i\}$ appropriately, the conditional events $\{\mathcal{E}_i | \mathcal{E}_{i-1}\}$ can be made more frequent, and their

probabilities can be made large enough to be amenable to efficient estimation by MCS-like methods.

The first probability $\mathbb{P}(\mathcal{E}_1|\mathcal{E}_0) = \mathbb{P}(\mathcal{E}_1)$ can be readily estimated by standard MCS:

$$\mathbb{P}(\mathcal{E}_1) \approx \frac{1}{n} \sum_{j=1}^n I_{\mathcal{E}_1}(U_j), \quad (30.22)$$

where U_1, \dots, U_n are i.i.d. samples from $p(u)$. Estimating the remaining probabilities $\mathbb{P}(\mathcal{E}_i|\mathcal{E}_{i-1})$, $i \geq 2$, is more challenging since one needs to generate samples from the conditional distribution $p(u|\mathcal{E}_{i-1}) = \frac{I_{\mathcal{E}_{i-1}}(u)p(u)}{\mathbb{P}(\mathcal{E}_{i-1})}$, which, in general, is not a trivial task. Notice that a sample U from $p(u|\mathcal{E}_{i-1})$ is one drawn from $p(u)$ that lies in \mathcal{E}_{i-1} . However, it is not efficient to use MCS for generating samples from $p(u|\mathcal{E}_{i-1})$: sampling from $p(u)$ and accepting only those samples that belong to \mathcal{E}_{i-1} is computationally very expensive, especially at higher levels i .

In standard SS, samples from the conditional distribution $p(u|\mathcal{E}_{i-1})$ are generated by the *modified Metropolis algorithm* (MMA) [4] which belongs to the family of MCMC methods for sampling from complex probability distributions that are difficult to sample directly from [35, 44]. An alternative strategy – *splitting* – is described in the next section.

The MMA algorithm is a component-wise version of the original Metropolis algorithm [38]. It is specifically tailored for sampling from high-dimensional conditional distributions and works as follows. First, without loss of generality, assume that $p(u) = \prod_{k=1}^D p_k(u_k)$, i.e., components of U are independent. This assumption is indeed not a limitation, since in simulation one always starts from independent variables to generate correlated excitation histories U . Suppose further that some vector $U_1 \in \mathbb{R}^D$ is already distributed according to the target conditional distribution, $U_1 \sim p(u|\mathcal{E}_{i-1})$. MMA prescribes how to generate another vector $U_2 \sim p(u|\mathcal{E}_{i-1})$, and it consists of two steps:

1. Generate a “candidate” state V as follows: first, for each component $k = 1, \dots, D$ of V , sample $v(k)$ from the symmetric univariate *proposal distribution* $q_{k,i}(v|U_1(k))$ centered on the k^{th} component of U_1 , where symmetry means that $q_{k,i}(v|u) = q_{k,i}(u|v)$; then, compute the *acceptance ratio* $r_k = \frac{p_k(v(k))}{p_k(U_1(k))}$; and finally, set

$$V(k) = \begin{cases} v(k), & \text{with probability } \min\{1, r_k\} \\ U_1(k), & \text{with probability } 1 - \min\{1, r_k\} \end{cases} \quad (30.23)$$

2. Accept or reject the candidate state V :

$$U_2 = \begin{cases} V, & \text{if } V \in \mathcal{E}_{i-1} \\ U_1, & \text{if } V \notin \mathcal{E}_{i-1} \end{cases} \quad (30.24)$$

It can be shown that U_2 generated by MMA is indeed distributed according to the target conditional distribution $p(u|\mathcal{E}_{i-1})$ when U_1 is [4]. For a detailed discussion of MMA, the reader is referred to [56].

The procedure for generating conditional samples at level i is as follows. Starting from a “seed” $U_1 \sim p(u|\mathcal{E}_{i-1})$, one can now use MMA to generate a sequence of random vectors U_1, \dots, U_n , called a *Markov chain*, distributed according to $p(u|\mathcal{E}_{i-1})$. At each step, U_j is used to generate the next state U_{j+1} . Note that although these MCMC samples are identically distributed, they are clearly not independent: the correlation between successive samples is due to the proposal PDFs $\{q_{k,i}\}$ at level i that govern the generation of U_{j+1} from U_j . Nevertheless, U_1, \dots, U_n can still be used for statistical averaging as if they were i.i.d., although with certain reduction in efficiency [4]. In particular, similar to (30.22), the conditional probability $\mathbb{P}(\mathcal{E}_i|\mathcal{E}_{i-1})$ can be estimated as follows:

$$\mathbb{P}(\mathcal{E}_i|\mathcal{E}_{i-1}) \approx \frac{1}{n} \sum_{j=1}^n I_{\mathcal{E}_i}(U_j) \quad (30.25)$$

To obtain an estimator for the target probability $p_{\mathcal{E}}$, it remains to multiply the MCS (30.22) and MCMC (30.25) estimators of all factors in (30.21). In real applications, however, it is often difficult to rationally define the subsets $\{\mathcal{E}_i\}$ in advance, since it is not clear how to specify the values of the intermediate thresholds $\{b_i\}$. In SS, this is done adaptively. Specifically, let $U_1^{(0)}, \dots, U_n^{(0)}$ be the MCS samples from $p(u)$, $X_1^{(0)}, \dots, X_n^{(0)}$ be the corresponding trajectories from (30.1), and $G_j^{(0)} = \max_{t=0, \dots, T} g(X_j^{(0)}(t))$ be the resulting performance values. Assume that the sequence $\{G_j^{(0)}\}$ is ordered in a nonincreasing order, i.e., $G_1^{(0)} \geq \dots \geq G_n^{(0)}$, renumbering the samples where necessary. Define the first intermediate threshold b_1 as follows:

$$b_1 = \frac{G_{np_0}^{(0)} + G_{np_0+1}^{(0)}}{2} \quad (30.26)$$

where p_0 is a chosen probability satisfying $0 < p_0 < 1$. This choice of b_1 has two immediate consequences: first, the MCS estimate of $\mathbb{P}(\mathcal{E}_1)$ in (30.22) is exactly p_0 , and, second, $U_1^{(0)}, \dots, U_{np_0}^{(0)}$ not only belong to \mathcal{E}_1 but also are distributed according to the conditional distribution $p(u|\mathcal{E}_1)$. Each of these np_0 samples can now be used as mother seeds in MMA to generate $(\frac{1}{p_0} - 1)$ offspring, giving a total of n samples $U_1^{(1)}, \dots, U_n^{(1)} \sim p(u|\mathcal{E}_1)$. Since these seeds start in the stationary state $p(u|\mathcal{E}_1)$ of the Markov chain, this MCMC method gives *perfect sampling*, i.e., no wasteful burn-in period is needed. Similarly, b_2 is defined as

$$b_2 = \frac{G_{np_0}^{(1)} + G_{np_0+1}^{(1)}}{2} \quad (30.27)$$

where $\{G_j^{(1)}\}$ are the (ordered) performance values corresponding to excitations $\{U_j^{(1)}\}$. Again by construction, the estimate (30.25) gives $\mathbb{P}(\mathcal{E}_2|\mathcal{E}_1) \approx p_0$, and $U_1^{(1)}, \dots, U_{n^{(1)}}^{(1)} \sim p(u|\mathcal{E}_2)$. The SS method proceeds in this manner until the target rare-event \mathcal{E} is reached and is sufficiently sampled. All but the last factor in (30.21) are approximated by p_0 , and the last factor $\mathbb{P}(\mathcal{E}|\mathcal{E}_{L-1}) \approx \frac{n_{\mathcal{E}}}{n} \geq p_0$, where $n_{\mathcal{E}}$ is the number of samples in \mathcal{E} among $U_1^{(L-1)}, \dots, U_n^{(L-1)} \sim p(u|\mathcal{E}_{L-1})$. The method is more formally summarized in the following pseudo-code.

Subset Simulation

Input :

- ▷ n , number of samples per conditional level.
- ▷ p_0 , level probability; e.g. $p_0 = 0.1$
- ▷ $\{q_{k,i}\}$, proposal distributions; e.g. $q_{k,i}(v|u) = \mathcal{N}(v|u, \sigma_{k,i}^2)$

Algorithm :

```

Set  $i = 0$ , number of conditional level.
Set  $n_{\mathcal{E}}^{(0)} = 0$ , number of the MCS samples in  $\mathcal{E}$ .
Sample the input excitations  $U_1^{(0)}, \dots, U_n^{(0)} \sim p(u)$ .
Compute the corresponding trajectories  $X_1^{(0)}, \dots, X_n^{(0)}$ .
for  $j = 1, \dots, n$  do
    if  $G_j^{(0)} = \max_{t=0, \dots, T} g(X_j^{(0)}(t)) > b$  do
         $n_{\mathcal{E}}^{(0)} \leftarrow n_{\mathcal{E}}^{(0)} + 1$ 
    end if
end for
while  $n_{\mathcal{E}}^{(i)}/n < p_0$  do
     $i \leftarrow i + 1$ , a new subset  $\mathcal{E}_i$  is needed.
    Sort  $\{U_j^{(i-1)}\}$  so that  $G_1^{(i-1)} \geq G_2^{(i-1)} \geq \dots \geq G_n^{(i-1)}$ 
    Define the  $i^{\text{th}}$  intermediate threshold:  $b_i = (G_{n^{(i-1)}}^{(i-1)} + G_{n^{(i-1)}+1}^{(i-1)})/2$ 
    for  $j = 1, \dots, n^{(i)}$  do
        Using  $W_{j,1} = U_j^{(i-1)} \sim p(u|\mathcal{E}_i)$  as a seed, use MMA to generate
         $(\frac{1}{p_0} - 1)$  additional states of a Markov chain
         $W_{j,1}, \dots, W_{j,1/p_0} \sim p(u|\mathcal{E}_i)$ .
    end for
    Renumber:  $\{W_{j,s}\}_{j=1,s=1}^{n^{(i-1)}/p_0} \mapsto U_1^{(i)}, \dots, U_n^{(i)} \sim p(u|\mathcal{E}_i)$ 
    Compute the corresponding trajectories  $X_1^{(i)}, \dots, X_n^{(i)}$ 
    for  $j = 1, \dots, n$  do
        if  $G_j^{(i)} = \max_{t=0, \dots, T} g(X_j^{(i)}(t)) > b$  do
             $n_{\mathcal{E}}^{(i)} \leftarrow n_{\mathcal{E}}^{(i)} + 1$ 
        end if
    end for
end while
 $L = i + 1$ , number of levels, i.e. subsets  $\mathcal{E}_i$  in (30.19) and (30.20)
 $N = n + n(1 - p_0)(L - 1)$ , total number of samples.

```

Output :

► $\hat{p}_{\mathcal{E}}^{SS} = p_0^{L-1} \frac{n_{\mathcal{E}}^{(L-1)}}{n}$, SS estimate of p_F :

Implementation details of SS, in particular the choice of level probability p_0 and proposal distributions $\{q_k\}$, are thoroughly discussed in [56]. It has been confirmed that $p_0 = 0.1$ proposed in the original paper [4] is a nearly optimal value. The choice of $\{q_{k,i}\}$ is more delicate, since the efficiency of MMA strongly depends on the proposal PDF variances in a nontrivial way: proposal PDFs with both small and large variance tend to increase the correlation between successive samples, making statistical averaging in (30.25) less efficient. In general, finding the optimal variance of proposal distributions is a challenging task not only for MMA but also for almost all MCMC algorithms. Nevertheless, it has been found in many applications that using $q_{k,i}(v|u) = \mathcal{N}(v|u, \sigma_{k,i}^2)$, the Gaussian distribution with mean u and variance $\sigma_{k,i}^2$ yields good efficiency if $\sigma_{k,i}^2 = \sigma_0^2$ and $p(u)$ is a multi-dimensional Gaussian with all variances equal to σ_0^2 . For an adaptive strategy for choosing $\{q_{k,i}\}$, the reader is referred to [56]; for example, $\sigma_{k,i}^2 = \sigma_i^2$ can be chosen so that the observed average acceptance rate in MMA, based on a subset of samples at level i , lies in the interval [0.3, 0.5].

It can be shown [4, 7] that, given p_ε , p_0 , and the total number of samples N , the c.o.v. of the SS estimator p_ε^{SS} is given by

$$\delta^2(p_\varepsilon^{SS}|p_\varepsilon, p_0, N) = \frac{(1 + \gamma)(1 - p_0)}{Np_0(\ln p_0^{-1})^r} (\ln p_\varepsilon^{-1})^r \quad (30.28)$$

where $2 \leq r \leq 3$ and γ is approximately a constant that depends on the state correlation of the Markov chain at each level. Numerical experiments show that $r = 2$ gives a good approximation to the c.o.v. and that $\gamma \approx 3$ if the proposal variance σ_i^2 for each level is appropriately chosen [4, 7, 56]. It follows from (30.13) that $\delta_{MCS}^2 \propto p_\varepsilon^{-1}$ for MCS, while for SS, $\delta_{SS}^2 \propto (\ln p_\varepsilon^{-1})^r$. This drastically different scaling behavior of the c.o.v.'s with small p_ε directly exhibits the improvement in efficiency.

To compare an advanced stochastic simulation algorithm directly with MCS, which is always applicable (but not efficient) for rare-event estimation, [11] introduced the relative computation efficiency of an algorithm, η_A , which is defined as the ratio of the number of samples N_{MCS} required by MCS to the number of samples N_A required by the algorithm for the same c.o.v. δ . The *relative efficiency* of SS is then

$$\eta_{SS} = \frac{N_{MCS}}{N_{SS}} = \frac{p_0(\ln p_0^{-1})^r}{(1 + \gamma)(1 - p_0)p_\varepsilon(\ln p_\varepsilon^{-1})^r} \approx \frac{0.03 p_\varepsilon^{-1}}{(\log_{10} p_\varepsilon^{-1})^2} \quad (30.29)$$

for $r = 2$, $\gamma = 3$, and $p_0 = 0.1$. For rare events, p_ε^{-1} is very large, and, as expected, SS outperforms MCS; for example, if $p_\varepsilon = 10^{-6}$, then $\eta_{SS} \approx 800$.

In recent years, a number of modifications of SS have been proposed, including SS with splitting [17] (described in the next section), hybrid SS [18], two-stage SS [30], spherical SS [31], and SS with delayed rejection [57]. A Bayesian post-processor for SS, which generalizes the Bayesian interpretation of MCS described

above, was developed in [56]. In the original paper [4], SS was developed for estimating reliability of complex civil engineering structures such as tall buildings and bridges at risk from earthquakes. It was applied for this purpose in [5] and [24]. SS and its modifications have also been successfully applied to rare-event simulation in fire risk analysis [8], aerospace [39, 52], nuclear [16], wind [49] and geotechnical engineering [46], and other fields. A detailed exposition of SS at an introductory level and a MATLAB code implementing the above pseudo-code are given in [55]. For more advanced and complete reading, the fundamental monograph on SS [7] is strongly recommended.

5 Splitting

In the previously presented stochastic simulation methods, samples of the input and output discrete-time histories, $\{U(t) : t = 0, \dots, T\} \subset \mathbb{R}^m$ and $\{X(t) : t = 0, \dots, T\} \subset \mathbb{R}^n$, are viewed geometrically as vectors U and X that define points in the vector spaces $\mathbb{R}^{(T+1)m}$ and $\mathbb{R}^{(T+1)n}$, respectively. In the splitting method, however, samples of the input and output histories are viewed as trajectories defining paths of length $(T + 1)$ in \mathbb{R}^m and \mathbb{R}^n , respectively. Samples that reach a certain designated subset in the input or output spaces at some time are treated as “mothers” and are then split into multiple offspring trajectories by separate sampling of the input histories subsequent to the splitting time. These multiple trajectories can themselves subsequently be treated as mothers if they reach another designated subset nested inside the first subset at some later time and so be split into multiple offspring trajectories. This is continued until a certain number of the trajectories reach the smallest nested subset corresponding to the rare event of interest.

Splitting methods were originally introduced by Kahn and Harris [28], and they have been extensively studied (e.g., [12, 17, 42, 54]). We describe splitting here by using the framework of subset simulation where the only change is that the conditional sampling in the nested subsets is done by splitting the trajectories that reach each subset, rather than using them as seeds to generate more samples from Markov chains in their stationary state. As a result, only standard Monte Carlo simulation is needed, instead of MCMC simulation.

The procedure in [17] is followed here to generate offspring trajectories at the i^{th} level ($i = 1, \dots, L$) of subset simulation from each of the mother trajectories in \mathcal{E}_i constructed from samples from the previous level, except that we present it from the viewpoint of trajectories in the input space, rather than the output space. Therefore, at the i^{th} level, each of the np_0 sampled input histories U_j , $j = 1, \dots, np_0$, from the previous level that satisfy $U_j \in \mathcal{E}_i$, as defined in (30.20) (so the corresponding output history X_j satisfies $\max_{t=0, \dots, T} g(X_j(t)) > b_i$), is split at their first-passage time

$$t_j = \min\{t = 0, \dots, T : g(X_j(t)) > b_i\} \quad (30.30)$$

This means that the mother trajectory U_j is partitioned as $[U_j^-, U_j^+]$ where $U_j^- = [U_j(0), \dots, U_j(t_j)]$ and $U_j^+ = [U_j(t_j + 1), \dots, U_j(T)]$; then a subtrajectory sample $\tilde{U}_j^+ = [\tilde{U}_j(t_j + 1), \dots, \tilde{U}_j(T)]$ is drawn from

$$p(u_j^+ | U_j^-, \mathcal{E}_i) = \frac{\mathbb{P}(\mathcal{E}_i | u_j^+, U_j^-)}{\mathbb{P}(\mathcal{E}_i | U_j^-)} p(u_j^+ | U_j^-) = p(u_j^+ | U_j^-) = p(u_j^+) \quad (30.31)$$

where the last equation follows if one assumes independence of the $U_j(t), t = 0, \dots, T$ (although it is not necessary). Also, $\mathbb{P}(\mathcal{E}_i | u_j^+, U_j^-) = 1 = \mathbb{P}(\mathcal{E}_i | U_j^-)$. Note that the new input sample $\tilde{U}_j = [U_j^-, \tilde{U}_j^+]$ also lies in \mathcal{E}_i since it has the subtrajectory U_j^- in common with U_j , which implies that the corresponding outputs at the first-passage time t_j are equal: $\tilde{X}_j(t_j) = X_j(t_j) > b_i$. The offspring trajectory \tilde{U}_j is a sample from $p(u)$ lying in \mathcal{E}_i , and so, like its mother U_j , it is a sample from $p(u|\mathcal{E}_i)$. This process is repeated to generate $(\frac{1}{p_0} - 1)$ such offspring trajectories from each mother trajectory, giving a total of $np_0(\frac{1}{p_0} - 1) + np_0 = n$ input histories that are samples from $p(u|\mathcal{E}_i)$ at the i^{th} level.

The pseudo-code for the splitting version of subset simulation is the same as the previously presented pseudo-code for the MCMC version except that the part describing the generation of conditional samples at level i using the MMA algorithm is replaced by

Generation of conditional samples at level i with Splitting

```

for  $j = 1, \dots, np_0$  do
    Using  $U_j^{(i-1)} \sim p(u|\mathcal{E}_i)$  as a mother trajectory, generate  $(\frac{1}{p_0} - 1)$  offspring
    trajectories by splitting of this input trajectory.
end for
```

To generate the same number of samples n at a level, the splitting version of subset simulation is slightly more efficient than the MCMC version using MMA because when generating the conditional samples, the input offspring trajectories $\tilde{U} = [\tilde{U}^-, \tilde{U}^+]$ already have made available the first part \tilde{X}^- of the corresponding output trajectory $\tilde{X} = [\tilde{X}^-, \tilde{X}^+]$. Thus, (30.1) need only be solved for \tilde{X}^+ starting from the final value of \tilde{X}^- (which corresponds to the first-passage time of the trajectory). A disadvantage of the splitting version is that it cannot handle parameter uncertainty in the model in (30.1) since the offspring trajectories must use (30.1) with the same parameter values as their mothers. Furthermore, the splitting version applies only to dynamic problems, as considered here. The MCMC version of subset simulation can handle parameter uncertainty and is applicable to both static and dynamic uncertainty quantification problems.

Ching, Au, and Beck [17] discuss the statistical properties of the estimators corresponding to (30.22) and (30.25) when the sampling at each level is done by the

trajectory splitting method. They show that as long as the conditional probability in subset simulation satisfies $p_0 \geq 0.1$, the coefficient of variation for $p_{\mathcal{E}}$ when estimating it by (30.21) and (30.25) is insensitive to p_0 .

Ching, Beck, and Au [18] also introduce a hybrid version of subset simulation that combines some advantages of the splitting and MCMC versions when generating the conditional samples $U_j, j = 1, \dots, n$ at each level. It is limited to dynamic problems because of the splitting, but it can handle parameter uncertainty through using MCMC. All three variants of subset simulation are applied to a series of benchmark reliability problems in [6]; their results imply that for the same computational effort in the dynamic benchmark problems, the hybrid version gives slightly better accuracy for the rare-event probability than the MCMC version. For a comparison between these results and those of other stochastic simulation methods that are applied to some of the same benchmark problems (e.g., spherical subset simulation, auxiliary domain method, and line sampling), the reader may wish to check [47].

6 Illustrative Example

To illustrate MCS, IS, and SS with MCMC and splitting for rare-event estimation, consider the following forced Lorenz system of ordinary differential equations:

$$\dot{X}_1 = \sigma(X_2 - X_1) + U(t) \quad (30.32)$$

$$\dot{X}_2 = rX_1 - X_2 - X_1X_3 \quad (30.33)$$

$$\dot{X}_3 = X_1X_2 - bX_3 \quad (30.34)$$

where $X(t) = (X_1(t), X_2(t), X_3(t))$ defines the system state at time t and $U(t)$ is the external excitation to the system. If $U(t) \equiv 0$, these are the original equations due to E. N. Lorenz that he derived from a model of fluid convection [36]. In this example, the three parameters σ , r , and b are set to $\sigma = 3$, $b = 1$, and $r = 26$. It is well known (e.g., [50]) that in this case, the Lorenz system has three unstable equilibrium points, one of which is

$$X^* = \left(\sqrt{b(r-1)}, \sqrt{b(r-1)}, r-1 \right) = (5, 5, 25) \quad (30.35)$$

that lies on one “wing” of the “butterfly” attractor. Let

$$X(0) = X^* + (1/2, 1/2, 1/2) = (5.5, 5.5, 25.5) \quad (30.36)$$

be the initial condition and $X(t)$ be the corresponding solution. Lorenz showed [36] that the solution of (30.32), (30.33), and (30.34) with $U(t) \equiv 0$ always (for any t) stays inside the bounding ellipsoid \mathbb{E} :

$$\frac{X_1(t)^2}{R^2 \frac{b}{\sigma}} + \frac{X_2(t)^2}{bR^2} + \frac{(X_3(t) - R)^2}{R^2} \leq 1, \quad R = r + \sigma \quad (30.37)$$

Suppose that the system is now excited by $U(t) = \alpha B(t)$, where $B(t)$ is the standard Brownian process (Gaussian white noise) and α is some scaling constant. The uncertain stochastic excitation $U(t)$ makes the corresponding system trajectory $X(t)$ also stochastic. Let us say that the event \mathcal{E} occurs if $X(t)$ leaves the bounding ellipsoid \mathbb{E} during the time interval of interest $[0, T]$.

The discretization of the excitation U is obtained by the standard discretization of the Brownian process:

$$U(0) = 0, \quad U(k) = \alpha B(k \Delta t) = U(k-1) + \alpha \sqrt{\Delta t} Z_k = \alpha \sqrt{\Delta t} \sum_{i=1}^k Z_i, \quad (30.38)$$

where $\Delta t = 0.1$ s is the sampling interval and $k = 1, \dots, D = T/\Delta t$, and Z_1, \dots, Z_D are i.i.d. standard Gaussian random variables. The target domain $\mathcal{E} \subset \mathbb{R}^D$ is then

$$\mathcal{E} = \{(Z_1, \dots, Z_D) : \max_{0 \leq k \leq D} g(k) > 1\}, \quad (30.39)$$

where the system response $g(k)$ at time $t = k \Delta t$ is

$$g(k) = \frac{X_1(k \Delta t)^2}{R^2 \frac{b}{\sigma}} + \frac{X_2(k \Delta t)^2}{bR^2} + \frac{(X_3(k \Delta t) - R)^2}{R^2} \quad (30.40)$$

Figure 30.1 shows the solution of the unforced Lorenz system (with $\alpha = 0$ so $U(t) = 0$), and an example of the solution of the forced system (with $\alpha = 3$) that corresponds to excitation $U \in \mathcal{E}$ (slightly abusing notation, $U = U(Z_1, \dots, Z_D) \in \mathcal{E}$ means that the corresponding Gaussian vector $(Z_1, \dots, Z_D) \in \mathcal{E}$).

Monte Carlo Simulation: For $\alpha = 3$, Fig. 30.2 shows the probability $p_{\mathcal{E}}$ of event \mathcal{E} as a function of T estimated using standard MCS:

$$\hat{p}_{\mathcal{E}}^{MCS} = \frac{1}{N} \sum_{i=1}^N I_{\mathcal{E}}(Z^{(i)}) \quad (30.41)$$

where $Z^{(i)} = (Z_1^{(i)}, \dots, Z_D^{(i)}) \sim \phi(z)$ are i.i.d. samples from the standard D -dimensional Gaussian PDF $\phi(z)$. For each value of T , $N = 10^4$ samples were used. When $T < 25$, the accuracy of the MCS estimate (30.41) begins to degenerate since the total number of samples N becomes too small for the corresponding target probability. Moreover, for $T < 15$, none of the N -generated MCS samples belong to the target domain \mathcal{E} , making the MCS estimate zero. Figure 30.2 shows, as expected, that $p_{\mathcal{E}}$ is an increasing function of T , since the more time the system has, the more likely its trajectory eventually penetrates the boundary of ellipsoid \mathbb{E} .

Importance Sampling: IS is a variance reduction technique, and, as it was discussed in previous sections, its efficiency critically depends on the choice of the

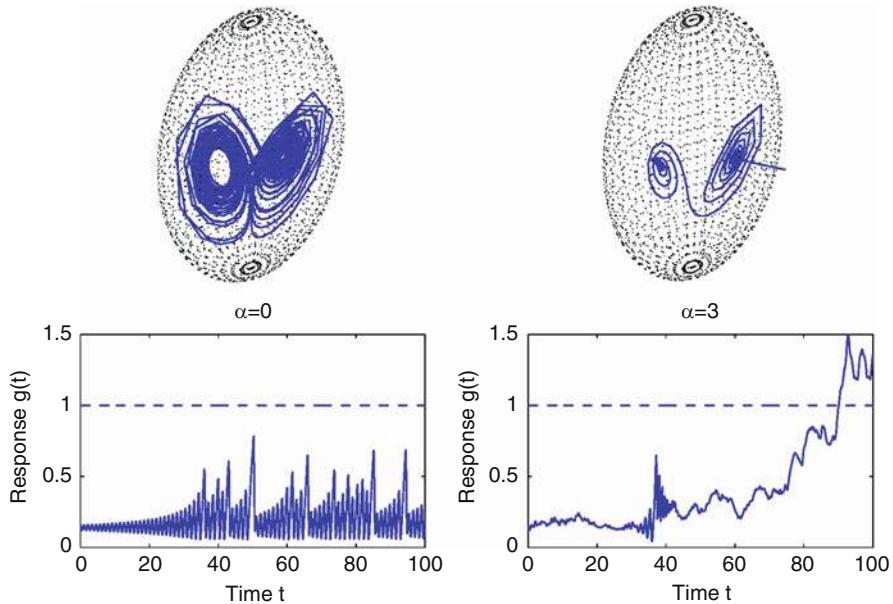

Fig. 30.1 The left column shows the solution of the unexcited Lorenz system ($\alpha = 0$) enclosed in the bounding ellipsoid \mathbb{E} (top) and the corresponding response function $g(t)$ (bottom), where $t \in [0, T]$, $T = 100$. The right top panel shows the solution of the forced Lorenz system ($\alpha = 3$) that corresponds to an excitation $U \in \mathcal{E}$. As it is clearly seen, this solution leaves the ellipsoid \mathbb{E} . According to the response function $g(t)$ shown in the right bottom panel, this first-passage event happens around $t = 90$

ISD q . Usually some geometric information about the target domain \mathcal{E} is needed for constructing a good ISD. To get some intuition, Fig. 30.3 shows the domain \mathcal{E} for two lower-dimensional cases: $T = 1$, $\Delta t = 0.5$ ($D = 2$) and $T = 1.5$, $\Delta t = 0.5$ ($D = 3$). Notice that in both cases, \mathcal{E} consists of two well-separated subsets, $\mathcal{E} = \mathcal{E}_- \cup \mathcal{E}_+$, which are approximately symmetric about the origin. This suggests that a good ISD must be a mixture of two distributions q_- and q_+ that effectively sample \mathcal{E}_- and \mathcal{E}_+ ,

$$q(z) = \frac{q_-(z) + q_+(z)}{2} \quad (30.42)$$

In this example, three different ISDs, denoted q_1 , q_2 , and q_3 , are considered:

Case 1: $q_{\pm}(z) = \phi(z| \pm z_{\mathcal{E}})$, where $z_{\mathcal{E}} \sim \phi(z|\mathcal{E})$. That is, we first generate a sample $z_{\mathcal{E}} \in \mathcal{E}$ and then take ISD q_1 as the mixture of Gaussian PDFs centered at $z_{\mathcal{E}}$ and $-z_{\mathcal{E}}$.

Case 2: $q_{\pm}(z) = \phi(z| \pm z_{\mathcal{E}}^*)$, where $z_{\mathcal{E}}^*$ is obtained as follows. First we generate $n = 1000$ samples from $\phi(z)$ and define $z_{\mathcal{E}}^*$ to be the sample in \mathcal{E} with the smallest norm. Sample $z_{\mathcal{E}}^*$ can be interpreted as the “best representative” of \mathcal{E}_- (or \mathcal{E}_+),

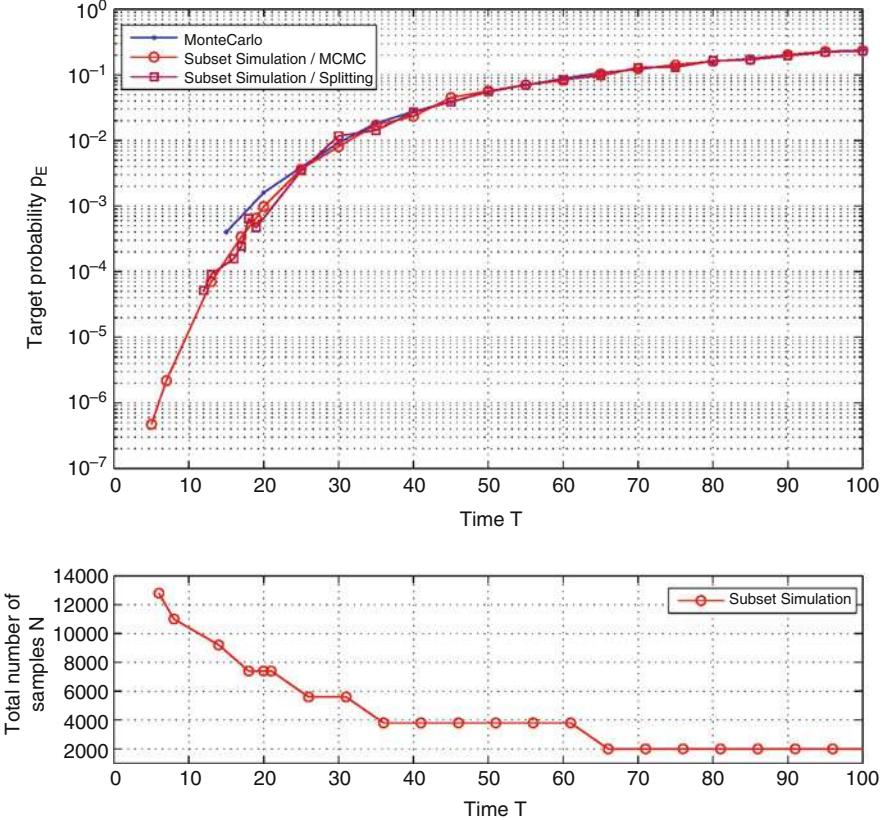

Fig. 30.2 Top panel shows the estimate of the probability $p_{\mathcal{E}}$ of event \mathcal{E} where $\alpha = 3$ as a function of duration time T . For each value of $T \in [5, 100]$, $N = 10^4$ samples were used in MCS, and $n = 2 \times 10^3$ samples per conditional level were used in the two versions of SS. The MCS and SS/splitting estimates for $p_{\mathcal{E}}$ are zero for $T < 15$ and $T < 12$, respectively. The bottom panel shows the total computational effort automatically chosen by both SS algorithms

since $\phi(z_{\mathcal{E}}^*)$ has the largest (among generated samples) value. We then take ISD q_2 as the mixture of Gaussian PDFs centered at $z_{\mathcal{E}}^*$ and $-z_{\mathcal{E}}^*$.

Case 3: To illustrate what happens if one ignores the geometric information about two components of \mathcal{E} , we choose $q_3(z) = \phi(z|z_{\mathcal{E}}^*)$, as given in Case 2.

Let $T = 1$ and $\alpha = 20$. The dimension of the uncertain excitation space is then $D = 10$. Table 30.1 shows the simulation results for the above three cases as well as for standard MCS. The IS method with q_1 , on average, correctly estimates $p_{\mathcal{E}}$. However, the c.o.v. of the estimate is very large, which results in large fluctuations of the estimate in independent runs. IS with q_2 works very well and outperforms MCS: the c.o.v. is reduced by half. Finally, IS with q_3 completely misses one component

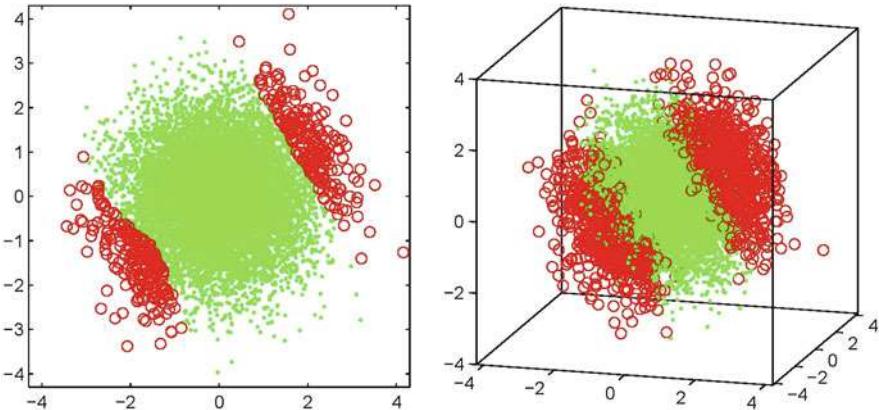

Fig. 30.3 Left panel: visualization of the domain \mathcal{E} in two-dimensional case $D = 2$, where $T = 1$, $\Delta t = 0.5$, and $\alpha = 20$. $N = 10^4$ samples were generated and marked by red circles (respectively, green dots) if they do (respectively, do not) belong to \mathcal{E} . Right panel: the same as on the left panel but with $D = 3$ and $T = 1.5$

Table 30.1 Simulation results for IS and MCS. For each method, mean values $\langle \hat{p}_{\mathcal{E}} \rangle$ of the estimates and their coefficient of variations $\delta(\hat{p}_{\mathcal{E}})$ are based on 100 independent runs

	$\langle \hat{p}_{\mathcal{E}} \rangle$	$\delta(\hat{p}_{\mathcal{E}})$
MCS	3.4×10^{-3}	17%
IS q_1	3.2×10^{-3}	132.4%
IS q_2	3.4×10^{-3}	8.3%
IS q_3	1.8×10^{-3}	5.5%

part of the target domain \mathcal{E} , and the resulting estimate is about half of the correct value. Note that the c.o.v. in this case is very small, which is very misleading.

It was mentioned in previous sections that IS is often not efficient in high dimensions because it becomes more difficult to construct a good ISD [5, 32]. To illustrate this effect, IS with q_2 was used to estimate $p_{\mathcal{E}}$ for a sequence of problems where the total duration time gradually grows from $T = 1$ to $T = 10$. This results in an increase of the dimension D of the underlying uncertain excitation space from 10 to 100. Figure 30.4 shows how the IS estimate degenerates as the dimension D of the problem increases. While IS is accurate when $D = 10$ ($T = 1$), it strongly underestimates the true value of $p_{\mathcal{E}}$ as D approaches 100 ($T = 10$).

Subset Simulation: SS is a more advanced simulation method, and, unlike IS, it does not suffer from the curse of dimensionality. For $\alpha = 3$, Fig. 30.2 shows the estimate of the target probability $p_{\mathcal{E}}$ as a function of T using SS with MCMC and splitting. For each value of T , $n = 2 \times 10^3$ samples were used in each conditional level in SS. Unlike MCS, SS is capable of efficiently simulating very rare events and estimating their small probabilities. The total computational effort, i.e., the total number N of samples automatically chosen by SS, is shown in the bottom panel of Fig. 30.2. Note that the larger the value of $p_{\mathcal{E}}$, the smaller the number of conditional levels in SS, and, therefore, the smaller the total number of samples N . The total

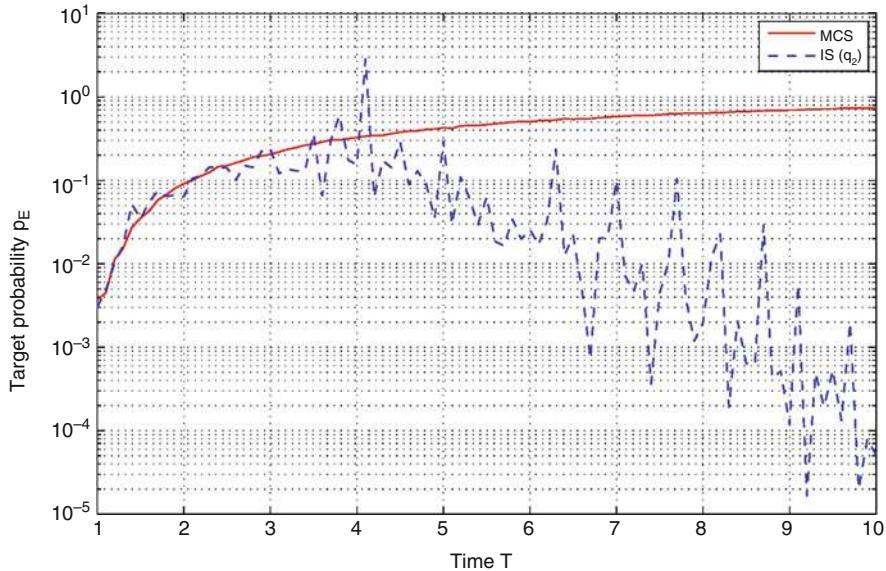

Fig. 30.4 Estimation of the target probability p_E as a function of duration time T . Solid red and dashed blue curves correspond to MCS and IS with q_2 , respectively. In this example, $\alpha = 20$ and $N = 10^4$ samples for each value of T are used. It is clearly visible how the IS estimate degenerates as the dimension D goes from 10 ($T = 1$) to 100 ($T = 10$)

computational effort in SS is thus a decreasing function of T . In this example, the original MCMC strategy [4] for generating conditional samples outperforms the splitting strategy [17] that exploits the causality of the system: while the SS/MCMC method works even in the most extreme case ($T = 5$), the SS/splitting estimate for p_E becomes zero for $T < 12$.

7 Conclusion

This chapter examines computational methods for rare-event simulation in the context of uncertainty quantification for dynamic systems that are subject to future uncertain excitation modeled as a stochastic process. The rare events are assumed to correspond to some time-varying performance quantity exceeding a specified threshold over a specified time duration, which usually means that the system performance fails to meet some design or operation specifications.

To analyze the reliability of the system against this performance failure, a computational model for the input-output behavior of the system is used to predict the performance of interest as a function of the input stochastic process discretized in time. This dynamic model may involve explicit treatment of parametric and non-parametric uncertainties that arise because the model only approximately describes

the real system behavior, implying that there are usually no true values of the model parameters and the accuracy of its predictions is uncertain. In the engineering literature, the mathematical problem to be solved numerically for the probability of performance failure, commonly called the failure probability, is referred to as the first-passage reliability problem. It does not have an analytical solution, and numerical solutions must face two challenging aspects:

1. The vector representing the time-discretized stochastic process that models the future system excitation lies in an input space of high dimension;
2. The dynamic systems of interest are assumed to be highly reliable so that their performance failure is a rare event, that is, the probability of its occurrence, $p_{\mathcal{E}}$, is very small.

As a result, standard Monte Carlo simulation and importance sampling methods are not computationally efficient for first-passage reliability problems. On the other hand, subset simulation has proved to be a general and powerful method for numerical solution of these problems. Like MCS, it is not affected by the dimension of the input space, and for a single run, it produces a plot of $p_{\mathcal{E}}$ vs. threshold b covering $p_{\mathcal{E}} \in [p_0^{-L}, 1]$, where L is the number of levels used. For a critical appraisal of methods for first-passage reliability problems in high dimensions, the reader may wish to check Schuëller et al. [48].

Several variants of subset simulation have been developed motivated by the goal of further improving the computational efficiency of the original version, although the efficiency gains, if any, are modest. All of them have an accuracy described by a coefficient of variation for the estimate of the rare-event probability that depends on $\ln(1/p_{\mathcal{E}})$ rather than $\sqrt{1/p_{\mathcal{E}}}$ as in standard Monte Carlo simulation. For all methods covered in this section, the dependence of this coefficient of variation on the number of samples N is proportional to $N^{-1/2}$. Therefore, in the case of very low probabilities, $p_{\mathcal{E}}$, it still requires thousands of simulations (large N) of the response time history based on a dynamic model as in (30.1) in order to get acceptable accuracy. For complex models, this computational effort may be prohibitive.

One approach to reduce the computational effort when estimating very low rare-event probabilities is to utilize additional information about the nature of the problem for specific classes of reliability problems (e.g., [2, 3]). Another more general approach is to construct surrogate models (meta-models) based on using a relatively small number of complex-model simulations as training data. The idea is to use a trained surrogate model to rapidly calculate an approximation of the response of the complex computational model as a substitute when drawing new samples. Various methods for constructing surrogate models have been applied in reliability engineering, including response surfaces [14], support vector machines [13, 23], neural networks [41], and Gaussian process modeling (Kriging) [21]. The latter method is a particularly powerful one because it also provides a probabilistic assessment of the approximation error. It deserves further exploration, especially with regard to the optimal balance between the accuracy of the surrogate model

as a function of the number of training samples from the complex model and the accuracy of the estimate of the rare-event probability as a function of the total number of samples from both the complex model and the surrogate model.

Part IV

Introduction to Sensitivity Analysis

Bertrand Iooss and Andrea Saltelli

Abstract

Sensitivity analysis provides users of mathematical and simulation models with tools to appreciate the dependency of the model output from model input and to investigate how important is each model input in determining its output. All application areas are concerned, from theoretical physics to engineering and socio-economics. This introductory paper provides the sensitivity analysis aims and objectives in order to explain the composition of the overall “Sensitivity Analysis” chapter of the Springer Handbook. It also describes the basic principles of sensitivity analysis, some classification grids to understand the application ranges of each method, a useful software package, and the notations used in the chapter papers. This section also offers a succinct description of sensitivity auditing, a new discipline that tests the entire inferential chain including model development, implicit assumptions, and normative issues and which is recommended when the inference provided by the model needs to feed into a regulatory or policy process. For the “Sensitivity Analysis” chapter, in addition to this introduction, eight papers have been written by around twenty practitioners from different fields of application. They cover the most widely used methods for this subject: the deterministic methods as the local sensitivity analysis, the experimental design strategies, the sampling-based and variance-based methods developed from the 1980s, and the new importance measures and metamodel-

1 Introduction

In many fields such as environmental risk assessment, behavior of agronomic systems, and structural reliability or operational safety, mathematical models are used for simulation, when experiments are too expensive or impracticable, and for prediction. Models are also used for uncertainty quantification and sensitivity analysis studies. Complex computer models calculate several output values (scalars or functions) that can depend on a high number of input parameters and physical variables. Some of these input parameters and variables may be unknown, unspecified, or defined with a large imprecision range. Inputs include engineering or operating variables, variables that describe field conditions, and variables that include unknown or partially known model parameters. In this context, the investigation of computer code experiments remains an important challenge.

This computer code exploration process is the main purpose of the sensitivity analysis (SA) process. SA allows the study of how uncertainty in the output of a model can be apportioned to different sources of uncertainty in the model input [51]. It may be used to determine the input variables that contribute the most to an output behavior, and the non-influential inputs, or to ascertain some interaction effects within the model. The SA process entails the computation and analysis of the so-called sensitivity or importance indices of the input variables with respect to a given quantity of interest in the model output. Importance measures of each uncertain input variable on the response variability provide a deeper understanding of the modeling in order to reduce the response uncertainties in the most effective way [23, 30, 57]. For instance, putting more efforts on knowledge of influential inputs will reduce their uncertainties. The underlying goals for SA are model calibration, model validation, and assisting with the decision-making process. This chapter is for engineers, researchers, and students who wish to apply SA techniques in any scientific field (physics, engineering, socio-economics, environmental studies, astronomy, etc.).

Several textbooks and specialist works [2, 3, 8, 10–12, 21, 56, 59] have covered most of the classic SA methods and objectives. In parallel, a scientific conference called SAMO (“Sensitivity Analysis on Model Output”) has been organized every 3 years since 1995 and extensively covers SA related subjects. Works presented at the different SAMO conferences can be found in their proceedings and several special issues published in international journals (mainly in “Reliability Engineering and System Safety”).

The main goal of this chapter is to provide an overview of classic and advanced SA methods, as none of the referenced works have reported all the concepts and methods in one single document. Researchers and engineers will find this document to be an up-to-date report on SA as it currently stands, although this scientific field remains very active in terms of new developments. The present chapter is only a snapshot in time and only covers well-established methods.

The next section of this paper provides the SA basic principles, including elementary graphic methods. In the third section, the SA methods contained in the chapter are described using a classification grid, together with the main mathematical notations of the chapter papers. Then, the SA-specialized packages developed in the R software environment are discussed. To finish this introductory paper, a process for the sensitivity auditing of models in a policy context is discussed, by providing seven rules that extend the use of SA. As discussed in Saltelli et al. [61], SA, mandated by existing guidelines as a good practice to use in conjunction with mathematical modeling, is insufficient to ensure quality in the treatment of scientific uncertainty for policy purposes. Finally, the concluding section lists some important and recent research works that could not be covered in the present chapter.

2 Basic Principles of Sensitivity Analysis

The first historical approach to SA is known as the local approach. The impact of small input perturbations on the model output is studied. These small perturbations occur around nominal values (the mean of a random variable, for instance). This deterministic approach consists of calculating or estimating the partial derivatives of the model at a specific point of the input variable space [68]. The use of adjoint-based methods allows models with a large number of input variables to be processed. Such approaches are particularly well-suited to tackling uncertainty analysis and SA and data assimilation problems in environmental systems such as those in climatology, oceanography, hydrogeology, etc. [3, 4, 48].

To overcome the limitations of local methods (linearity and normality assumptions, local variations), another class of methods has been developed in a statistical framework. In contrast to local SA, which studies how small variations in inputs around a given value change the value of the output, global sensitivity analysis (“global” in opposition to the local analysis) does not distinguish any initial set of model input values, but considers the numerical model in the entire domain of possible input parameter variations [57]. Thus, the global SA is an instrument used

to study a mathematical model as a whole rather than one of its solution around parameters specific values.

Numerical model users and modelers have shown high interest in these global tools that take full advantage of the development of computing equipment and numerical methods (see Helton [20], de Rocquigny et al. [10], and [11] for industrial and environmental applications). Saltelli et al. [58] emphasized the need to specify clearly the objectives of a study before performing an SA. These objectives may include:

- The factor prioritization setting, which aims at identifying the most important factors. The most important factor is the one that, if fixed, would lead to the greatest reduction in the uncertainty of the output;
- The factor fixing setting, which aims at reducing the number of uncertain inputs by fixing unimportant factors. Unimportant factors are the ones that, if fixed to any value, would not lead to a significant reduction of the output uncertainty. This is often a preliminary step before the calibration of model inputs using some available information (real output observations, constraints, etc.);
- The variance cutting setting, which can be a part of a risk assessment study. Its aim is to reduce the output uncertainty from its initial value to a lower pre-established threshold value;
- The factor mapping setting, which aims at identifying the important inputs in a specific domain of the output values, for example, which combination of factors produce output values above or below a given threshold.

In a deterministic framework, the model is analyzed at specific values for inputs, and the space of uncertain inputs may be explored in statistical approaches. In a probabilistic framework instead, the inputs are considered as random variables $\mathbf{X} = (X_1, \dots, X_d) \in \mathbb{R}^d$. The random vector \mathbf{X} has a known joint distribution, which reflects the uncertainty of the inputs. The computer code (also called “model”) is denoted $G(\cdot)$, and for a scalar output $Y \in \mathbb{R}$, the model formula writes

$$Y = G(\mathbf{X}). \quad (31.1)$$

Model function G can represent a system of differential equations, a program code, or any other correspondence between \mathbf{X} and Y values that can be calculated for a finite period of time. Therefore, the model output Y is also a random variable whose distribution is unknown (increasing the knowledge of it is the goal of the uncertainty propagation process). SA statistical methods consist of techniques stemming from the design of experiments theory (in the case of a large number of inputs), the Monte Carlo techniques (to obtain precise sensitivity results), and modern statistical learning methods (for complex CPU time-consuming numerical models).

For example, to begin with the most basic (and essential) methods, simple graphical tools can be applied on an initial sample of inputs/output $(x_1^{(i)}, \dots, x_d^{(i)}, y^{(i)})_{i=1 \dots n}$ (sampling strategies are numerous and are described in

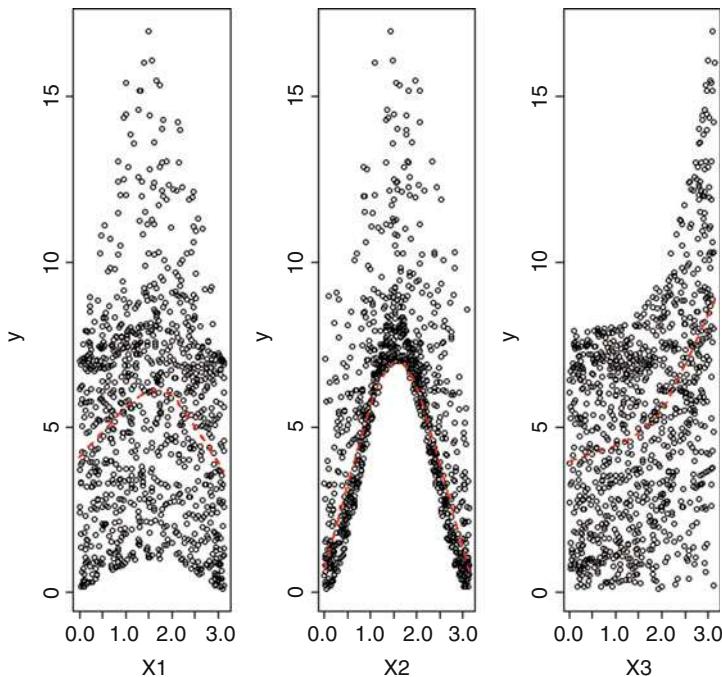

Fig. 31.1 Scatterplots of 200 simulations on a numerical model with three inputs (in abscissa of each plot) and one output (in ordinate). *Dotted curves* are local-polynomial-based smoothers

many other chapters of this handbook). To begin with, simple scatterplots between each input variable and the model output can allow the detection of linear or nonlinear input/output relation. Figure 31.1 gives an example of scatterplots on a simple function with three input variables and one output variable. As the two-dimensional scatterplots do not capture the possible interaction effects between the inputs, the cobweb plots [32] can be used. Also known as parallel coordinate plots, cobweb plots allow to visualize the simulations as a set of trajectories by joining the value (or the corresponding quantile) of each variables' combination of the simulation sample by a line (see Fig. 31.2): Each vertical line represents one variable, the last vertical line representing the output variable. In Fig. 31.2, the simulations leading to the smallest values of the model output have been highlighted in red. This allows to immediately understand that these simulations correspond to combinations of small and large values of the first and second inputs, respectively.

Moreover, from the same sample $\left(x_1^{(i)}, \dots, x_d^{(i)}, y^{(i)}\right)_{i=1 \dots n}$, quantitative global sensitivity measures can be easily estimated, as the linear (or Pearson) correlation coefficient and the rank (or Spearman) correlation coefficient [56]. It is also possible to fit a linear model explaining the behavior of Y given the values of \mathbf{X} , provided that the sample size n is sufficiently large (at least $n > d$). The main indices are then

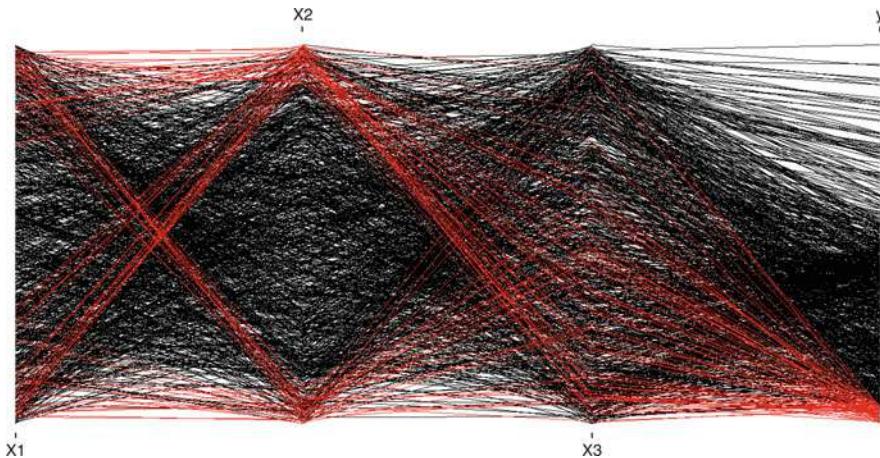

Fig. 31.2 Cobweb plot of 200 simulations of a numerical model with three inputs (first three columns) and one output (last column)

the Standard Regression Coefficients $\text{SRC}_j = \beta_j \sqrt{\frac{\text{Var}(X_j)}{\text{Var}(Y)}}$, where β_j is the linear regression coefficient associated to X_j . SRC_j^2 represents a share of variance if the linearity hypothesis is confirmed. Among many simple sensitivity indices, all these indices are included in the so-called sampling-based sensitivity analysis methods (see the description of the content of this chapter in the next section and Helton et al. [23]).

3 Methods Contained in the Chapter

Three families of methods are described in this chapter, based on which is the objective of the analysis:

1. First, screening techniques aim to a qualitative ranking of input factors at minimal cost in the number of model evaluations. Paper 2 (see ▶ Chap. 32, “Variational Methods”, written by Maëlle Nodet and Arthur Vidard) introduces the local SA based on variational methods, while Paper 3 (see ▶ Chap. 33, “Design of Experiments for Screening”, written by Sue Lewis and David Woods) makes an extensive review on design of experiments techniques, including some screening designs and numerical exploration designs specifically developed in the context of computer experiments;
2. Second, sampling-based methods are described. Paper 4 (see ▶ Chap. 34, “Weights and Importance in Composite Indicators: Mind the Gap”, written by William Becker, Paolo Paruolo, Michaela Saisana, and Andrea Saltelli)

shows how, from an initial sample of input and output values, quantitative sensitivity indices can be obtained by various methods (correlation, multiple linear regression, nonparametric regression) and applied in analyzing composite indicators. In Paper 5 (see ► Chap. 35, “[Variance-Based Sensitivity Analysis: Theory and Estimation Algorithms](#)”, written by Clémentine Prieur and Stefano Tarantola), the definitions of the variance-based importance measures (the so-called Sobol indices) and the algorithms to calculate them will be detailed. In Paper 6 (see ► Chap. 36, “[Derivative-Based Global Sensitivity Measures](#)”, written by Sergeï Kucherenko and Bertrand Iooss), the global SA based on derivatives sample (the DGSM indices) are explained, while in Paper 7 (see ► Chap. 37, “[Moment-Independent and Reliability-Based Importance Measures](#)”, written by Emanuele Borgonovo and Bertrand Iooss), the moment-independent and reliability importance measures are described.

3. Third, in-depth exploration of model behavior with respect to input variation can be carried out. Paper 8 (see ► Chap. 38, “[Metamodel-Based Sensitivity Analysis: Polynomial Chaos Expansions and Gaussian Processes](#)”, written by Loïc Le Gratiet, Stefano Marelli, and Bruno Sudret) includes recent advances made in the modeling of computer experiments. A metamodel is used as a surrogate model of the computer model with any SA techniques, when the computer model is too CPU time-consuming to allow a sufficient number of model calculations. Special attention is paid to two of the most popular metamodels: the polynomial chaos expansion and the Gaussian process model, for which the Sobol indices can be efficiently obtained. Finally, Paper 9 (see ► Chap. 39, “[Sensitivity Analysis of Spatial and/or Temporal Phenomena](#)”, written by Amandine Marrel, Nathalie Saint Geours, and Matthias De Lozzo) extends the SA tools in the context of temporal and/or spatial phenomena.

All the SA techniques explained in this chapter present a trade-off between the number of model computations required and the assumed model complexity. Figure 31.3 proposes a coarse classification of the global method families described before. This figure shows how to place a method depending on its required number of computations and its underlying hypothesis on the complexity of the G model. For example, “non-monotonic” means that the method can be applied to non-monotonic models, as of course to monotonic and linear ones. A distinction is made between screening techniques (identification of non-influential variables among a large number of variables) and more precise variance-based quantitative methods. As most of the methods have a dimension-dependent cost in terms of required model evaluations, another distinction is made with the few methods whose costs are dimension independent.

With the same axes than the previous figure, Fig. 31.4 proposes a more accurate classification of the classic global SA methods described in the present SA chapter. Note that this classification is not exhaustive and does not take full account of ongoing attempts to improve the existing methods. Overall, this classification tool has several levels of reading:

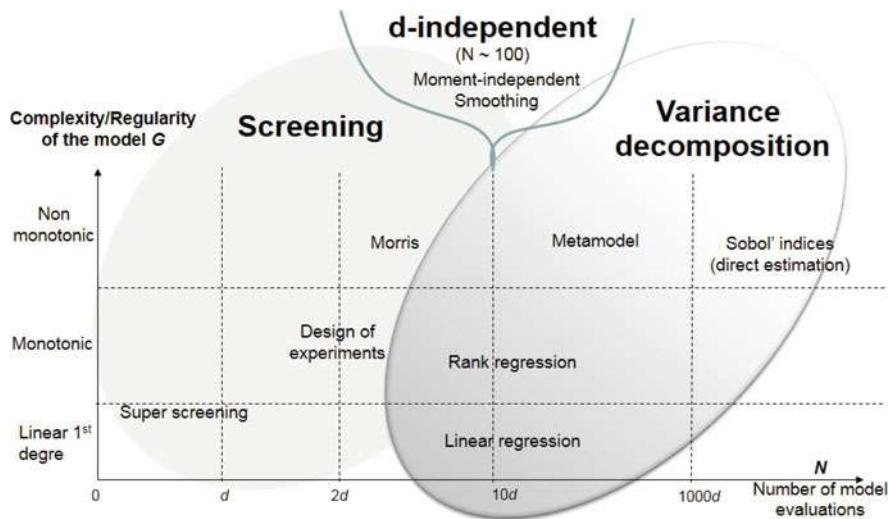

Fig. 31.3 Coarse classification of main global SA methods in terms of required number of model evaluations and model complexity

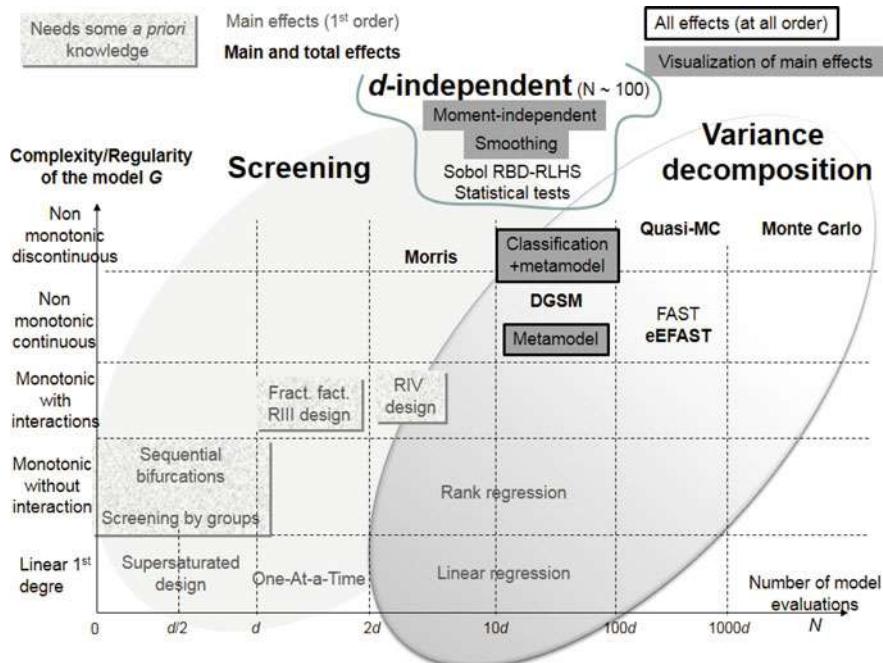

Fig. 31.4 Classification of global SA methods in terms of the required number of model evaluations and model complexity

- positioning methods based on their cost in terms of the number of model calls. Most of these methods linearly depend on the dimension (number of inputs), except for the moment-independent measures (estimated with given-data approaches), smoothing methods, Sobol-RBD (random balance design), Sobol-RLHS (replicated Latin hypercube sampling) and statistical tests;
- positioning methods based on assumptions about model complexity and regularity;
- distinguishing the type of information provided by each method;
- identifying methods which require some prior knowledge about the model behavior.

Each of these techniques corresponds to different categories of problems met in practice. One should use the simplest method that is adapted to the study's objectives, the number of numerical model evaluations that can be performed, and the prior knowledge on the model's regularity. Each sensitivity analysis should include a validation step, which helps to understand if another method should be applied, if the number of model evaluations should be increased, and so on. Based on the characteristics of the different methods, some authors [10, 26] have proposed decision trees to help the practitioner to choose the most appropriate method for their problem and model.

Finally, the different papers of this chapter use the same mathematical notations, which are summarized below:

$G(\cdot)$	Numerical model
N, n	Sample sizes
d	Dimension of an input vector
p	Dimension of an output vector
$\mathbf{x} = (x_1, \dots, x_d)$	Deterministic input vector
$\mathbf{X} = (X_1, \dots, X_d)$	Random input vector
x_j, X_j	Deterministic and random input variable
\mathbf{x}^T	Transpose of \mathbf{x}
$\mathbf{x}_{\sim i} = \mathbf{x}_{-i} = \mathbf{x}_{\bar{i}}$	$= (X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_d)$
$\mathbf{x}^{(i)}$	Sample vector of \mathbf{x}
$y, Y \in \mathbb{R}$	Deterministic and random output variable when $p = 1$
$y^{(i)}$	Sample of y
$f_X(\cdot)$	Density function of a real random variable X
$F_X(\cdot)$	Distribution function of X
μ_X, σ_X	Mean and standard deviation of X
$x_\alpha = q_\alpha(X)$	α -quantile of X
$V = \text{Var}(Y)$	Total variance of the model output Y
A	Subset of indices in the set $\{1, \dots, d\}$
V_A	Partial variance
S_A, S_A^{tot}	First order and total Sobol indices of A

4 Specialized R Software Packages

From a practical point of view, the application of SA methods by researchers, engineers, end users, and students is conditioned by the availability of an easy-to-use software. Several software include some SA methods (see the Software chapter of the Springer Handbook), but only a few are specialized on the SA issues. In this section, the **sensitivity** package of the R environment is presented [49]. Its development has started since 2006 and the several contributions that this package has received have made it particularly complete. It includes most of the methods presented in the papers of this chapter.

The R software is a powerful tool for knowledge diffusion in the statistical community. The open source and availability have made R the software of choice for many statisticians in education and industry. The characteristics of R are the following:

- R is easy to run and install on main operating systems. It can be efficiently used with an old computer, with a single workstation and with one of the most recent supercomputer;
- R is a programming language which is interpreted and object oriented and which contains vector operators and matrix computation;
- The main drawbacks of R are its virtual memory limits and non-optimized computation times. To overcome these problems, compiled languages as Fortran or C are much more efficient and can be introduced as compiled codes inside R algorithms requiring huge computation time.
- R contains a lot of built-in statistical functions;
- R is extremely well documented with built-in help system;
- R encourages the collaboration, the discussion forums, and the creation of new packages by researchers and students. Thousands of packages are made available on the CRAN website (<http://cran.r-project.org/>).

All these benefits highlight the interest to develop specific softwares in R and many packages have been developed on SA. For instance, the **FME** package contains basic SA and local SA methods (see ▶ Chap. 32, “Variational Methods”), while the **spartan** package contains basic methods for exploring stochastic numerical models.

For global SA, the **sensitivity** package includes a collection of functions for factor screening, sensitivity index estimation, and reliability sensitivity analysis of model outputs. It implements:

- A few screening techniques as the sequential bifurcations and the Morris method (see ▶ Chap. 33, “Design of Experiments for Screening”). Note that the R package **planor** allows to build fractional factorial design (see ▶ Chap. 33, “Design of Experiments for Screening”);
- The main sampling-based procedures as linear regression coefficients, partial correlations, and rank transformation (see ▶ Chap. 34, “Weights and Importance in Composite Indicators: Mind the Gap”). Note that the **ipcp** function of the R package **ipplots** provides an interactive cobweb graphical tool (see Fig. 31.2),

while the R package **CompModSA** implements various nonparametric regression procedures for SA (see ► Chap. 34, “Weights and Importance in Composite Indicators: Mind the Gap”);

- The variance-based sensitivity indices (Sobol indices), by various schemes of the so-called pick-freeze method, the Extended-FAST method, and the replicated orthogonal array-based Latin hypercube sample (see ► Chap. 35, “Variance-Based Sensitivity Analysis: Theory and Estimation Algorithms”). The R package **fast** is fully devoted to the FAST method;
- The Poincaré constants for the derivative-based global sensitivity measures (DGSM) (see ► Chap. 36, “Derivative-Based Global Sensitivity Measures”);
- The sensitivity indices based on Csiszar f-divergence and Hilbert-Schmidt Independence Criterion of [6] (see ► Chap. 37, “Moment-Independent and Reliability-Based Importance Measures”);
- The reliability sensitivity analysis by the perturbation law-based indices (PLI) (see ► Chap. 37, “Moment-Independent and Reliability-Based Importance Measures”);
- The estimation of the Sobol indices with a Gaussian process metamodel (see ► Chap. 38, “Metamodel-Based Sensitivity Analysis: Polynomial Chaos Expansions and Gaussian Processes”) with a Gaussian process metamodel coming from the R package **DiceKriging**. Note that the R package **tgp** performs the same job using treed Gaussian process and that the R package **GPC** allows to estimate the Sobol indices by building a polynomial chaos metamodel (see ► Chap. 38, “Metamodel-Based Sensitivity Analysis: Polynomial Chaos Expansions and Gaussian Processes”);
- Sobol indices for multidimensional outputs: Aggregated Sobol indices and functional (1D) Sobol indices (see ► Chap. 39, “Sensitivity Analysis of Spatial and/or Temporal Phenomena”). Note that the R package **multisensi** is fully devoted to this subject, while the R package **safi** implements new SA methods of models with functional inputs;
- The Distributed Evaluation of Local Sensitivity Analysis (DELSA) described in Rakovec et al. [50].

The **sensitivity** package has been designed to work either models written in R than external models such as heavy computational codes. This is achieved with the input argument `model` present in all functions of this package. The argument `model` is expected to be either a function or a predictor (i.e., an object with a `predict` function such as `lm`). The model is invoked once for the whole design of experiment. The argument `model` can be left to `NULL`. This is referred to as the decoupled approach and used with external computational codes that rarely run on the statistician’s computer. Examples of use of all the **sensitivity** functions can be found using the R built-in help system.

As a global and generic platform allowing to include all the methods of these different R packages, the **mtk** package [70] has recently been proposed. It is an object-oriented framework which aims at dealing with external simulation platforms and managing all the different tasks of uncertainty and sensitivity analyses. Finally, the **ATmet** and **pse** packages interface several **sensitivity** package functions for, respectively, metrology applications and parameter space exploration.

5 Sensitivity Auditing

It may happen that a sensitivity analysis of a model-based study is meant to underpin an inference and to certify its robustness, in a context where the inference feeds into a policy or decision-making process. In these cases the framing of the analysis itself, its institutional context, and the motivations of its author may become a matter of great importance, and a pure SA – with its emphasis on parametric uncertainty – may be seen as insufficient. The emphasis on the framing may derive inter alia from the relevance of the policy study to different constituencies that are characterized by different norms and values and hence by a different story about “what the problem is” and foremost about “who is telling the story.” Most often the framing includes more or less implicit assumptions, which could be political (e.g., which group needs to be protected) all the way to technical (e.g., which variable can be treated as a constant).

These concerns about how the story is told and who tells it are all the more urgent in a climate as today’s where science’s own quality assurance criteria are under scrutiny due to a systemic crisis in reproducibility [25], and the explosion of the blogosphere invites more open debates on the scientific basis of policy decisions [42]. The Economist, a weekly magazine, has entered the fray by commenting on the poor state of current scientific practices and devoting its cover to “How Science goes wrong.” It adds that, *The false trails laid down by shoddy research are an unforgivable barrier to understanding* (The Economist [66], p. 11). Among the possible causes of such a predicament is a process of hybridization [33] of fact and values and of public and private institutions and actors. Thus, the classical division of roles among science, providing tested fact, and policy, providing legitimized norms, becomes arduous to maintain.

As an additional difficulty, according to Grundmann [19], *One might suspect that the more knowledge is produced in hybrid arrangements, the more the protagonists will insist on the integrity, even veracity of their findings.*

In order to take these concerns into due consideration, the instruments of SA have been extended to provide an assessment of the entire knowledge and model-generating process. This approach has been called sensitivity auditing. It takes inspiration from NUSAP, a method used to qualify the worth of quantitative information with the generation of “pedigrees” of numbers [17, 69]. Likewise, sensitivity auditing has been developed to provide pedigrees of models and model-based inferences [53, 54, 61].

Sensitivity auditing has been especially designed for an adversarial context, where not only the nature of the evidence but also the degree of certainty and uncertainty associated to the evidence will be the subject of partisan interests. Sensitivity auditing is structured along a set of seven rules/imperatives:

1. Check against the rhetorical use of mathematical modeling. Question addressed: is the model being used to elucidate or to obfuscate?;

2. Adopt an “assumption hunting” attitude. Question addressed: what was “assumed out”? What are the tacit, pre-analytical, possibly normative assumptions underlying the analysis?;
3. Detect garbage in, garbage out (GIGO). Issue addressed: artificial deflation of uncertainty operated in order to achieve a desired inference at a desired level of confidence. It also works on the reverse practice, the artificial inflation of uncertainties, e.g., to deter regulation;
4. Find sensitive assumptions before they find you. Issue addressed: anticipate criticism by doing careful homework via sensitivity and uncertainty analyses before publishing results.
5. Aim for transparency. Issue addressed: stakeholders should be able to make sense of, and possibly replicate, the results of the analysis;
6. Do the right sums, which is more important than “Do the sums right.” Issue addressed: is the viewpoint of a relevant stakeholder being neglected? Who decided that there was a problem and what the problem was?
7. Focus the analysis on the key question answered by the model, exploring the entire space of the assumptions holistically. Issue addressed: don’t perform perfunctory analyses that just “scratch the surface” of the system’s potential uncertainties.

The first rule looks at the instrumental use of mathematical modeling to advance one’s agenda. This use is called rhetorical, or strategic, like the use of Latin by the elites and clergy before the Reformation. At times the use of models is driven a simple pursuit of profit; according to Stiglitz [64], this was the case for the modelers “pricing” the derivatives at the root of the sub-prime mortgages crisis:

[...] Part of the agenda of computer models was to maximize the fraction of, say, a lousy sub-prime mortgage that could get an AAA rating, then an AA rating, and so forth, [...] This was called rating at the margin, and the solution was still more complexity, p. 161.

At times this use of models can be called “ritual,” in the sense that it offers a false sense of reassurance. An example is Fisher [13] (quoting Szenberg [65]):

Kenneth Arrow, one of the most notable Nobel Laureates in economics, has his own perspective on forecasting. During World War II, he served as a weather officer in the U.S. Army Air Corps and worked with a team charged with the particularly difficult task of producing month-ahead weather forecasts. As Arrow and his team reviewed these predictions, they confirmed statistically what you and I might just as easily have guessed: The Corps’ weather forecasts were no more useful than random rolls of a die. Understandably, the forecasters asked to be relieved of this seemingly futile duty. Arrow’s recollection of his superiors’ response was priceless: “The commanding general is well aware that the forecasts are no good. However, he needs them for planning purposes” Szenberg [65].

The second rule about “assumption hunting” is a reminder to look for what was assumed when the model was originally framed. Modes are full of *caeteris paribus* assumptions, meaning that, e.g., in economics the model can predict the result of a

shock to a given set of equations assuming that all the rest – all other input variables and inputs – remains equal, but in real life *caeteris* are never *paribus*, the meaning by this that variables tend to be linked with one another, so that they can hardly change in isolation.

Furthermore, at times the assumption made by modelers do not to withstand scrutiny. A good example of assumption hunting is from John Kay [28], where the author takes issue with modeling used in transport policy. This author discovered that among the input values assumed (and hence fixed) in the model was *average car occupancy rates, differentiated by time of day, in 2035*. The point is that such assumptions are very difficult to justify. This comment was published in the Financial Times (where John Kay is a columnist) showing that at present times controversies that could be called epistemological evade the confines of academia and populate the media.

Rule three is about artificially exaggerating or playing down uncertainties wherever convenient. The tobacco lobbies exaggerated the uncertainties about the health effects of smoking according to Oreskes and Conway [44], while advocates of the death penalty played down the uncertainties in the negative relations between capital punishment and crime rate [34]. Clearly the latter wanted the policy, in this case the death penalty, and were interested in showing that the supporting evidence was robust. In the former case the lobbies did not want regulation (e.g., bans on tobacco smoking in public places) and were hence interested in amplifying the uncertainty in the smoking-health effect causality relationship.

Rule four is about “confessing” uncertainties before going public with the analysis. This rule is also one of the commandments of applied econometrics according to Kennedy [29]: *Thou shall confess in the presence of sensitivity. Corollary: Thou shall anticipate criticism.* According to this rule a sensitivity analysis should be performed before the results of a modeling study are published. There are many good reasons for doing this, one being that a carefully performed sensitivity analysis often uncovers plain coding mistakes or model inadequacies. The other is that most often than not the analysis reveals uncertainties that are larger than those anticipated by the model developers. Econometrician Edward Leamer in discussing this [34] argues that *One reason these methods are rarely used is their honesty seems destructive.* In Saltelli and d’Hombres [52], the negative consequences of doing a sensitivity analysis *a posteriori* are discussed. The case is the first review of the cost of offsetting climate change done by Nicholas Stern of the London School of Economics (the so-called Stern Review) which was criticized by William Nordhaus, of the University of Yale, on the basis of large sensitivity of the estimates upon the discount factors employed by Stern. Stern’s own sensitivity analysis, published as an annex to the review, revealed according to the authors in Saltelli and d’Hombres [52] that while the discount factors were not the only important factors determining the cost estimate, the estimates were indeed very uncertain. For the large uncertainties of integrated assessment models of climate’s impact, see also Saltelli et al. [62].

Rule five is about presenting the results of the modeling study in a transparent fashion. Both rules originate from the practice of impact assessment, where a

modeling study presented without a proper SA, or as originating from a model which is in fact a black box, may end up being rejected by stakeholders [52]. Both rules four and five suggest that reproducibility may be a condition for transparency and that this latter may be a condition for legitimacy. This debate on science's transparency is very much alive in the USA, in the dialectic relationship between the US Environmental Protection Agency (EPA) and the US Congress (especially the Republican Party) which objects to EPA's regulations on the basis that these are based on "secret science."

Rule six, about doing the right sum, is not far from the "assumption hunting" rule; it is just more general. It deals with the fact that often an analyst is set to work on an analysis arbitrarily framed to the advantage of a party. Sometime this comes via the choice of the discipline selected to do the analysis. Thus, an environmental impact problem may be framed through the lenses of economics and presented as a cost benefit or risk analysis, while the issue has little to do with costs or benefits or risks and a lot to do with profits, controls, and norms. An example is in Marris et al. [41] on the issue of GMOs, mostly presented in the public discourse as a food safety issue, while the spectrum of concerns of GMO opponents – including lay citizens – appears broader. According to Winner [71] (pp. 138–163), ecologists should not be led into the trap of arguing about the "safety" of a technology after the technology has been introduced. They should instead question the broader power, policy, and profit implications of that introduction and its desirability.

Rule seven is about avoiding perfunctory sensitivity analyses. As discussed in Saltelli et al. [60], an SA where each uncertain input is moved at a time while leaving all other inputs fixed is perfunctory. A true SA should make an honest effort at activating all uncertainties simultaneously, leaving the model free to display its full nonlinear and possibly nonadditive behavior. A similar point is made in Sam L. Savage's book, *The Flaw of Averages* [63].

In conclusion, these rules are meant to help an analyst to anticipate criticism. In drafting these rules, the authors in [53, 54, 61] have tried to put themselves in the shoes of a modeler also based on their own experience and tried to imagine a model-based inference feeding into an impact assessment. What questions and objections may be received by the modeler? Here is a possible list:

- "You treated X as a constant when we know it is uncertain by at least 30%"
- "It would be sufficient for a 5% error in X to make your statement about Z fragile"
- "Your model is but one of the plausible models – you neglected model uncertainty"
- "You have instrumentally maximized your level of confidence in the results"
- "Your model is a black box – why should I trust your results?"
- "You have artificially inflated the uncertainty"
- "Your framing is not socially robust"
- "You are answering the wrong question"

The reader may easily check that carefully going through the sensitivity auditing checklist should provide ammunition to anticipate objections of this nature.

Sensitivity auditing can then be seen as a user guide to criticize the model-based studies, and SA is a part of this guide. In the following section, we go back to sensitivity analysis in order to conclude and give some perspectives.

6 Conclusion

This introductory paper has presented the SA aims and objectives, the SA and sensitivity auditing basic principles, the different methods explained in the chapter papers by positioning them in a classification grid, and the useful R software packages and the notations used in the chapter papers. The chapter's Editor, Bertrand Iooss, would like to sincerely thank all authors and co-authors of the "Sensitivity Analysis" chapter for their efforts and the quality of their contributions. Dr. Jean-Philippe Argaud (EDF R&D), Dr. Géraud Blatman (EDF R&D), Dr. Nicolas Bousquet (EDF R&D), Dr. Sébastien da Veiga (Safran), Dr. Hervé Monod (INRA), Dr. Matieyendou Lamboni (INRA), and Dr. Loïc Le Gratiet (EDF R&D) are also greatly thanked for their advices on the different chapter papers.

The papers in this chapter include the most widely used methods for sensitivity analysis: the deterministic methods as the local sensitivity analysis, the experimental design strategies, the sampling-based and variance-based methods developed from the 1980s, and the new importance measures and metamodel-based techniques established and studied since the 2000s. However, with such a rich subject, choices had to be made for the different chapter papers, and some important omissions are present. For instance, the robust Bayesian analysis [1, 24] is not discussed, while it is nevertheless a great ingredient in the study of the sensitivity of Bayesian answers to assumptions and uncertain calculation inputs. Moreover, in the context of non-probabilistic representation of uncertainty (as in the interval analysis, the evidence theory and the possibility theory), a small amount of SA methods has been developed [22]. This subject is deferred to a future review work.

Due to their very new or incomplete nature, several other SA issues are not discussed in this chapter. For instance, estimating total Sobol indices at low cost remains a problem of primary importance in many applications (see Saltelli et al. [60] for a recent review on the subject). Second-order Sobol index estimations have recently been considered by Fruth et al. [16] (by way of total interaction indices) and Tissot and Prieur [67] (by way of replicated orthogonal-array LHS). The latter work offers a powerful estimation method because the number of model calls is independent of the number of inputs (as in the spirit of permutation-based technique [37, 38]). However, for high-dimensional models (several hundreds inputs), estimation biases and computational costs remain considerable; De Castro and Janon [9] have proposed to introduce modern statistical techniques based on variable selection in regression models. Owen [46] has introduced generalized Sobol indices allowing to compare and search efficient estimators (as the new one found in Owen [45]).

Another mathematical difficulty is the consideration of the dependence between the inputs X_i ($i = 1 \dots d$). Nonindependence between inputs in SA has been

discussed by many authors such as Saltelli and Tarantola [55], Jacques et al. [27], Xu and Gertner [72], Da Veiga et al. [7], Li et al. [36], Kucherenko et al. [31], Mara and Tarantola [39], and Chastaing et al. [5]. Despite all these works, much confusion still exists in practical applications. In practice, it would be useful to be able to measure the influence of the potential dependence between some inputs on the output quantity of interest.

Note that most of the works in this chapter focus on SA relative to the overall variability of model output (second-order statistics). In practice, one can be interested in other quantities of interest, such as the output entropy, the probability that the output exceeds a threshold and a quantile estimation [15,35,56]. This is an active area of research as shown in this chapter (see ► Chap. 37, “[Moment-Independent and Reliability-Based Importance Measures](#)”), but innovative and powerful ideas have recently been developed by Owen et al. [47] and Geraci et al. [18] using higher-order statistics, Fort et al. [14] using contrast functions, and Da Veiga [6] using a kernel point of view.

Finally, in some situations, the computer code is not a deterministic simulator but a stochastic one. This means that two model calls with the same set of input variables lead to different output values. Typical stochastic computer codes are queuing models, agent-based models, and models involving partial differential equations applied to heterogeneous or Monte Carlo-based numerical models. For this type of code, Marrel et al. [40] have proposed a first solution for dealing with Sobol indices. Moutoussamy et al. [43] have also tackled the issue in the context of the metamodel building of the output probability density function. Developing relevant SA methods in this context will certainly be subject of future works.

Maelle Nodet and Arthur Vidard

Abstract

This contribution presents derivative-based methods for local sensitivity analysis, called *Variational Sensitivity Analysis* (VSA). If one defines an output called the *response function*, its sensitivity to input variations around a nominal value can be studied using derivative (gradient) information. The main issue of VSA is then to provide an efficient way of computing gradients.

This contribution first presents the theoretical grounds of VSA: framework and problem statement and tangent and adjoint methods. Then it covers practical means to compute derivatives, from naive to more sophisticated approaches, discussing their various merits. Finally, applications of VSA are reviewed, and some examples are presented, covering various applications fields: oceanography, glaciology, and meteorology.

1 Introduction

This contribution presents derivative-based methods for local sensitivity analysis, gathered under the name *Variational Sensitivity Analysis* (VSA). The aim of VSA is to provide sensitivity information using derivatives. This is indeed a valuable information, as the derivative of a function at a given point gives the growth rate at that point, in other words the tendency of the function to grow (or not) when the input varies. Approximately one could say *the larger the derivative, the more sensitive the parameter*.

Note that VSA can be extended to global analysis (GSA) and the reader is referred to contribution (see ▶ Chap. 36, “Derivative-Based Global Sensitivity Measures”). Here the focus will be solely on local derivative-based sensitivity analysis. Contrary to GSA, LSA aims to compute sensitivities when the parameters vary *locally* around their nominal values and not *globally* over a potentially large subset.

VSA is closely related to the research domain called *data assimilation*. This one consists in adjusting input parameters of a model so that the system state fits a given set of observations (data). Variational data assimilation translates this into an optimal control problem whose aim is to minimize the model-observation misfit. This minimization is performed using descent methods, and the gradient is computed using the so-called adjoint method, which is also at the core of VSA. Moreover, improving parameters and models through data assimilation assumes that the most sensitive parameters are known, which in turn creates the need to perform VSA beforehand.

This contribution is divided in two parts. First, it will cover the methods of local VSA: the derivative is first defined, then the adjoint method is shown to provide a powerful way to compute it, then a brief overview about practical derivatives computation is given, and finally stability analysis is mentioned, which is closely related to sensitivity analysis.

In a second part, some applications are presented. VSA has been used in a wide range of domains: e.g., meteorology [1, 5, 8, 23, 33, 34], cyclone tracking [14, 22, 32], air quality [25, 26], oceanography [2, 27, 30, 31], surface hydrology [4], groundwater modeling [28], glaciology [13], agronomy [15], chemistry [24], etc. Historically, the adjoint method was first applied to numerical weather prediction, so that meteorology is a primary application domain, with many references on VSA.

As in other geophysical domains, meteorological models are in general of very large dimension, so that GSA is mostly out of reach, which motivates the introduction of the adjoint method and VSA. This contribution chose to focus on a small number of example applications in geophysics.

2 Methods

2.1 Problem Statement

In this section, the sensitivity of the output vector \mathbf{y} with respect to the input vector \mathbf{x} is considered. This output is often called the *response function*, since it represents the response of the system to variation on the input. In the variational framework, practitioners are generally interested in studying sensitivities of given numerical models \mathcal{M} coming from various application domains (physics, geosciences, biology, etc.), so that the output is a function of a state vector $\mathbf{u}(\mathbf{x}; t) \in \mathbb{R}^p$, which depends on the input $\mathbf{x} \in \mathbb{R}^d$ and on time t and represents the state of a given system of interest:

$$\begin{cases} \frac{d\mathbf{u}}{dt} = \mathcal{M}(\mathbf{u}; \mathbf{x}), & t \in [0, T] \\ \mathbf{u}(t = 0) = \mathbf{u}_0(\mathbf{x}) \end{cases} \quad (32.1)$$

As \mathbf{u} lies in \mathbb{R}^p , the model \mathcal{M} is a (possibly nonlinear) operator from $\mathbb{R}^p \times \mathbb{R}^d$ to \mathbb{R}^p .

In that case, the dependency between the input and the output reads

$$\mathbf{y} = G(\mathbf{x}) = \mathcal{G}(\mathbf{u}(\mathbf{x})) \quad (32.2)$$

where G is the response function and \mathcal{G} maps the state space into the output space.

Remark 1. In the definition of the response function G lies all the art of sensitivity analysis. It should be designed carefully depending on the aim of the study (model validation, physical phenomenon study, etc.). This is discussed in depth in the contributions ▶ [Chap. 39, “Sensitivity Analysis of Spatial and/or Temporal Phenomena”](#) and [Variables Weights and Importance in Arithmetic Averages: Two Stories to Tell](#).

Remark 2. A more general case would be $\mathbf{y} = \mathcal{G}(\mathbf{u}(\mathbf{x}), \mathbf{x})$. The theory easily extends to that case, but for readability, only this simpler case will be presented here.

In order to simplify the notations and clarify the reading, scalar outputs will be considered in this chapter, i.e., $\mathbf{y} \in \mathbb{R}$, but vector-valued outputs can of course be considered as well.

Variational sensitivity consists in finding the sensitivity of G with respect to the variations of \mathbf{x} , in other words the derivative of G with respect to the vector \mathbf{x} :

$$\frac{dG}{d\mathbf{x}}(\mathbf{x})$$

In this framework, G is differentiable from \mathbb{R}^d to \mathbb{R} , with continuous derivative, i.e., G is of class C^1 . Then the derivative can be identified (using the Euclidean scalar product in \mathbb{R}^d) with the gradient:

$$\nabla_{\mathbf{x}} G(\mathbf{x}) = \left(\frac{\partial G}{\partial x_1}(\mathbf{x}), \frac{\partial G}{\partial x_2}(\mathbf{x}), \dots, \frac{\partial G}{\partial x_d}(\mathbf{x}) \right)^T$$

The partial derivatives of G are particular cases of the directional derivative, also called the Gâteau derivative, which is defined by $G'(\mathbf{x})[\mathbf{h}]$ such that

$$G'(\mathbf{x})[\mathbf{h}] = \lim_{\alpha \rightarrow 0} \frac{G(\mathbf{x} + \alpha \mathbf{h}) - G(\mathbf{x})}{\alpha}$$

where the direction \mathbf{h} is a vector of \mathbb{R}^d . The partial derivative is simply the directional derivative in the direction of a basis vector; it is given by

$$G'(\mathbf{x})[\mathbf{e}_i] = \frac{\partial G}{\partial x_i}(\mathbf{x})$$

As G is a continuously differentiable function, the link between the directional derivative and the gradient is immediate:

$$G'(\mathbf{x})[\mathbf{h}] = \nabla_{\mathbf{x}} G(\mathbf{x}) \cdot \mathbf{h}$$

where “ \cdot ” represents the Euclidean scalar product in \mathbb{R}^d .

2.2 Tangent and Adjoint Models

The most naive approach to track sensitive variables consists in fixing all parameters except one, increasing it by a given percentage (of its standard deviation or its absolute value) and then evaluating its impact on the output. This type of analysis can allow for a quick ranking of the variables if there are not too many of them. The reader can refer to [11] for a brief review on this subject.

A more refined approach would be to obtain a numerical approximation of the gradient using finite differences, i.e., computing the gradient as a limit of a growth rate (see [11] and next paragraph about practical aspects). This method is very simple but has two main drawbacks. First, its computational cost increases rapidly

with the dimension d of \mathbf{x} . Second, the choice of δx_i is critical: if too large, the truncation error becomes large; if too small, rounding error occurs.

To address this last point, one can obtain an exact calculation for the Gâteau derivatives (FSAP, *Forward Sensitivity Analysis Procedure* in [3]’s terminology). Assuming the output is given by Eqs. (32.1) and (32.2),

$$G'(\mathbf{x})[\mathbf{h}] = \nabla_{\mathbf{u}} \mathcal{G}(\mathbf{u}(\mathbf{x})).\mathbf{u}'(\mathbf{x})[\mathbf{h}] = \mathcal{G}'(\mathbf{u}(\mathbf{x}))[\mathbf{u}'(\mathbf{x})[\mathbf{h}]]$$

where $\mathbf{u}'(\mathbf{x})[\mathbf{h}]$ is the Gâteau derivative of \mathbf{u} at \mathbf{x} in the direction \mathbf{h} . If \mathbf{v} denotes $\mathbf{u}'(\mathbf{x})[\mathbf{h}]$, then \mathbf{v} is given by the following equations, called the Tangent Linear Model (TLM):

$$\begin{cases} \frac{d\mathbf{v}}{dt} = \frac{\partial \mathcal{M}}{\partial \mathbf{u}}(\mathbf{u}(\mathbf{x}); \mathbf{x}).\mathbf{v} + \frac{\partial \mathcal{M}}{\partial \mathbf{x}}(\mathbf{u}(\mathbf{x}); \mathbf{x}).\mathbf{h}, & t \in [0, T] \\ \mathbf{v}(t=0) = \mathbf{u}'_0(\mathbf{x})[\mathbf{h}] = \nabla_{\mathbf{x}} \mathbf{u}_0. \mathbf{h} \end{cases} \quad (32.3)$$

where $\frac{\partial \mathcal{M}}{\partial \mathbf{u}}$ and $\frac{\partial \mathcal{M}}{\partial \mathbf{x}}$ are the Jacobian matrices of the model with respect to the state \mathbf{u} and the parameters \mathbf{x} . The Tangent Linear Model allows to compute exactly the directional derivative of the response function G , for a given direction \mathbf{h} . To get the entire gradient, all the partial derivatives need to be computed; therefore, d integrations of the TLM are required. The accuracy problem may be solved, but for a large-dimensional set of parameters, the computing cost of the FSAP method remains prohibitive.

In large-dimensional cases, however, an adjoint method can be used to compute the gradient (ASAP, *Adjoint Sensitivity Analysis Procedure* in [3]’s terminology). As the derivation of the adjoint model is tedious in the general abstract case, this contribution will focus on common examples.

One will first consider the case where G and \mathcal{G} are given by

$$G(\mathbf{x}) = \mathcal{G}(\mathbf{u}(\mathbf{x})) = \int_{t=0}^{t=T} \mathcal{H}(\mathbf{u}(\mathbf{x}; t)) dt \quad (32.4)$$

where \mathcal{H} is the single time output function, from \mathbb{R}^p to \mathbb{R} .

Then the Gâteau derivative of G with respect to \mathbf{x} in the direction \mathbf{h} is given by

$$G'(\mathbf{x})[\mathbf{h}] = \nabla_{\mathbf{x}} G(\mathbf{x}).\mathbf{h} = \int_{t=0}^{t=T} \nabla_{\mathbf{u}} \mathcal{H}(\mathbf{u}(\mathbf{x}; t)).\mathbf{v} dt \quad (32.5)$$

where \mathbf{v} is as before $\mathbf{u}'(\mathbf{x})[\mathbf{h}]$.

Now the adjoint method consists in introducing a wisely chosen so-called adjoint variable so that the previous gradient can be formulated without the tangent variable \mathbf{v} . To do so, the tangent model (32.3) is multiplied by a variable $\mathbf{p}(t)$, and an integration by parts is performed in order to obtain a formula $\int_{t=0}^{t=T} (\dots).\mathbf{v} dt$, which

will later be identified with (32.5). So first a multiplication by \mathbf{p} is performed and then an integration:

$$0 = - \int_0^T \mathbf{p} \frac{d\mathbf{v}}{dt} dt + \int_0^T \mathbf{p} \left(\frac{\partial \mathcal{M}}{\partial \mathbf{u}}(\mathbf{u}(\mathbf{x}); \mathbf{x}) \cdot \mathbf{v} + \frac{\partial \mathcal{M}}{\partial \mathbf{x}}(\mathbf{u}(\mathbf{x}); \mathbf{x}) \cdot \mathbf{h} \right) dt$$

Then the integration by parts gives

$$\begin{aligned} 0 &= -\mathbf{p}(T)\mathbf{v}(T) + \mathbf{p}(0)\mathbf{v}(0) + \int_0^T \left(\frac{d\mathbf{p}}{dt} + \frac{\partial \mathcal{M}}{\partial \mathbf{u}}(\mathbf{u}(\mathbf{x}); \mathbf{x})^T \mathbf{p} \right) \cdot \mathbf{v} dt \\ &\quad + \int_0^T \left(\left(\frac{\partial \mathcal{M}}{\partial \mathbf{x}}(\mathbf{u}(\mathbf{x}); \mathbf{x}) \right)^T \mathbf{p} \right) \cdot \mathbf{h} dt \end{aligned}$$

Using the initial condition (32.3) on \mathbf{v} , it becomes

$$\begin{aligned} \mathbf{p}(T)\mathbf{v}(T) - \int_0^T \left(\frac{d\mathbf{p}}{dt} + \frac{\partial \mathcal{M}}{\partial \mathbf{u}}(\mathbf{u}(\mathbf{x}); \mathbf{x})^T \mathbf{p} \right) \cdot \mathbf{v} dt \\ = \mathbf{p}(0)\nabla_{\mathbf{x}}\mathbf{u}_0 \cdot \mathbf{h} + \int_0^T \left(\left(\frac{\partial \mathcal{M}}{\partial \mathbf{x}}(\mathbf{u}(\mathbf{x}); \mathbf{x}) \right)^T \mathbf{p} \right) \cdot \mathbf{h} dt \\ = \left(\mathbf{p}(0)\nabla_{\mathbf{x}}\mathbf{u}_0 + \int_0^T \left(\frac{\partial \mathcal{M}}{\partial \mathbf{x}}(\mathbf{u}(\mathbf{x}); \mathbf{x}) \right)^T \mathbf{p} dt \right) \cdot \mathbf{h} \end{aligned} \quad (32.6)$$

As Eq. (32.5) needs to be rewritten, the following backward equation for \mathbf{p} is set and called the adjoint model:

$$\begin{cases} -\frac{d\mathbf{p}}{dt} = \left[\frac{\partial \mathcal{M}}{\partial \mathbf{u}}(\mathbf{u}(\mathbf{x}); \mathbf{x}) \right]^T \cdot \mathbf{p} + \nabla_{\mathbf{u}}\mathcal{H}(\mathbf{u}(\mathbf{x}); t), & t \in [0, T] \\ \mathbf{p}(t = T) = 0 \end{cases} \quad (32.7)$$

Combining (32.5), (32.6), and (32.7), the following formula for the Gâteau derivative is obtained:

$$G'(\mathbf{x})[\mathbf{h}] = \nabla_{\mathbf{x}}G(\mathbf{x}) \cdot \mathbf{h} = \left(\mathbf{p}(0)\nabla_{\mathbf{x}}\mathbf{u}_0 + \int_0^T \left(\frac{\partial \mathcal{M}}{\partial \mathbf{x}}(\mathbf{u}(\mathbf{x}); \mathbf{x}) \right)^T \mathbf{p} dt \right) \cdot \mathbf{h}$$

leading to the gradient:

$$\nabla_{\mathbf{x}}G(\mathbf{x}) = [\nabla_{\mathbf{x}}\mathbf{u}_0]^T \mathbf{p}(t = 0) + \int_{t=0}^{t=T} \left[\frac{\partial \mathcal{M}}{\partial \mathbf{x}}(\mathbf{u}(\mathbf{x}); \mathbf{x}) \right]^T \mathbf{p}(t) dt \quad (32.8)$$

which does not involve variable \mathbf{v} anymore. Thus, the computing cost is independent from the number of parameters, and $\nabla_{\mathbf{x}}G(\mathbf{x})$ can be computed *exactly* using one

integration of the direct model and one backward integration of the adjoint model. Note that if the model is linear, only the adjoint integration is needed.

Similarly, the adjoint model can be computed for the following type of output:

$$G(\mathbf{x}) = \mathcal{G}(\mathbf{u}(\mathbf{x}; t_1)) \quad (32.9)$$

for $t_1 \in]0; T[$, by noticing that it can be written as

$$G(\mathbf{x}) = \int_{t=0}^{t=T} \mathcal{H}(\mathbf{u}(\mathbf{x}; t)) \delta_{t=t_1}(t) dt$$

where $\delta_{t=t_1}(t)$ is the Dirac function of t at point t_1 . The adjoint model is then

$$\begin{cases} -\frac{d\mathbf{p}}{dt} = \left[\frac{\partial \mathcal{M}}{\partial \mathbf{u}}(\mathbf{u}(\mathbf{x}); \mathbf{x}) \right]^T \cdot \mathbf{p} + \nabla_{\mathbf{u}} \mathcal{H}(\mathbf{u}(\mathbf{x}; t)) \delta_{t=t_1}(t), & t \in [0, T] \\ \mathbf{p}(t = T) = 0 \end{cases} \quad (32.10)$$

Notice here that the adjoint variable is equal to zero up to time t_1 . Computationally speaking, it is therefore sufficient to run the adjoint model from t_1 to 0.

Then the gradient is unchanged:

$$\nabla_{\mathbf{x}} G(\mathbf{x}) = [\nabla_{\mathbf{x}} \mathbf{u}_0]^T \mathbf{p}(t = 0) + \int_{t=0}^{t=T} \left[\frac{\partial \mathcal{M}}{\partial \mathbf{x}}(\mathbf{u}(\mathbf{x}); \mathbf{x}) \right]^T \mathbf{p}(t) dt \quad (32.11)$$

One can also be interested in an output at final time:

$$G(\mathbf{x}) = \mathcal{G}(\mathbf{u}(\mathbf{x}; T)), \quad G'(\mathbf{x})[\mathbf{h}] = \nabla_{\mathbf{u}} \mathcal{H}(\mathbf{u}(\mathbf{x}; T)) \cdot \mathbf{v}(T)$$

Then the adjoint model writes

$$\begin{cases} -\frac{d\mathbf{p}}{dt} = \left[\frac{\partial \mathcal{M}}{\partial \mathbf{u}}(\mathbf{u}(\mathbf{x}); \mathbf{x}) \right]^T \cdot \mathbf{p}, & t \in [0, T] \\ \mathbf{p}(t = T) = \nabla_{\mathbf{u}} \mathcal{H}(\mathbf{u}(\mathbf{x}; T)) \end{cases} \quad (32.12)$$

and the gradient is unchanged:

$$\nabla_{\mathbf{x}} G(\mathbf{x}) = [\nabla_{\mathbf{x}} \mathbf{u}_0]^T \mathbf{p}(t = 0) + \int_{t=0}^{t=T} \left[\frac{\partial \mathcal{M}}{\partial \mathbf{x}}(\mathbf{u}(\mathbf{x}); \mathbf{x}) \right]^T \mathbf{p}(t) dt \quad (32.13)$$

Note here that this adjoint method allows to obtain directly every component of the gradient vector with a single run of the adjoint model, thus avoiding the curse of dimensionality on the parameter set dimension.

2.3 Practical Gradient Computation

Practical aspects are an important incentive for the choice of either of gradient computation methods presented above. For a small dimension problem, the finite difference approximation route is pretty straightforward, and unless a high precision is required, it is probably the better choice. For larger dimension problems, however, either choice will require some efforts in terms of computing cost and/or code developments. This section presents practical aspects of such developments, as well as a further approximation of the finite difference method tailored for high dimension problems.

2.3.1 Finite Difference Approximation

By definition, one has

$$\frac{\partial G}{\partial x_i}(\mathbf{x}) = \lim_{\alpha_i \rightarrow 0} \frac{G(\mathbf{x} + (0, \dots, \alpha_i, \dots, 0)^T) - G(\mathbf{x})}{\alpha_i}$$

Thus, the partial derivative (and therefore the gradient) can be numerically approximated by

$$\frac{\partial G}{\partial x_i}(\mathbf{x}) \approx \frac{G(\mathbf{x} + (0, \dots, \delta x_i, \dots, 0)^T) - G(\mathbf{x})}{\delta x_i}$$

where δx_i is “small”; see, e.g., [11]. As it has been mentioned before, this method, although very simple, has two main drawbacks (computational cost, rounding issues), which motivates the need for the adjoint code.

2.3.2 Discrete vs. Continuous Adjoint

There are two approaches to obtain an adjoint code:

- Discretize the continuous direct model, and then write the adjoint of the discrete direct model. This is generally called the *discrete adjoint* approach; see, e.g., [17].
- Write the continuous adjoint from the continuous direct model (as explained before), and then discretize the continuous adjoint equations. This is called the *continuous adjoint approach*.

The two approaches are not equivalent. As an example, a simple ordinary differential equation can be considered:

$$c'(t) = F(t).c(t)$$

where F is a time-dependant linear operator acting on the vector $c(t)$. If this model is discretized using a forward Euler scheme, a typical time step writes as

$$c_{n+1} = (I + \Delta_t F_n)c_n$$

where I is the identity matrix and n the time index. Then the adjoint of this discrete equation would give the following typical time step (*discrete adjoint*):

$$c_n^* = (I + \Delta_t F_n)^T c_{n+1}^*$$

where $*$ denotes the adjoint variable. On the other hand, the continuous adjoint equation is

$$-c^{*'}(t) = F(t)^T \cdot c^*(t)$$

If the same forward Euler explicit scheme is chosen, one obtains for the *continuous adjoint*

$$c_n^* = (I + \Delta_t F_{n+1})^T c_{n+1}^*$$

and the time dependency on F then implies that both approaches are not identical. This illustrates the fact that discretization and transposition (the word “adjointization” does not exist; the process of obtaining an adjoint code is called “transposition” or “derivation”) do not, in general, commute.

The choice of the discrete adjoint approach should be immediate for two main reasons:

1. The response function $G(\mathbf{x})$ is computed through the discrete direct model; its gradient is therefore given by the *discrete adjoint*. The *continuous adjoint* gives only an approximation of this gradient.
2. The discrete adjoint approach allows for the use of automatic adjoint compilers (software that takes in input the direct model code and produces as output the tangent and adjoint codes, e.g., Tapenade [12]).

However, it must be noted here that, for large complex systems, obtaining the discrete adjoint can be a time- and expertise-demanding task. Therefore, if one has limited time and experience in adjoint coding and if one can be satisfied with just an approximation of the gradient, the continuous adjoint approach can be considered. Moreover, for complex nonlinear or non-differentiable equations, the discrete adjoint has been shown in [29] to present problems to compute the sensitivities, so that other approaches may be considered. Similarly, [18] presents an application with adaptive mesh, where it is preferable to go through the continuous adjoint route. In any case, the validation of the gradient (see below) should give a good idea about the quality of the chosen gradient.

2.3.3 Adjoint Code Derivation

As it has been mentioned above, obtaining a *discrete* adjoint code is a complex task. A numerical code is ultimately a sequence of single-line instructions. In other words, a code can be seen as a composition of a (large) number of functions, each line code representing one function in this composition. To obtain the tangent code

(and then the adjoint code, by transposition), it is necessary to apply the chain rule to this function composition. Because of nonlinearities, dependencies, and inputs/outputs, applying the chain rule to a large code is very complex. There exist recipes for adjoint code construction, explaining in details how to get the adjoint for various instruction types (assignment, loop, conditional statements, inputs/outputs, and so on); see, e.g., [9, 10]. Code differentiation can be done by hand following these recipes.

An alternative to adjoint handwriting is to use specially designed softwares that automate the writing of the adjoint code, called automatic differentiation tools, such as the software Tapenade [12]. These tools are powerful, always improving, and can now derive large computer codes in various programming languages. It should be mentioned, however, that these tools cannot be used completely in black box mode and may require some preparatory work on the direct code. Despite these difficulties, some large-scale usages of automatic differentiation have been performed, e.g., for the ocean model of the MIT (MITgcm, see [20]) or a Greenland ice model (see below the Applications section and [13]).

2.3.4 Monte Carlo Approximation

Monte Carlo approximation allows to obtain an approximate gradient using a reasonable number of response function evaluations. Here the approximation proposed in [1] is presented.

Assume that \mathbf{h} is small enough, so that the following approximation holds:

$$\delta G = G(\mathbf{x} + \mathbf{h}) - G(\mathbf{x}) \approx G'(\mathbf{x})[\mathbf{h}] = \nabla_{\mathbf{x}}G(\mathbf{x}).\mathbf{h} \quad (32.14)$$

By right-multiplying by \mathbf{h}^T both sides of Eq. (32.14), one gets

$$\delta G \mathbf{h}^T \approx (\nabla_{\mathbf{x}}G(\mathbf{x}).\mathbf{h})\mathbf{h}^T$$

Considering that \mathbf{h} is a stochastic perturbation, one can take the expectation

$$\mathbb{E}(\delta G \mathbf{h}^T) \approx \mathbb{E}([\nabla_{\mathbf{x}}G(\mathbf{x}).\mathbf{h}]\mathbf{h}^T) = \nabla_{\mathbf{x}}G(\mathbf{x}).\mathbf{A}$$

where $\mathbf{A} = \mathbb{E}(\mathbf{h}\mathbf{h}^T)$ is the covariance matrix of \mathbf{h} . Therefore,

$$\nabla_{\mathbf{x}}G(\mathbf{x}) \approx \mathbb{E}(\delta G \mathbf{h}^T)\mathbf{A}^{-1} \quad (32.15)$$

In practice, \mathbf{A} is a large matrix and may be difficult to inverse; therefore, the authors propose to replace \mathbf{A} by its diagonal. In the end, an approximate gradient is given by the formula:

$$\widetilde{\nabla_{\mathbf{x}}G(\mathbf{x})} = \mathbb{E}(\delta G \mathbf{h}^T) (\text{Diag}(\mathbf{A}))^{-1} \quad (32.16)$$

where the expectation is computed using a Monte Carlo method, requiring a certain number of model runs. This formula is simple enough but should be handled with care; indeed, it holds three successive approximations: finite differences instead of true gradient, Monte Carlo approximation (usually carried over with a small sample size), and A replaced by $\text{Diag}(A)$. However, this kind of approach has been successfully used in data assimilation, to obtain gradient-like information without resorting to adjoint code construction; see, e.g., [7, 19].

2.3.5 Gradient Code Validation

First-Order Test

The first-order test is very simple; the idea is just to check the following approximation at the first order in $\alpha \rightarrow 0$:

$$\frac{G(\mathbf{x} + \alpha \cdot \mathbf{h}) - G(\mathbf{x})}{\alpha} = (\nabla G, \mathbf{h}) + o(1)$$

The principle of the test is then to compute, for various perturbation directions \mathbf{h} and various values of α (with $\alpha \rightarrow 0$, e.g., $\alpha = 10^{-n}, n = 1 \dots 8$), the two following quantities: first one computes

$$\tau(\alpha, \mathbf{h}) = \frac{G(\mathbf{x} + \alpha \cdot \mathbf{h}) - G(\mathbf{x})}{\alpha}$$

with the direct code, and then one computes $\delta(\mathbf{h}) = (\nabla G, \mathbf{h})$, where ∇G is given by the adjoint code. Then one just has to measure the relative error

$$\varepsilon(\alpha, \mathbf{h}) = \frac{|\tau(\alpha, \mathbf{h}) - \delta(\mathbf{h})|}{|\delta(\mathbf{h})|}$$

and check that $\varepsilon(\alpha, \mathbf{h})$ tends to 0 with α for various directions \mathbf{h} .

Second-Order Test

For this test, the Taylor expansion at second order is written:

$$G(\mathbf{x} + \alpha \mathbf{h}) = G(\mathbf{x}) + \alpha (\nabla G, \mathbf{h}) + \frac{\alpha^2}{2} (\mathbf{h}, \nabla^2 G \mathbf{h}) + o(\alpha^2)$$

When \mathbf{h} is given, the last term is therefore a constant: $G(\mathbf{x} + \alpha \mathbf{h}) = G(\mathbf{x}) + \alpha (\nabla G, \mathbf{h}) + \frac{\alpha^2}{2} C(\mathbf{h}) + o(\alpha^2)$. In that case, the second-order test writes as follows. Let $\tau(\alpha, \mathbf{h})$ be defined as previously:

$$\tau(\alpha, \mathbf{h}) = \frac{G(\mathbf{x} + \alpha \cdot \mathbf{h}) - G(\mathbf{x})}{\alpha} \quad \text{and} \quad \delta(\mathbf{h}) = (\nabla G, \mathbf{h})$$

The Taylor expansion gives $\frac{\tau(\alpha, \mathbf{h}) - \delta(\mathbf{h})}{\alpha} = \frac{1}{2}C(\mathbf{h}) + o(1)$. The test consists in computing the quantity $r(\alpha, \mathbf{h})$:

$$r(\alpha, \mathbf{h}) = \frac{\tau(\alpha, \mathbf{h}) - \delta(\mathbf{h})}{\alpha}$$

for various directions \mathbf{h} and various α and checks that it tends to a constant (depending on \mathbf{h}) when $\alpha \rightarrow 0$.

2.4 Stability Analysis

Stability analysis is the study of how perturbations on the system will grow. Such tools, and in particular the so-called singular vectors, can be used for sensitivity analysis. Indeed, looking at extremal perturbations gives an input on sensitivities of the system (see [22, 23, 27] for application examples).

The growth rate of a given perturbation \mathbf{h}_0 of, say, the initial condition \mathbf{u}_0 of the model is classically defined by

$$\rho(\mathbf{h}_0) = \frac{\|\mathcal{M}(\mathbf{u}_0 + \mathbf{h}_0, T) - \mathcal{M}(\mathbf{u}_0, T)\|}{\|\mathbf{h}_0\|} \quad (32.17)$$

where $\|\cdot\|$ is a given norm.

One can then define the optimal perturbation \mathbf{h}_0^1 so that $\rho(\mathbf{h}_0^1) = \max_{\mathbf{h}_0} \rho(\mathbf{h}_0)$ and then deduce a family of maximum growth vectors:

$$\rho(\mathbf{h}_0^i) = \max_{\mathbf{h}_0 \perp \text{Span}(\mathbf{h}_0^1, \dots, \mathbf{h}_0^{i-1})} \rho(\mathbf{h}_0), i \geq 2 \quad (32.18)$$

By restricting the study to the linear part of the perturbation behavior, the growth rate becomes (denoting $\mathbf{L} = \frac{\partial \mathcal{M}}{\partial \mathbf{u}}$ for clarity)

$$\begin{aligned} \rho^2(\mathbf{h}_0) &= \frac{\|\mathbf{L}\mathbf{h}_0\|^2}{\|\mathbf{h}_0\|^2} = \frac{<\mathbf{L}\mathbf{h}_0, \mathbf{L}\mathbf{h}_0>}{<\mathbf{h}_0, \mathbf{h}_0>} \\ &= \frac{<\mathbf{h}_0, \mathbf{L}^*\mathbf{L}\mathbf{h}_0>}{<\mathbf{h}_0, \mathbf{h}_0>} \end{aligned} \quad (32.19)$$

$\mathbf{L}^*\mathbf{L}$ being a symmetric positive definite matrix, its eigenvalues are nonnegative real, and its eigenvectors are (or can be chosen) orthonormal. The strongest growth vectors are the eigenvectors of $\mathbf{L}^*\mathbf{L}$ which correspond to the greatest eigenvalues. They are called forward singular vectors and denoted f_i^+ :

$$\mathbf{L}^*\mathbf{L}f_i^+ = \mu_i f_i^+ \quad (32.20)$$

One can notice then that $\mathbf{L}f_i^+$ is an eigenvector of \mathbf{LL}^* , which allows to define the backward singular vectors, noted f_i^- , as

$$\mathbf{L}f_i^+ = \sqrt{\mu_i} f_i^-$$

The eigenvalue corresponding to f_i^- is μ_i as well. Forward singular vectors represent the directions of perturbation that will grow fastest, while backward singular vectors represent the directions of perturbation that have grown the most.

The computation of the f_i^+ and f_i^- generally requires numerous matrix-vector multiplications, i.e., direct integrations of the model and backward adjoint integrations. The result of these calculations depends on the norm used, the time window, and the initial state if the model is nonlinear. For an infinite time window, singular vectors converge toward Lyapunov vectors. The full nonlinear model can be retained in Eq. (32.17) leading to the computation of so-called nonlinear singular vectors. They are obtained by optimizing directly Eq. (32.17). However, due to nonlinear dissipation, they tend to converge toward infinitesimal perturbations as the time window lengthens; this can be sorted out by adding some constraints on the norm of the perturbation [21].

3 Applications

Applications of VSA can be generally divided into two classes: sensitivity to initial or boundary condition changes and sensitivity to parameter changes. However, one can extend the notion of sensitivity analysis to second-order sensitivity and stability analysis. This section is organized following this classification. Even though VSA has been used extensively in a wide range of problems, examples given here come from geophysical applications. Indeed, in that case, the control vector is generally of very large dimension; therefore, global SA techniques are out of reach. Moreover, quite often tangent and/or adjoint models are already available since they are used for data assimilation.

3.1 Sensitivity to Initial or Boundary Condition Changes

Sensitivity to initial condition changes ($\mathbf{x} = \mathbf{u}_0$) is routinely used in numerical weather prediction systems. In that case, the model (32.1) describes the evolution of the atmosphere, initialized with \mathbf{u}_0 . The parameter vector $\mathbf{x} = \mathbf{u}_0$ represents the full state of the atmosphere. In modern atmospheric models, that amounts to $10^9 - 10^{10}$ unknowns that are correlated.

The response function follows the form of (32.4), with:

$$\mathcal{H}(\mathbf{u}(\mathbf{u}_0)) = \| \mathbf{z}^{\text{obs}}(t) - H[\mathbf{u}(\mathbf{u}_0; t)] \|_{\mathcal{O}}^2$$

where \mathbf{z}^{obs} are observations of the system, H maps the state vector to the observation space, and $\| \cdot \|_{\mathcal{O}}$ is typically a weighted L^2 norm. Following (32.4), the response function is then

$$G(\mathbf{u}_0) = \frac{1}{2} \int_0^T \| \mathbf{z}^{\text{obs}}(t) - H[\mathbf{u}(\mathbf{u}_0; t)] \|_{\mathcal{O}}^2 dt \quad (32.21)$$

Local sensitivities of such functions can be very useful to understand the behavior of a system and have been extensively used in geosciences (see, for instance, [8, 28, 34], or [2]).

One can find an example of application of such methods on the Mercator Ocean's 1/4° global ocean model in [31]. The initial objective was to try to estimate the influences of geographical areas to reduce the forecast error using an adjoint method to compute the sensitivities. A preliminary study has been conducted by considering the misfit to observations as a proxy of the forecast error and sought to determine the sensitivity of this misfit to regional changes in the initial condition and/or to forcing. That should give an indication about the important phenomena to consider to improve this system.

The most easily interpreted case in this study is to consider a sensitivity criterion coming from the difference in sea surface temperature (SST) maps at the final instant of the assimilation cycle, because of its dense coverage in space. The response function (32.21) is a discrete version of the time integral, in which the operator H (mapping the state vector \mathbf{u} to the observation space) simply extracts the SST of the state vector. This can be translated into computing the gradient:

$$G(\mathbf{u}_0, \mathbf{q}) = \frac{1}{2} \sum_{n=1}^{N_{\text{SST}}} \| H_{\text{SST}}(\mathbf{u}_n) - \text{SST}^{\text{obs}} \|_{\mathbf{R}^{-1}}^2 \quad (32.22)$$

with a parameter vector $\mathbf{x} = (\mathbf{u}_0, \mathbf{q})$ made of $\mathbf{u}_0 = (u_0, v_0, T_0, S_0, \eta_0)^T$ the initial state vector (current velocity components, temperature, salinity, and sea level) and of $\mathbf{q} = (q_{sr}, q_{ns}, emp)^T$ (radiative fluxes, total heat fluxes, freshwater fluxes) and SST^{obs} observations of SST.

One can see an example of sensitivity to initial temperature (surface and 100 m) as shown in the two bottom panels of Fig. 32.1. High sensitivity will give a signal similar to the gap in observations (top left), while low sensitivity will show a white area. In this example, it is clear that the SST misfit is highly sensitive to changes in surface temperature where the initial mixed layer depth (top right) is low and insensitive elsewhere. The opposite conclusion can be drawn from the sensitivity to the initial temperature at 100 m. This is obviously not a surprise and corresponds more to the purpose of verification of the model rather than system improvement. However, it highlights the importance of having a good estimate of the vertical mixing. Other components of the gradient show the important role of atmospheric forcing (again this could have been anticipated), and ways to improve the system also appear to point to that direction.

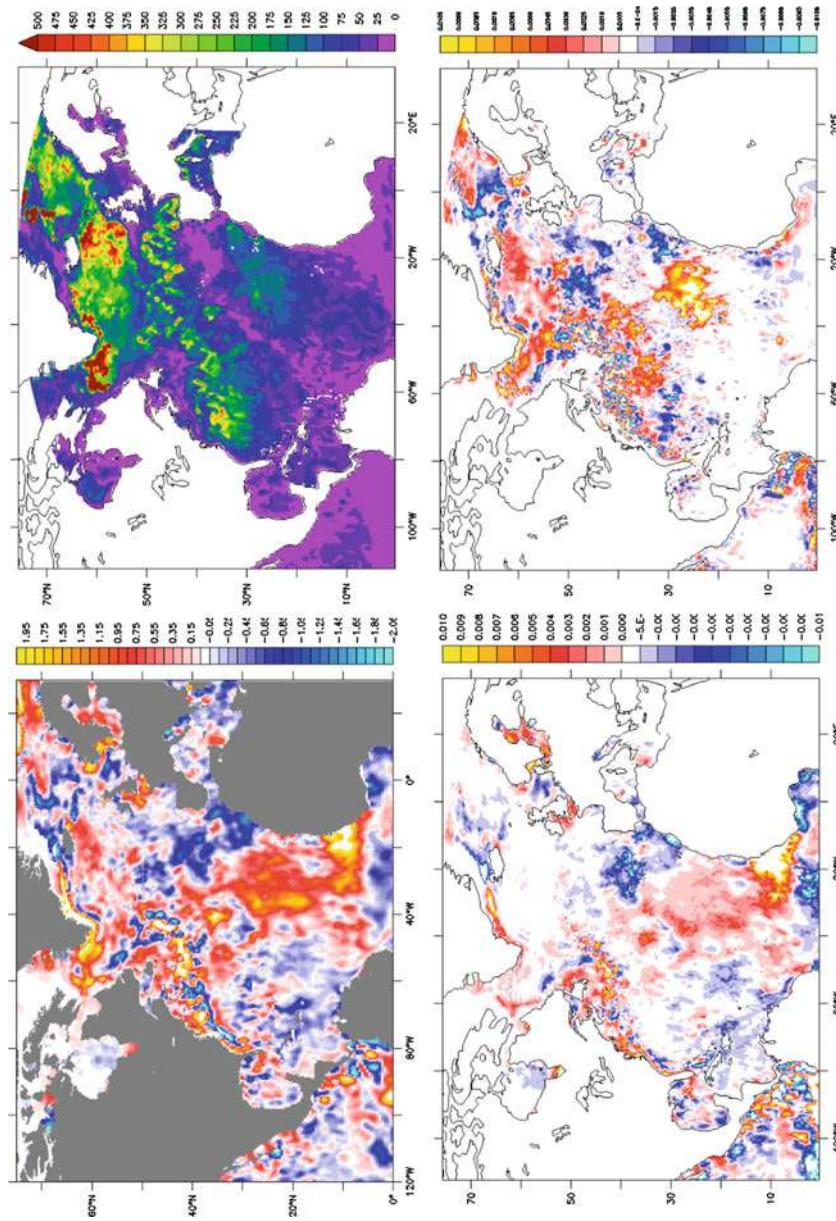

Fig. 32.1 Top: misfit between forecast and observed SST (left) and mixed layer depth (right). Bottom: sensitivity to 1-week lead time SST error with respect to variations in initial surface (left) and 100 m (right) and 1000 m temperature (From [31])

This kind of study is also routinely used to target observations. For example, in order to be able to track tropical cyclones, it is possible to use the so-called adjoint-derived sensitivity steering vectors (ADSSV, [5, 14, 32]). In that case, the model Eq. (32.1) represents the evolution of the atmosphere, starting from an initial state vector \mathbf{u}_0 . Some technicalities allow to choose the parameter vector \mathbf{x} equal to the vorticity at initial time $\mathbf{x} = \xi_0 = \frac{\partial v_0}{\partial x} - \frac{\partial u_0}{\partial y}$. Then the response function follows the form (32.9); it is a two-criteria function at a given verification time t_1 :

$$G(\xi_0) = \left(\frac{1}{|A|} \int_A u(t_1) dx, \frac{1}{|A|} \int_A v(t_1) dx \right)^T \quad (32.23)$$

where $\frac{1}{|A|} \int_A u dx$ and $\frac{1}{|A|} \int_A v dx$ are the zonal and meridional averaged wind velocities over a given area of interest A . By looking at the sensitivities to ξ_0 : $\frac{\partial G_u}{\partial \xi_0}$ and $\frac{\partial G_v}{\partial \xi_0}$, one will get information about the way the tropical cyclone is likely to go. For example, if at a given forecast time at one particular grid point the ADSSV vector points to the east, an increase in the vorticity at this very point at the observing time would be associated with an increase in the eastward steering flow of the storm at the verifying time [32]. This information, in turn, helps to decide where to launch useful observations.

3.2 Parameter Sensitivity

The previous section focuses on variable input quantities (initial/boundary conditions or forcings); however, most of numerical models also rely on a set of physical parameters. They are generally only approximatively known and their settings depend on the studied case. Methods to measure sensitivities to parameter changes are the same as before; differences mostly lie in the parameter set nature: it is generally of small to medium size and elements are mostly uncorrelated. To both respect, they may be better suited for GSA. However, in some cases, these parameters can, for instance, vary spatially and therefore be out of reach of global analysis.

Examples of spatially varying parameters are quite common in geophysics, and an example in glaciology will be given here. In the framework of global change and in particular sea-level change, the volume evolution of the two main ice caps (Antarctica and Greenland) is of crucial interest. In ice cap modeling, experts consider that the basal characteristics of the ice cap are particularly important: basal melt rate and basal sliding coefficient (linked to the sliding velocity). These basal characteristics can be considered as parameters (they are intrinsic to the modeled system) while being spatially varying, and their influence on the ice cap volume must be quantified in order to better understand and predict the future volume evolution.

This has been studied, for example, in [13], where the authors use adjoint methods to compute the sensitivities of the ice volume V over Greenland to

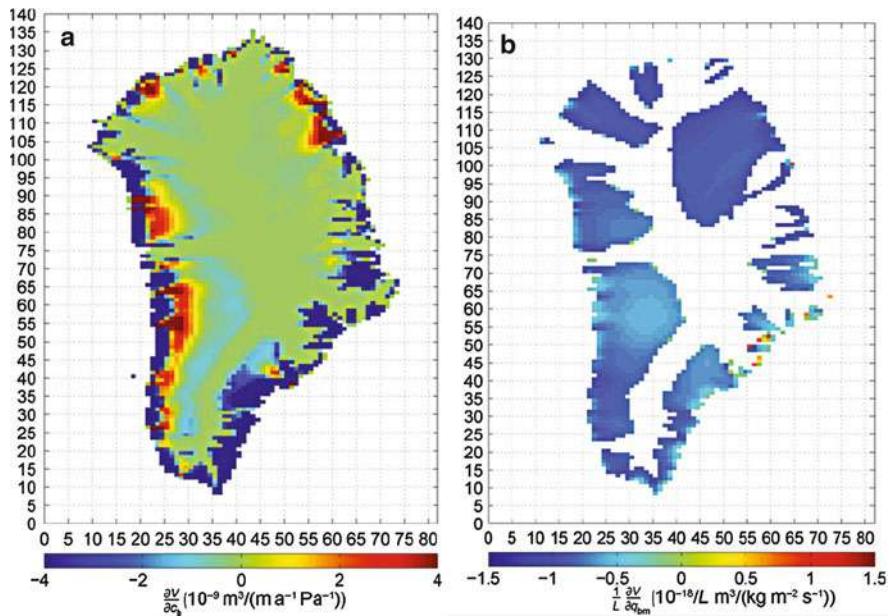

Fig. 32.2 Adjoint sensitivity maps of the total Greenland ice volume V related to (a) basal sliding c_b and (b) basal melt rate q_{bm} (From [13], copyright International Glaciological Society)

perturbations on the basal sliding c_b and the basal melt rate q_{bm} . Let us note here that in this case, the adjoint model has been obtained using automatic differentiation tools. Figure 32.2 shows that sliding sensitivities exhibit significant regional variations and are mostly located in the coastal areas, whereas melt-rate sensitivities are either fairly uniform or they completely vanish. This kind of information is of prime importance when tuning the model parameter and/or designing an observation campaign for measuring said parameters. For instance, in this particular system, there is no gain to be expected by focusing on the interior of the domain.

3.3 Sensitivity of Complex Systems

Previously presented examples focus on looking for sensitivities of a given model to perturbations. However, these approaches can be extended to more complex problems such as coupled models, for instance, or even a forecasting system, i.e., a modeling system that also includes an initialization scheme. Most of the time, this initialization is done through the so-called data assimilation techniques, where observations from the past are used to adjust the present state of the system. There are two kinds of such techniques, either based on filtering approaches or variational methods. Filtering techniques aim at bringing the model trajectory closer

to observations through a sequence of prediction and correction steps, i.e., the model is corrected as follows:

$$\frac{d\mathbf{u}}{dt} = \mathcal{M}(\mathbf{u}; \mathbf{x}) + \mathbf{K} (H(\mathbf{u}(t)) - \mathbf{y}^{\text{obs}}(t)) \quad (32.24)$$

where \mathbf{K} is a gain matrix. For the simplest versions of filtering data assimilation, \mathbf{K} does not depend on $\mathbf{u}(t)$, so computing sensitivities to such system can be done similarly as before (see [33] for an example). However, in more sophisticated approach, like variational data assimilation, it is less straightforward. In that case, the data assimilation problem is solved through the minimization of a cost function that is typically Eq. (32.21). Looking for local sensitivities on the forecasting system would mean to look for sensitivities to the optimal solution of the minimization of (32.21), that is to say to compute the gradient of the whole optimality system (direct model, adjoint model, cost function); doing so by adjoint method may require the second-order adjoint model [6, 16].

Another example of complex system is to perform a sensitivity analysis on a stability analysis (i.e., how given perturbations will affect the stability of a system).

In [27], the authors use stability analysis to study the sensitivity of the thermohaline oceanic circulation (large-scale circulation, mostly dominated by density variations, i.e., temperature and salinity variations). To do so, they look for the optimal initial perturbation of the sea surface salinity that induces the largest variation of the thermohaline circulation.

In [23], the authors are interested in the moist predictability in meteorological models. Since this is a very nonlinear process, they propose to use nonlinear singular vectors as response function G :

$$G(\mathbf{u}_0) = \arg \max_{\|\mathbf{h}_0\|=E_0} \left(\frac{\|\mathcal{M}(\mathbf{u}_0 + \mathbf{h}_0, T) - \mathcal{M}(\mathbf{u}_0, T)\|}{\|\mathbf{h}_0\|} \right) \quad (32.25)$$

This tells which variation in the initial condition will affect the most the optimal perturbations and then the predictability. Note that in that case, computing $\nabla_{\mathbf{u}_0} G(\mathbf{u}_0)$ also requires the second-order adjoint.

Obviously, these are only a handful of possible applications among many; as long as one defines a response function, one could be interested by studying its sensitivities.

4 Conclusion

Variational methods are local sensitivity analysis techniques; they gather a set of methods from very basic to sophisticated as presented above. The main advantage is that they can be used for very large dimension problems if using adjoint methods; the downside is that it may require some heavy developments. This burden can be reduced however by the use of automatic differentiation tools. They have been

used for a very wide range of applications and even on a daily basis in operational numerical weather prediction. Although they are local by essence, adjoint-based variational methods can be extended to global sensitivity analysis as will be presented in ► Chap. 36, “Derivative-Based Global Sensitivity Measures”.

Methods presented here are dedicated to first-order local sensitivity analysis. This can be extended to interaction studies by using the second-order derivatives (Hessian), which can be computed similarly using so-called second-order adjoint models.

Readers interested in going further could start with clearly written and easy to read papers such as [4, 13, 17]. To go further, the book [3] and the application paper [2] are recommended. And, finally, about second-order derivatives, [16] provides a nice introduction, and [23] offers an advanced application.

Abstract

The aim of this paper is to review methods of designing screening experiments, ranging from designs originally developed for physical experiments to those especially tailored to experiments on numerical models. The strengths and weaknesses of the various designs for screening variables in numerical models are discussed. First, classes of factorial designs for experiments to estimate main effects and interactions through a linear statistical model are described, specifically regular and nonregular fractional factorial designs, supersaturated designs, and systematic fractional replicate designs. Generic issues of aliasing, bias, and cancellation of factorial effects are discussed. Second, group screening experiments are considered including factorial group screening and sequential bifurcation. Third, random sampling plans are addressed including Latin hypercube sampling and sampling plans to estimate elementary effects. Fourth, a variety of modeling methods commonly employed with screening designs are briefly described. Finally, a novel study demonstrates six screening methods on two frequently-used exemplars, and their performances are compared.

1 Introduction

Screening [32] is the process of discovering, through statistical design of experiments and modeling, those controllable factors or input variables that have a substantive impact on the response or output which is either calculated from a numerical model or observed from a physical process.

Knowledge of these *active* input variables is key to optimization and control of the numerical model or process. In many areas of science and industry, there are often a large number of potentially important variables. Effective screening experiments are then needed to identify the active variables as economically as possible. This may be achieved through careful choice of experiment size and the set of combinations of input variable values (the design) to be run in the experiment. Each run determines an evaluation of the numerical model or an observation to be made on the physical process. The variables found to be active from the experiment are further investigated in one or more follow-up experiments that enable estimation of a detailed predictive statistical model of the output variable.

The need to screen a large number of input variables in a relatively small experiment presents challenges for both design and modeling. Crucial to success is the principle of *factor sparsity* [16] which states that only a small proportion of the input variables have a substantive influence on the output. If this widely observed principle does not hold, then a small screening experiment may fail to reliably detect the active variables, and a much larger investigation will be required.

While most literature has focused on designs for physical experiments, screening is also important in the study of numerical models via computer experiments [97].

Such models often describe complex input-output relationships and have numerous input variables. A primary reason for building a numerical model is to gain better understanding of the nature of these relationships, especially the identification of the active input variables. If a small set of active variables can be identified, then the computational costs of subsequent exploration and exploitation of the numerical model are reduced. Construction of a surrogate model from the active variables requires less experimentation, and smaller Monte Carlo samples may suffice for uncertainty analysis and uncertainty propagation.

The effectiveness of screening can be evaluated in a variety of ways. Suppose there are d input variables held in vector $\mathbf{x} = (x_1, \dots, x_d)^T$ and that $\mathcal{X} \subset \mathbb{R}^d$ contains all possible values of \mathbf{x} , i.e., all possible combinations of input variable values. Let $A_T \subseteq \{1, \dots, d\}$ be the set of indices of the truly active variables and $A_S \subseteq \{1, \dots, d\}$ consist of the indices of those variables selected as active through screening. Then, the following measures may be defined: (i) sensitivity, $\phi_s = |A_S \cap A_T|/|A_T|$, the proportion of active variables that are successfully detected, where ϕ_s is defined as 1 when $A_T = \emptyset$; (ii) false discovery rate [8], $\phi_{\text{fdr}} = |A_S \cap \bar{A}_T|/|A_S|$, where \bar{A}_T is the complement of A_T , the proportion of variables selected as active that are actually inactive, and ϕ_{fdr} is defined as 0 when $A_S = \emptyset$; and (iii) type I error rate, $\phi_I = |A_S \cap \bar{A}_T|/|\bar{A}_T|$, the proportion of inactive variables that are selected as active. In practice, high sensitivity is often considered more important than a low type I error rate or false discovery rate [34] because failure to detect an active input variable results in no further investigation of the variable and no exploitation of its effect on the output for purposes of optimization and control.

The majority of designs for screening experiments are tailored to the identification and estimation of a surrogate model that approximates an output variable $Y(\mathbf{x})$. A class of surrogate models which has been successfully applied in a variety of fields [80] has the form

$$Y(\mathbf{x}) = \mathbf{h}^T(\mathbf{x})\boldsymbol{\beta} + \varepsilon(\mathbf{x}), \quad (33.1)$$

where \mathbf{h} is a $p \times 1$ vector of known functions of \mathbf{x} , $\boldsymbol{\beta} = (\beta_0, \dots, \beta_{p-1})^T$ are unknown parameters, and $\varepsilon(\mathbf{x})$ is a random variable with a $N(0, \sigma^2)$ distribution for constant σ^2 . Note that if multiple responses are obtained from each run of the experiment, then the simplest and most common approach is separate screening of the variables for each response using individual models of the form (33.1).

An important decision in planning a screening experiment is the level of fidelity, or accuracy, required of a surrogate model for effective screening including the choice of the elements of \mathbf{h} in (33.1). Two forms of (33.1) are commonly used for screening variables in numerical models: linear regression models and Gaussian process models.

1.1 Linear Regression Models

Linear regression models assume that $\varepsilon(\mathbf{x}_0)$ and $\varepsilon(\mathbf{x}'_0)$, $\mathbf{x}_0 \neq \mathbf{x}'_0 \in \mathcal{X}$, are independent random variables. Estimation of detailed mean functions $\mathbf{h}^T(\mathbf{x})\boldsymbol{\beta}$ with a large number of terms requires large experiments which can be prohibitively expensive. Hence, many popular screening strategies investigate each input variable x_i at two levels, often coded +1 and -1 and referred to as “high” and “low,” respectively [15, chs. 6 and 7]. Interest is then in identifying those variables that have a large *main effect*, defined for variable x_i as the difference between the average expected responses for the 2^{d-1} combinations of variable values with $x_i = +1$ and the average for the 2^{d-1} combinations with $x_i = -1$. Main effects may be estimated via a *first-order surrogate model*

$$\mathbf{h}^T(\mathbf{x})\boldsymbol{\beta} = \beta_0 + \beta_1 x_1 + \dots + \beta_d x_d, \quad (33.2)$$

where $p = d + 1$. Such a “main effects screening” strategy relies on a firm belief in *strong effect heredity* [46], that is, important interactions or other nonlinearities involve only those input variables that have large main effects. Without this property, active variables may be overlooked.

There is evidence, particularly from industrial experiments [18, 99], that strong effect heredity may fail to hold in practice. This has led to the recent development and assessment of design and data analysis methodology that also allows screening of interactions between pairs of variables [34, 57]. For two-level variables, the interaction between x_i and x_j ($i, j = 1, \dots, d; i \neq j$) is defined as one-half of the difference between the conditional main effect for x_i given $x_j = +1$ and the conditional main effect of x_i given $x_j = -1$. Main effects and two-variable interactions can be estimated via a *first-order surrogate model supplemented by two-variable product terms*

$$\mathbf{h}^T(\mathbf{x})\boldsymbol{\beta} = \beta_0 + \beta_1 x_1 + \dots + \beta_d x_d + \beta_{12} x_1 x_2 + \dots + \beta_{(d-1)d} x_{d-1} x_d, \quad (33.3)$$

where $p = 1 + d(d + 1)/2$ and $\beta_{d+1}, \dots, \beta_{p-1}$ in (33.1) are relabeled $\beta_{12}, \dots, \beta_{(d-1)d}$ for notational clarity.

The main effects and interactions are collectively known as the factorial effects and can be shown to be the elements of $2\boldsymbol{\beta}$. The screening problem may be cast as variable or model selection, that is, choosing a statistical model composed of a subset of the terms in (33.3).

The parameters in $\boldsymbol{\beta}$ can be estimated by least squares. Let $x_i^{(j)}$ be the value taken by the i th variable in the j th run ($i = 1, \dots, d; j = 1, \dots, n$). Then, the rows of the $n \times d$ *design matrix* $\mathbf{X}^n = (x_1^{(j)}, \dots, x_d^{(j)})_{j=1, \dots, n}$ each hold one run of the design. Let $\mathbf{Y}^n = (Y^{(1)}, \dots, Y^{(n)})$ be the output vector. Then, the least squares estimator of $\boldsymbol{\beta}$ is

$$\hat{\boldsymbol{\beta}} = (\mathbf{H}^T \mathbf{H})^{-1} \mathbf{H}^T \mathbf{Y}^n, \quad (33.4)$$

where $\mathbf{H} = (\mathbf{h}(\mathbf{x}_1^n), \dots, \mathbf{h}(\mathbf{x}_n^n))^T$ is the *model matrix* and $(\mathbf{x}_j^n)^T$ is the j th row of \mathbf{X}^n . For the least squares estimators to be uniquely defined, \mathbf{H} must be of full column rank.

In physical screening experiments, often no attempt is made to estimate nonlinear effects other than two-variable interactions. This practice is underpinned by the principle of *effect hierarchy* [112] which states that low-order factorial effects, such as main effects and two-variable interactions, are more likely to be important than higher-order effects. This principle is supported by substantial empirical evidence from physical experiments.

However, the exclusion of higher-order terms from surrogate model (33.1) can result in biased estimators (33.4). Understanding, and minimizing, this bias is key to effective linear model screening. Suppose that a more appropriate surrogate model is

$$Y(\mathbf{x}) = \beta_0 + \mathbf{h}^T(\mathbf{x})\boldsymbol{\beta} + \tilde{\mathbf{h}}^T(\mathbf{x})\tilde{\boldsymbol{\beta}} + \varepsilon,$$

where $\tilde{\mathbf{h}}(\mathbf{x})$ is a \tilde{p} -vector of model terms, additional to those held in $\mathbf{h}(\mathbf{x})$, and $\tilde{\boldsymbol{\beta}}$ is a \tilde{p} -vector of constants. Then, the expected value of $\hat{\boldsymbol{\beta}}$ is given by

$$\mathbb{E}(\hat{\boldsymbol{\beta}}) = \boldsymbol{\beta} + \mathbf{A}\tilde{\boldsymbol{\beta}}, \quad (33.5)$$

where

$$\mathbf{A} = (\mathbf{H}^T \mathbf{H})^{-1} \mathbf{H}^T \tilde{\mathbf{H}}, \quad (33.6)$$

and $\tilde{\mathbf{H}} = (\tilde{\mathbf{h}}(\mathbf{x}_j^n))_j$. The *alias matrix* \mathbf{A} determines the pattern of bias in $\hat{\boldsymbol{\beta}}$ due to omitting the terms $\tilde{\mathbf{h}}^T(\mathbf{x})\tilde{\boldsymbol{\beta}}$ from the surrogate model and can be controlled through the choice of design. The size of the bias is determined by $\tilde{\boldsymbol{\beta}}$ which is outside the experimenter's control.

1.2 Gaussian Process Models

Gaussian process (GP) models are used when it is anticipated that understanding more complex relationships between the input and output variables is necessary for screening. Under a GP model, it is assumed that $\varepsilon(\mathbf{x}_0), \varepsilon(\mathbf{x}'_0)$ follow a bivariate normal distribution with correlation dependent on a distance metric applied to $\mathbf{x}_0, \mathbf{x}'_0$; see [93] and *Metamodel-based sensitivity analysis: polynomial chaos and Gaussian process*.

Screening with a GP model requires interrogation of the parameters that control this correlation. A common correlation function employed for GP screening has the form

$$\text{cor}(\mathbf{x}, \mathbf{x}') = \prod_{i=1}^d \exp(-\theta_i |x_i - x'_i|^{\alpha_i}), \quad \theta_i \geq 0, 0 < \alpha_i \leq 2. \quad (33.7)$$

Conditional on $\theta_1, \dots, \theta_d$, closed-form maximum likelihood or generalized least squares estimators for β and σ^2 are available. However, θ_i requires numerical estimation. Reliable estimation of these more sophisticated and flexible surrogate models for a large number of variables requires larger experiments and may incur an impractically large number of evaluations of the numerical model.

1.3 Screening without a Surrogate Model

The selection of active variables using a surrogate model relies on the model assumptions and their validation. An alternative model-free approach is the estimation of elementary effects [74]. The elementary effect for the i th input variable for a combination of input values $\mathbf{x}_0 \in \mathcal{X}$ is an approximation to the derivative of $Y(\mathbf{x}_0)$ in the direction of the i th variable. More formally,

$$\text{EE}_i(\mathbf{x}_0) = \frac{Y(\mathbf{x}_0 + \Delta \mathbf{e}_{id}) - Y(\mathbf{x}_0)}{\Delta}, \quad i = 1, \dots, d, \quad (33.8)$$

where \mathbf{e}_{id} is the i th unit vector of length d (the i th column of the $d \times d$ identity matrix) and $\Delta > 0$ is a given constant such that $\mathbf{x} + \Delta \mathbf{e}_{id} \in \mathcal{X}$. Repeated random draws of \mathbf{x}_0 from \mathcal{X} according to a chosen distribution enable an empirical, model-free distribution for the elementary effect of the i th variable to be estimated. The moments (e.g., mean and variance) of this distribution may be used to identify active effects, as discussed later.

In the remainder of the paper, a variety of screening methods are reviewed and discussed, starting with (regular and nonregular) factorial and fractional factorial designs in the next section. Later sections cover methods of screening groups of variables, such as factorial group screening and sequential bifurcation; random sampling plans and space-filling designs, including sampling plans for estimating elementary effects; and model selection methods. The paper finishes by comparing and contrasting the performance of six screening methods on two examples from the literature.

2 Factorial Screening Designs

In a full factorial design, each of the d input variables is assigned a fixed number of values or levels, and the design consists of one run of each of the distinct combinations of these values. Designs in which each variable has two values are mainly considered here, giving $n = 2^d$ runs in the full factorial design. For even moderate values of d , experiments using such designs may be infeasibly large due to the costs or computing resources required. Further, such designs can be wasteful as they allow estimation of all interactions among the d variables, whereas effect hierarchy suggests that low-order factorial effects (main effects and two-variable interactions) will be the most important. These problems may be overcome by using a carefully chosen subset, or *fraction*, of the combinations of variable values in the full factorial design. Such fractional factorial designs have a long history of use in

physical experiments [39] and, more recently, have also been used in the study of numerical models [36]. However, they bring the complication that the individual main effects and interactions cannot be estimated independently. Two classes of designs are discussed here.

2.1 Regular Fractional Factorial Designs

The most widely used two-level fractional factorial designs are $1/2^q$ fractions of the 2^d full factorial design, known as 2^{d-q} designs [112, ch. 5] ($1 \leq q < d$ is integer). As the outputs from all the combinations of variable values are not available from the experiment, the individual main effects and interactions cannot be estimated. However, in a *regular* fractional factorial design, 2^{d-q} linear combinations of the factorial effects can be estimated. Two factorial effects that occur in the same linear combination cannot be independently estimated and are said to be *aliased*. The designs are constructed by choosing which factorial effects should be aliased together.

The following example illustrates a full factorial design, the construction of a regular fractional factorial design, and the resulting aliasing among the factorial effects. Consider first a 2^3 factorial design in variables x_1, x_2, x_3 . Each run of this design is shown as a row across the columns 3–5 in Table 33.1. Thus, these three columns form the design matrix. The entries in these columns are the coefficients of the expected responses in the linear combinations that constitute the main effects, ignoring constants. Where interactions are involved, as in model (33.3), their corresponding coefficients are obtained as elementwise products of columns 3–5. Thus, columns 2–8 of Table 33.1 give the model matrix for model (33.3).

A 2^{4-1} regular fractional factorial design in $n = 8$ runs may be constructed from the 2^3 design by assigning the fourth variable, x_4 , to one of the interaction columns. In Table 33.1, x_4 is assigned to the column corresponding to the highest-order interaction, $x_1x_2x_3$. Each of the eight runs now has the property that $x_1x_2x_3x_4 = +1$, and hence, as each variable can only take values ± 1 , it follows that $x_1 = x_2x_3x_4$, $x_2 = x_1x_3x_4$, and $x_3 = x_1x_2x_4$. Similarly, $x_1x_2 = x_3x_4$, $x_1x_3 = x_2x_4$, and $x_1x_4 = x_2x_3$. Two consequences are: (i) each main effect is aliased with

Table 33.1 A 2^{4-1} fractional factorial design constructed from the 2^3 full factorial design showing the aliased effects

a three-variable interaction and (ii) each two-variable interaction is aliased with another two-variable interaction. However, for each variable, the *sum* of the main effect and the three-variable interaction not involving that variable can be estimated. These two effects are said to be aliased. The other pairs of aliased effects are shown in Table 33.1. The four-variable interaction cannot be estimated and is said to be aliased with the mean, denoted by $I = x_1x_2x_3x_4$ (column 2 of Table 33.1).

An estimable model for this 2^{4-1} design is

$$\tilde{\mathbf{h}}^T(\mathbf{x})\boldsymbol{\beta} = \beta_0 + \beta_1x_1 + \dots + \beta_4x_4 + \beta_{12}x_1x_2 + \beta_{13}x_1x_3 + \beta_{23}x_2x_3,$$

with model matrix \mathbf{H} given by columns 2–9 of Table 33.1. The columns of \mathbf{H} are mutually orthogonal, $\mathbf{h}(\mathbf{x}_j^n)^T\mathbf{h}(\mathbf{x}_k^n) = 0$ for $j \neq k$; $j, k = 1, \dots, 8$. The aliasing in the design will result in a biased estimator of $\boldsymbol{\beta}$. This can be seen by setting

$$\tilde{\mathbf{h}}^T(\mathbf{x})\tilde{\boldsymbol{\beta}} = \beta_{14}x_1x_4 + \beta_{24}x_2x_4 + \beta_{34}x_3x_4 + \sum_{1 \leq j < k < l \leq 4} \beta_{jkl}x_jx_kx_l + \beta_{1234}x_1x_2x_3x_4,$$

which leads to the alias matrix $\mathbf{A} = \sum_{j=1}^8 \mathbf{e}_{j8}\mathbf{e}_{(8-j+1)8}$, which is an anti-diagonal identity matrix, and

$$\mathbb{E}(\hat{\beta}_0) = \beta_0 + \beta_{1234},$$

$$\mathbb{E}(\hat{\beta}_1) = \beta_1 + \beta_{234}, \quad \mathbb{E}(\hat{\beta}_2) = \beta_2 + \beta_{134}, \quad \mathbb{E}(\hat{\beta}_3) = \beta_3 + \beta_{124}, \quad \mathbb{E}(\hat{\beta}_4) = \beta_4 + \beta_{123}$$

$$\mathbb{E}(\hat{\beta}_{12}) = \beta_{12} + \beta_{34}, \quad \mathbb{E}(\hat{\beta}_{13}) = \beta_{13} + \beta_{24}, \quad \mathbb{E}(\hat{\beta}_{23}) = \beta_{23} + \beta_{14}.$$

More generally, to construct a 2^{d-q} fractional factorial design, a set $\{v_1, \dots, v_q\}$ of *defining words*, such as $x_1x_2x_3x_4$, must be chosen and the corresponding factorial effects aliased with the mean. That is, the product of variable values defined by each of these words is constant in the design (and equal to either -1 or $+1$). As the product of any two columns of constants in the design must also be constant, there is a total of $2^q - 1$ effects aliased with the mean. The list of all effects aliased with the mean is called the defining relation and is written as $I = v_1 = \dots = v_q = v_1v_2 = \dots = v_1 \cdots v_q$. Products of the defining words are straightforward to calculate as $x_i^2 = 1$, so that $v_j^2 = 1$ ($i = 1, \dots, d$; $j = 1, \dots, 2^d$).

The aliasing scheme for a design is easily obtained from the defining relation. A factorial effect with corresponding word v_j is aliased with each factorial effect corresponding to the words $v_jv_1, v_jv_2, \dots, v_jv_1 \cdots v_q$ formed by the product of v_j with every word in the defining relation. Hence, the defining relation $I = x_1x_2x_3x_4$ results in $x_1 = x_2x_3x_4, x_2 = x_1x_3x_4$, and so on; see Table 33.1.

As demonstrated above, the impact of aliasing is bias in the estimators of the regression coefficients in (33.1) which can be formulated through the alias matrix. For a regular fractional factorial design, the columns of \mathbf{H} are mutually orthogonal and hence $\mathbf{A} = \frac{1}{n}\mathbf{H}^T\tilde{\mathbf{H}}$. If the functions in $\tilde{\mathbf{h}}$ correspond to those high-order interactions not included in \mathbf{h} , then the elements of A are all either 0 or ± 1 . This is because the aliasing of factorial effects ensures that each column of $\tilde{\mathbf{H}}$ is either

orthogonal to all columns in \mathbf{H} or identical to a column of \mathbf{H} up to a change of sign. Thus, \mathbf{A} identifies the aliasing among the factorial effects.

Crucial to fractional factorial design is the choice of a defining relation to ensure that effects of interest are not aliased together. Typically, this involves choosing defining words to ensure that only words corresponding to higher-order factorial effects are included in the defining relation.

Regular fractional factorial designs are classed according to their *resolution*. A *resolution III* design has at least one main effect aliased with a two-variable interaction. A *resolution IV* design has no main effects aliased with interactions but at least one pair of two-variable interactions aliased together. A *resolution V* design has no main effects or two-variable interactions aliased with any other main effects or two-variable interactions. A more detailed and informative classification of regular fractional factorial designs is obtained via the aberration criterion [25].

Although resolution V designs allow for the estimation of higher-fidelity surrogate models, they typically require too many runs for screening studies. The most common regular fractional factorial designs used in screening are resolution III designs as part of a main-effects screening strategy. The design in Table 33.1 has resolution IV.

2.2 Nonregular Fractional Factorial Designs

The regular designs discussed above require n to be a power of two, which limits their application to some experiments. Further, even resolution III regular fractional factorials may require too many runs to be feasible for large numbers of variables. For example, with 11 variables, a resolution III regular fractional design requires $n = 16$ runs. Smaller experiments with n not equal to a power of two can often be performed by using the wider class of *nonregular* fractional factorial designs [115] that cannot be constructed via a set of defining words. For 11 variables, a design with $n = 12$ runs can be constructed that can estimate all 11 main effects independently of each other. While these designs are more flexible in their run size, the cost is a more complex aliasing scheme that makes interpretation of experimental results more challenging and requires the use of more sophisticated modeling methods.

Many nonregular designs are constructed via *orthogonal arrays* [92]. A symmetric orthogonal array of strength t , denoted by $\text{OA}(n, s^d, t)$, is an $n \times d$ matrix of s different symbols such that all ordered t -tuples of the symbols occur equally often as rows of any $n \times t$ submatrix of the array. Each such array defines an n -run factorial design in d variables, each having s levels. Here, only arrays with $s = 2$ symbols, ± 1 , will be discussed. The strength of the array is closely related to the resolution of the design. An array of strength $t = 2$ allows estimation of all main effects independently of each other but not of the two-variable interactions (cf. resolution III); a strength 3 array allows estimation of main effects independently of two-variable interactions (cf. resolution IV). Clearly, the two-level regular fractional factorial designs are all orthogonal arrays. However, the class of orthogonal arrays is wider and includes many other designs that cannot be obtained via a defining relation.

Table 33.2 The $n = 12$ -run nonregular Plackett-Burman design

Run	x_1	x_2	x_3	x_4	x_5	x_6	x_7	x_8	x_9	x_{10}	x_{11}

8	1	-1	1	-1	1	1	1	-1	-1	-1	1
9	1	-1	-1	1	1	1	-1	1	1	-1	-1
10	1	1	1	-1	-1	-1	-1	1	1	-1	1
11	1	1	-1	1	-1	1	-1	-1	-1	1	1
12	1	1	-1	-1	1	-1	1	-1	1	1	-1

An important class of orthogonal arrays are constructed from Hadamard matrices [44]. A Hadamard matrix \mathbf{C} of order n is an $n \times n$ matrix with entries ± 1 such that $\mathbf{C}^T \mathbf{C} = n\mathbf{I}_n$, where \mathbf{I}_n is the $n \times n$ identity matrix. An $\text{OA}(n, 2^{n-1}, 2)$ is obtained by multiplying rows of \mathbf{C} by -1 as necessary to make all entries in the first column equal to $+1$ and then removing the first column. Such a design can estimate the main effects of all $d = n - 1$ variables independently, assuming negligible interactions. This class of designs includes the regular fractional factorials (e.g., for $n = 4, 8, 16, \dots$) but also other designs with n a multiple of four but not a power of two ($n = 12, 20, 24, \dots$). These designs were first proposed by Plackett and Burman [84]. Table 33.2 gives the $n = 12$ -run Plackett-Burman (PB) design, one of the most frequently used for screening.

The price paid for the greater economy of run size offered by nonregular designs is more complex aliasing. Although designs formed from orthogonal arrays, including PB designs, allow estimation of each main effect independently of all other main effects, these estimators will usually be *partially aliased* with many two-variable interactions. That is, the alias matrix \mathbf{A} will contain many entries with $0 < |a_{ij}| < 1$. For example, consider the aliasing between main effects and two-variable interactions for the 12-run PB design in Table 33.2, as summarized in the 11×55 alias matrix. The main effect of each variable is partially aliased with all 45 interactions that do not include that variable. That is, for the i th variable,

$$\mathbb{E}(\hat{\beta}_i) = \beta_i + \frac{1}{3} \sum_{j=1}^{11} \sum_{k>j}^{11} (-1)^{b_{ijk}} (1 - \mathbb{1}_{i=j \cap i=k}) \beta_{jk},$$

where $\mathbb{1}_A$ is the indicator function for the set A and $b_{ijk} = 0$ or 1 ($i, j, k = 1, \dots, 11$). For this design, each interaction is partially aliased with nine main effects. The competing 16-run resolution III 2^{11-7} regular fraction has each main effect aliased with at most four two-variable interactions, and each interaction aliased only with at most one main effect. Hence, while an active interaction would

Table 33.3 The definitive screening design for $d = 6$ variables

Run	x_1	x_2	x_3	x_4	x_5	x_6
1	0	1	-1	-1	-1	-1
2	0	-1	1	1	1	1
3	1	0	-1	1	1	-1
4	-1	0	1	-1	-1	1
5	-1	-1	0	1	-1	-1

7	-1	1	1	0	1	-1
8	1	-1	-1	0	-1	1
9	1	-1	1	-1	0	-1
10	-1	1	-1	1	0	1
11	1	1	1	1	-1	0
12	-1	-1	-1	-1	1	0
13	0	0	0	0	0	0

bias only one main effect for the regular design, it would bias nine main effects for the PB design, albeit to a lesser extent.

However, an important advantage of partial aliasing is that it allows interactions to be considered through the use of variable selection methods (discussed later) without requiring a large increase in the number of runs. For example, the 12-run PB design has been used to identify important interactions [26, 46].

A wide range of nonregular designs can be constructed. An algorithm has been developed for constructing designs which allow orthogonal estimation of all main effects together with catalogues of designs for $n = 12, 16, 20$ [101]. Other authors have used computer search and criteria based on model selection properties to find nonregular designs [58]. A common approach is to use criteria derived from D -optimality [4, ch. 11] to find fractional factorial designs for differing numbers of variables and runs [35]. Designs from these methods may or may not allow independent estimation of the variable main effects dependent on the models under investigation and the number of runs available.

Most screening experiments use designs at two levels, possibly with the addition of one or more center points to provide a portmanteau test for curvature. Recently, an economic class of three-level screening designs have been proposed, called “definitive screening designs” (DSDs) [53], to investigate d variables, generally in as few as $n = 2d + 1$ runs. The structure of the designs is illustrated in Table 33.3 for $d = 6$. The design has a single center point and $2d$ runs formed from d mirrored pairs. The j th pair has the j th variable set to zero and the other $d - 1$ variables set to ± 1 . The second run in the pair is formed by multiplying all the elements in the first run by -1 . That is, the $2d$ runs form a *foldover* design [17]. This foldover property ensures that main effects and two-variable interactions are orthogonal and hence main effects are estimated independently from these interactions, unlike for resolution III or PB designs. Further, all quadratic effects are estimated independently of the main effects but not independently of the two-variable interactions. Finally, the two-variable interactions will be partially aliased

with each other. These designs are growing in popularity, with a sizeable literature available on their construction [79, 82, 113].

2.3 Supersaturated Designs for Main Effects Screening

For experiments with a large number of variables or runs that are very expensive or time consuming, *supersaturated* designs have been proposed as a low-resource (small n) solution to the screening problem [42]. Originally, supersaturated designs were defined as having too few runs to estimate the intercept and the d main effects in model (33.2), that is, $n < d + 1$. The resulting partial aliasing is more complicated than for the designs discussed so far, in that at least one main effect estimator is biased by one or more other main effects. Consequently, there has been some controversy about the use of these designs [1]. Recently, evidence has been provided for the effectiveness of the designs when factor sparsity holds and the active main effects are large [34, 67]. Applications of supersaturated designs include screening variables in numerical models for circuit design [65], extraterrestrial atmospheric science [27], and simulation models for maritime terrorism [114].

Supersaturated designs were first proposed in the discussion [14] of random balance designs [98]. The first systematic construction method [11] found designs via computer search that have pairs of columns of the design matrix \mathbf{X}^n as nearly orthogonal as possible through use of the $\mathbb{E}(s^2)$ design selection criterion (defined below). There was no further research in the area for more than 30 years until Lin [61] and Wu [111] independently revived interest in the construction of these designs. Both their methods are based on Hadamard matrices and can be understood, respectively, as (i) selecting a half-fraction from a Hadamard matrix (Lin) and (ii) appending one or more interaction columns to a Hadamard matrix and assigning a new variable to each of these columns (Wu).

Both methods can be illustrated using the $n = 12$ -run PB design in Table 33.2. To construct a supersaturated design for $d = 10$ variables in $n = 6$ runs by method (i), all six runs of the PB design with $x_{11} = -1$ are removed, followed by deletion of the x_{11} column. The resulting design is shown in Table 33.4. To obtain a design by method (ii) for $d = 21$ variables in $n = 12$ runs, ten columns are appended that correspond to the interactions of x_1 with variables x_2 to x_{11} , and variables x_{12} to x_{21} are assigned to these columns; see Table 33.5.

Table 33.4 An $n = 6$ -run supersaturated design for $d = 10$ variables obtained by the method of Lin [61]

Run	x_1	x_2	x_3	x_4	x_5	x_6	x_7	x_8	x_9	x_{10}

10	1	1	-1	-1	-1	-1	1	1	-1	1	1	-1	-1	-1	-1	1	1	1	-1	1	1
11	1	1	-1	1	-1	1	-1	-1	1	1	1	-1	1	-1	1	-1	-1	-1	-1	1	1
12	1	1	-1	-1	1	-1	1	-1	1	-1	1	-1	-1	1	-1	1	-1	1	-1	1	-1

Since 1993, there has been a substantial research effort on construction methods for supersaturated designs; see, for example, [62, 77, 78]. The most commonly used criterion for design selection in the literature is $\mathbb{E}(s^2)$ -optimality [11]. More recently, the Bayesian D -optimality criterion [35, 51] has become popular.

2.3.1 $\mathbb{E}(s^2)$ -Optimality

This criterion selects a *balanced* design, that is, a design with $n = 2m$ for some integer $m > 0$ where each column of \mathbf{X}^n contains m entries equal to -1 and m entries equal to $+1$. The $\mathbb{E}(s^2)$ -optimal design minimizes the average of the squared inner products between columns i and j of \mathbf{X}^n ($i, j = 1, \dots, d; i \neq j$),

$$\mathbb{E}(s^2) = \frac{2}{d(d-1)} \sum_{i < j} s_{ij}^2, \quad (33.9)$$

where s_{ij} is the ij th element of $(\mathbf{X}^n)^T \mathbf{X}^n$ ($i, j = 1, \dots, d$). A lower bound on $\mathbb{E}(s^2)$ is available [19, 94]. The designs in Tables 33.4 and 33.5 achieve the lower bound and hence are $\mathbb{E}(s^2)$ -optimal. For the design in Table 33.4, each $s_{ij}^2 = 4$. For the design in Table 33.5, $\mathbb{E}(s^2) = 6.857$ (to 3 dp), with 120 pairs of columns being orthogonal ($s_{ij}^2 = 0$) and the remaining 90 pairs of columns having $s_{ij}^2 = 16$. Recently, the definition of $\mathbb{E}(s^2)$ has been extended to unbalanced designs [52, 67] by including the inner product between each column of \mathbf{X}^n and the vector $\mathbf{1}_n$, the $n \times 1$ vector with every entry 1, which corresponds to the intercept term in model (33.1). This extension widens the class of available designs.

2.3.2 Bayesian D -Optimality

This criterion selects a design that maximizes the determinant of the posterior variance-covariance matrix for $(\beta_0, \boldsymbol{\beta}^T)^T$,

$$\Psi_D = |(\mathbf{H}^*)^T \mathbf{H}^* + \mathbf{K}/\tau^2|^{1/(d+1)}, \quad (33.10)$$

where $\mathbf{H}^* = [\mathbf{1}_n | \mathbf{X}^n]$, $\mathbf{K} = \mathbf{I}_{d+1} - \mathbf{e}_{1(d+1)} \mathbf{e}_{1(d+1)}^T$, $\tau^2 > 0$, and $\tau^2 \mathbf{K}^{-1}$ is the prior variance-covariance matrix for $\boldsymbol{\beta}$. Equation (33.10) results from assuming an informative prior distribution for each β_i ($i = 1, \dots, d$) with mean zero and small prior variance, to reflect factor sparsity, and a non-informative prior distribution for β_0 . The prior information can be regarded as equivalent to having sufficient additional runs to allow estimation of all parameters β_0, \dots, β_d , with the value of τ^2 reflecting the quantity of available prior information. However, the optimal designs obtained tend to be insensitive to the choice of τ^2 [67].

Both $\mathbb{E}(s^2)$ - and D -optimal designs may be found numerically, using algorithms such as columnwise-pairwise [59] or coordinate exchange [71]. From simulation studies, it has been shown that there is little difference in the performance of $\mathbb{E}(s^2)$ - and Bayesian D -optimal designs assessed by, for example, sensitivity and type I error rate [67].

Supersaturated designs have also been constructed that allow the detection of two-variable interactions [64]. Here, the definition of supersaturated has been widened to include designs that have fewer runs than the total number of factorial effects to be investigated. In particular, Bayesian D -optimal designs have been shown to be effective in identifying active interactions [34]. Note that under this expanded definition of supersaturated designs, all fractional factorial designs are supersaturated under model (33.1) when $n < p$.

2.4 Common Issues with Factorial Screening Designs

The analysis of unreplicated factorial designs commonly used for screening experiments has been a topic of much research [45, 56, 105]. In a physical experiment, the lack of replication to provide a model-free estimate of σ^2 can make it difficult to assess the importance of individual factorial effects. The most commonly applied method for orthogonal designs treats this problem as analogous to the identification of outliers and makes use of (half-) normal plots of the factorial effects. For many nonregular and supersaturated designs, more advanced analysis methods are necessary; see later. For studies on numerical models, provided all the input variables are controlled, the problem of assessing statistical significance does not occur as no unusually large observations can have arisen due to “chance.” Here, factorial effects may be ranked by size and those variables whose effects lead to a substantive change in the response declared active.

Biased estimators of factorial effects, however, are an issue for experiments on both numerical models and physical processes. Complex (partial) aliasing can produce two types of bias in the estimated parameters in model (33.1): upward bias so that a type I error may occur (amalgamation) or downward bias leading to missing active variables (cancellation). Simulation studies have been used to assess these risks [31, 34, 67].

Bias may also, of course, be induced by assuming a form of the surrogate model that is too simple, for example, through the surrogate having too few turning points (e.g., being a polynomial of too low order) or lacking the detail to explain the local behavior of the numerical model. This kind of bias is potentially the primary source of mistakes in screening variables in numerical models. When prior scientific knowledge suggests that the numerical model is highly nonlinear, screening methods should be employed that have fewer restrictions on the surrogate model or are model-free. Such methods, including designs for the estimation of elementary effects (33.8), are described later in this paper. Typically, they require larger experiments than the designs in the present section.

2.5 Systematic Fractional Replicate Designs

Systematic fractional replicate designs [28] enable expressions to be estimated that indicate the influence of each variable on the output, through main effects and

interactions, without assumptions in model (33.1) on the order of interactions that may be important. These designs have had considerable use for screening inputs to numerical models, especially in the medical and biological sciences [100, 116]. In these designs, each variable takes two levels and there are $n = 2d + 2$ runs.

The designs are simple to construct as (i) one run with all variables set to -1 , (ii) d runs with each variable in turn set to $+1$ and the other variables set to -1 , (iii) d runs with each variable in turn set to -1 and the other variables set to $+1$, and (iv) one run with all variables set to $+1$. Let the elements of vector \mathbf{Y}^n be such that $Y^{(1)}$ is the output from the run in (i), $Y^{(2)}, \dots, Y^{(d+1)}$ are the outputs from the runs in (ii), $Y^{(d+2)}, \dots, Y^{(2d+1)}$ are from the runs in (iii), and Y^{2d+2} is from the run in (iv). In such a design, each main effect can be estimated independently of all two-variable interactions. This can easily be seen from the alternative construction as a foldover from a *one-factor-at-a-time* (OFAAT) design with $n = d + 1$, that is, a design having one run with each variable set to -1 and d runs with each variable in turn set to $+1$ with all other variables set to -1 .

For each variable x_i ($i = 1, \dots, d$), two linear combinations, $S_o(i)$ and $S_e(i)$, of “odd order” and “even order” model parameters, respectively, can be estimated:

$$S_o(i) = \beta_i + \sum_{j=1}^d \sum_{\substack{k=1 \\ i \neq j \neq k}}^d \beta_{ijk} + \dots, \quad (33.11)$$

and

$$S_e(i) = \sum_{\substack{j=1 \\ i \neq j}}^d \beta_{ij} + \sum_{j=1}^d \sum_{\substack{k=1 \\ i \neq j \neq k}}^d \sum_{l=1}^d \beta_{ijkl} + \dots, \quad (33.12)$$

with respective unbiased estimators

$$C_0(i) = \frac{1}{4} \{ (Y^{(2d+2)} - Y^{(d+i+1)}) + (Y^{(i+1)} - Y^{(1)}) \},$$

and

$$C_e(i) = \frac{1}{4} \{ (Y^{(2d+2)} - Y^{(d+i+1)}) - (Y^{(i+1)} - Y^{(1)}) \}.$$

Under effect hierarchy, it may be anticipated that a large absolute value of $C_o(i)$ is due to a large main effect for the i th variable, and a large absolute value of $C_e(i)$ is due to large two-variable interactions. A design that also enables estimation of two-variable interactions independently of each other is obtained by appending $(d-1)(d-2)/2$ runs, each having two variables set to $+1$ and $d-2$ variables set to -1 [91].

For numerical models, where observations are not subject to random error, active variables are selected by ranking the sensitivity indices defined by

$$S(i) = \frac{M(i)}{\sum_{j=1}^d M(j)}, \quad i = 1, \dots, d, \quad (33.13)$$

where $M(i) = |C_o(i)| + |C_e(i)|$. This methodology is potentially sensitive to the cancellation or amalgamation of factorial effects, discussed in the previous section.

From (33.8), it can also be seen that use of a systematic fractional replicate design is equivalent to calculating two elementary effects (with $\Delta = 2$) for each variable at the extremes of the design region. Let $EE_{1i} = (Y^{(2d+2)} - Y^{(d+i+1)})/2$ and $EE_{2i} = (Y^{(i+1)} - Y^{(1)})/2$ be these elementary effects for the i th variable. Then, it follows directly that $S(i) \propto \max(|EE_{1i}|, |EE_{2i}|)$, and the above method selects as active those variables with elementary effects that are large in absolute value.

3 Screening Groups of Variables

Early work on group screening used pooled blood samples to detect individuals with a disease as economically as possible [33]. The technique was extended, almost 20 years later, to screening large numbers of two-level variables in factorial experiments where a main effects only model is assumed for the output [108]. For an overview of this work and several other strategies, see [75].

In group screening, the set of variables is partitioned into groups, and the values of the variables within each group are varied together. Smaller designs can then be used to experiment on these groups. This strategy deliberately aliases the main effects of the individual variables. Hence, follow-up experimentation is needed on those variables in the groups found to be important in order to detect the individual active variables. The main screening techniques that employ grouping of variables are described below.

3.1 Factorial Group Screening

The majority of factorial group screening methods apply to variables with two levels and use two stages of experimentation. At the first stage, the d variables are partitioned into g groups, where the j th group contains $g_j \geq 1$ variables ($j = 1, \dots, g$). High and low levels for each of the g grouped variables are defined by setting all the individual variables in a group to either their high level or their low level simultaneously. The first experiment with n_1 runs is performed on the relatively small number of grouped variables. *Classical group screening* then estimates the main effects for each of the grouped variables and takes those variables involved in groups that have large estimated main effects through to a second-stage experiment. Individual variables are investigated at this stage, and their main effects, and possibly interactions, are estimated.

For sufficiently large groups of variables, highly resource-efficient designs can be employed at stage 1 of classical group screening for even very large numbers of factors. Under the assumption of negligible interactions, orthogonal nonregular designs, such as PB designs, may be used. For screening variables from a deterministic numerical model, designs in which the columns corresponding to the grouped main effects are not orthogonal can be effective [9] provided $n_1 > g + 1$, as the precision of factorial effect estimators is not a concern.

Effective classical group screening depends on strong effect heredity, namely, that important two-variable interactions occur only between variables both having important main effects. More recently, strategies for group screening that also investigate interactions at stage 1 have been developed [57]. In *interaction group screening*, both main effects and two-variable interactions between the grouped variables are estimated at stage 1. The interaction between two grouped variables is the summation of the interactions between all pairs of variables where one variable comes from each group; interactions between two variables in the same group are aliased with the mean. Variables in groups found to have large estimated main effects or to be involved in large interactions are carried forward to the second stage. From the second-stage experiment, main effects and interactions are examined between the individual variables within each group declared active. Where the first stage has identified a large interaction between two grouped variables, the interactions between pairs of individual variables, one from each group, are also investigated. For this strategy, larger resolution V designs, capable of independently estimating all grouped main effects and two-variable interactions, have so far been used at stage 1, when decisions to drop groups of variables are made.

Group screening experiments can be viewed as supersaturated experiments in the individual variables. However, when orthogonal designs are used for the stage 1 experiment, decisions on which groups of variables to take forward can be made using t -tests on the grouped main effects and interactions. When smaller designs are used, particularly if n_1 is less than the number of grouped effects of interest, more advanced modeling methods are required, in common with other supersaturated designs (see later). Incorrectly discarding active variables at stage 1 may result in missed opportunities to improve process control or product quality. Hence, it is common to be conservative in the choice of design at stage 1, for example, in the number of runs, and also to allow a higher type I error rate.

In the two-stage process, the design for the second experiment cannot be decided until the stage 1 data have been collected and the groups of factors deemed active have been identified. In fact, the size, N_2 , of the second-stage experiment required by the group screening strategy is a random variable. The distribution of N_2 is determined by features under the experimenter's control, such as d , g , g_1, \dots, g_g , n_1 , the first-stage design, and decision rules for declaring a grouped variable active at stage 1. It also depends on features outside the experimenter's control, such as the number of active individual variables and the size and nature of their effects, and the signal-to-noise ratio if the process is noisy. Given prior knowledge of these uncontrollable features, the grouping strategy, designs, and analysis methods can be tailored, for example, to produce a smaller expected experiment size, $n_1 + \mathbb{E}(N_2)$,

or to minimize the probability of missing active variables [57, 104]. Of course, these two goals are usually in conflict and hence a trade-off has to be made. In practice, the design used at stage 2 depends on the number of variables brought forward and the particular effects requiring estimation; options include regular or nonregular fractional factorial designs and D -optimal designs.

Original descriptions of classical group screening made the assumption that all the active variable main effects have the same sign to avoid the possibility of cancellation of the main effects of two or more active variables in the same group. As discussed previously, cancellation can affect any fractional factorial experiment. Group screening is often viewed as particularly susceptible due to the complete aliasing of main effects of individual variables and the screening out of whole groups of variables at stage 1. Often, particularly for numerical models, prior knowledge makes reasonable the assumption of active main effects having the same sign. Otherwise, the risks of missing active variables should be assessed by simulation [69], and, in fact, the risk can be modest under factor sparsity [34].

3.2 Sequential Bifurcation

Screening groups of variables is also used in sequential bifurcation, proposed originally for deterministic simulation experiments [10]. The technique can investigate a very large number of variables, each having two levels, when a sufficiently accurate surrogate for the output is a first-order model (33.2). It is assumed that each parameter β_i ($i = 1, \dots, d$) is positive (or can be made positive by interchanging the variable levels) to avoid cancellation of effects.

The procedure starts with a single group composed of all the variables which is split into two new groups (bifurcation). For a deterministic numerical model, the initial experiment has just two runs: all variables set to the low levels ($\mathbf{x}^{(1)}$) and all variables set to the high levels ($\mathbf{x}^{(2)}$). If the output $Y^{(2)} > Y^{(1)}$, then the group is split, with variables x_1, \dots, x_{d_1} placed in group 1 and x_{d_1+1}, \dots, x_d placed in group 2. At the next stage, a single further run $\mathbf{x}^{(3)}$ is made which has all group 1 variables set to their high levels and all group 2 variables set low. If $Y^{(3)} > Y^{(1)}$, then group 1 is split further, and group 2 is split if $Y^{(2)} > Y^{(3)}$. These comparisons can be replaced by $Y^{(3)} - Y^{(1)} > \delta$ and $Y^{(2)} - Y^{(3)} > \delta$, where δ is an elicited threshold. This procedure of performing one new run and assessing the split of each subsequent group continues until singleton groups, containing variables deemed to be active, have been identified. Finally, these individual variables are investigated. If the output variable is stochastic, the replications of each run are made, and a two-sample t -test can be used to decide whether or not to split a group.

Typically, if $d = 2^k$ for some integer $k > 0$, then at each split, half the variables are assigned to one of the groups, and the other half are assigned to the second group. Otherwise, use of unequal group sizes can increase the efficiency (in terms of overall experiment size) of sequential bifurcation when there is prior knowledge of effect sizes. Then, at each split, the first new group should have size equal to the largest possible power of 2. For example, if the group to be split contains m variables, then

the first new group should contain 2^l variables such that $2^l < m$. The remaining $m - 2^l$ variables are assigned to the second group. If variables have been ordered by an a priori assessment of increasing importance, the most important variables will be in the second, smaller group, and hence more variables can be ruled out as unimportant more quickly.

The importance of two-variable interactions may be investigated by using the output from the following runs to assess each split. The first is run \mathbf{x} used in the standard sequential bifurcation method; the second is the mirror image of \mathbf{x} in which each variable is set low that is set high in \mathbf{x} and vice versa. This foldover structure ensures that any two-variable interactions will not bias estimators of grouped main effects at each stage. This alternative design also permits standard sequential bifurcation to be performed and, if the variables deemed active differ from those found via the foldover, then the presence of active interactions is indicated. Again, successful identification of the active variables relies on the principle of strong effect heredity.

A variety of adaptations of sequential bifurcation have been proposed, including methods of controlling type I and type II error rates [106, 107] and a procedure to identify dispersion effects in robust parameter design [3]. For further details, see [55, ch. 4].

3.3 Iterated Fractional Factorial Designs

These designs [2] also group variables in a sequence of applications of the same fractional factorial design. Unlike factorial group screening and sequential bifurcation, the variables are assigned at random to the groups at each stage. Individual variables are identified as active if they are in the intersection of those groups having important main effects at each stage.

Suppose there are $g = 2^l$ groups, for integer $l > 0$. The initial design has $2g$ runs obtained as a foldover of a $g \times g$ Hadamard matrix; for details, see [23]. This construction gives a design in which main effects are not aliased with two-variable interactions. The $d \geq g$ variables are assigned at random to the groups, and each grouped variable is then assigned at random to a column of the design. The experiment is performed and analyzed as a stage 1 group screening design. Subsequent stages repeat this procedure, using the same design but with different, independent assignments of variables to groups and groups to columns. Individual variables which are common to groups of variables found to be active across several stages of experimentation are deemed to be active. Estimates of the main effects using data from all the stages can also be constructed.

There are two further differences from the other grouping methods discussed in this section. First, for a proportion of the stages, the variables are set to a mid-level value (0), rather than high (+1) or low (-1). These runs allow an estimate of curvature to be made and some screening of quadratic effects to be undertaken. Second, to mitigate cancellation of main effects, the coding of the high and low levels may be swapped at random, that is, the sign of the main effect reversed.

The use of iterated fractional factorial designs requires a larger total number of runs than other group screening methods, as a sequence of factorial screening designs is implemented. However, the method has been suggested for use when there are many variables (thousands) arranged in a few large groups. Simulation studies [95, 96] have indicated that it can be effective here, provided there are very few active variables.

3.4 Two-Stage Group Screening for Gaussian Process Models

More recently, methodology for group screening in two stages of experimentation using Gaussian process modeling to identify the active variables has been developed for numerical models [73]. At the first stage, an initial experiment that employs an orthogonal space-filling design (see the next section) is used to identify variables to be grouped together. Examples are variables that are inert or those having a similar effect on the output, such as having a common sign and a similarly-sized linear or quadratic effect. A sensitivity analysis on the grouped variables is then performed using a Gaussian process model, built from the first-stage data. Groups of variables identified as active in this analysis are investigated in a second-stage experiment in which the variables found to be unimportant are kept constant. The second-stage data are then combined with the first-stage data and a further sensitivity analysis performed to make a final selection of the active variables. An important advantage of this method is the reduced computational cost of performing a sensitivity study on the grouped variables at the first stage.

4 Random Sampling Plans and Space Filling

4.1 Latin Hypercube Sampling

The most common experimental design used to study deterministic numerical models is the Latin hypercube sample (LHS) [70]. These designs address the difficult problem of space filling in high dimensions, that is, when there are many controllable variables. Even when adequate space filling in d dimensions with n points may be impossible, an LHS design offers n points that have good one-dimensional space-filling properties for a chosen distribution, usually a uniform distribution. Thus, use of an LHS at least implicitly invokes the principle of factor sparsity and hence is potentially suited for use in screening experiments.

Construction of a standard d -dimensional LHS is straightforward: generate d random permutations of the integers $1, \dots, n$ and arrange them as an $n \times d$ matrix \mathbf{D} (one permutation forming each column); transform each element of \mathbf{D} to obtain a sample from a given distribution $F(\cdot)$, that is, define the coordinates of the design points as $x_j^{(i)} = F^{-1} \left\{ (d_j^{(i)} - 1)/(n - 1) \right\}$, where $d_j^{(i)}$ is the ij th element of \mathbf{D} ($i = 1, \dots, n$; $j = 1, \dots, d$). Typically, a (small) random perturbation is added to

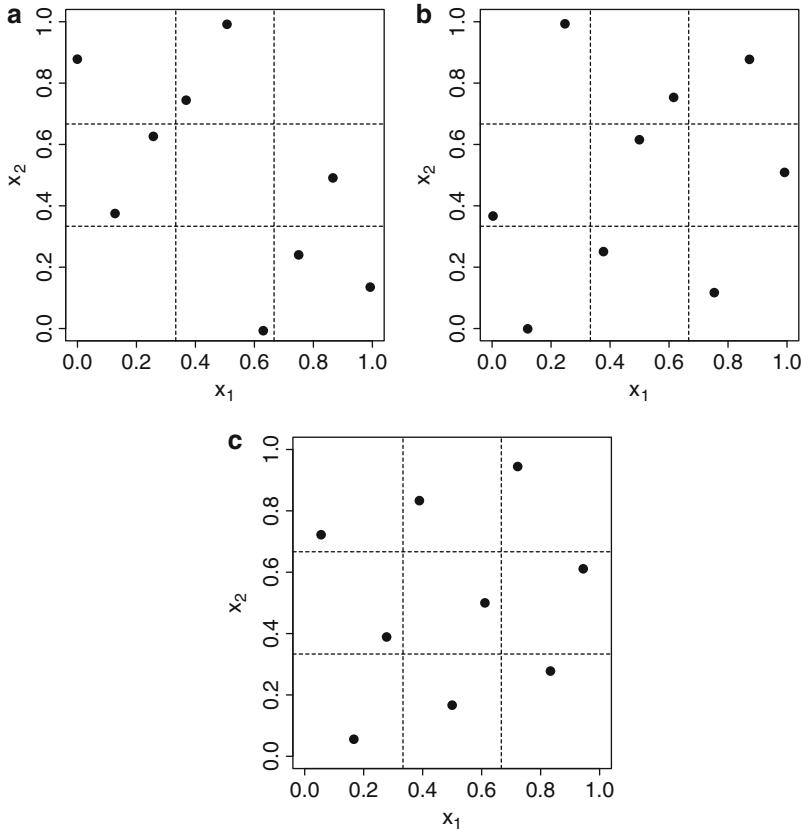

Fig. 33.1 Latin hypercube samples with $n = 9$ and $d = 2$: (a) random LHS, (b) random LHS generated from an orthogonal array, (c) maximin LHS

each $d_j^{(i)}$ or some equivalent operation performed, prior to transformation to $x_j^{(i)}$. An LHS design generated by this method is shown in Fig. 33.1a.

There may be great variation in the overall space-filling properties of LHS designs. For example, the LHS design in Fig. 33.1a clearly has poor two-dimensional space-filling properties. Hence, a variety of extensions to Latin hypercube sampling have been proposed. Most prevalent are orthogonal array-based and maximin Latin hypercube sampling.

To generate an orthogonal array-based LHS [81, 102], the matrix \mathbf{D} is formed from an orthogonal array. Hence, the columns of \mathbf{D} are no longer independent permutations of $1, \dots, d$. For simplicity, assume \mathbf{O} is a symmetric OA(n, s^d, t) with symbols $1, \dots, s$ and $t \geq 2$. The j th row of \mathbf{D} is formed by mapping the n/s occurrences of each symbol in the j th column of \mathbf{O} to a random permutation, α , of n/s new symbols, i.e., $1 \rightarrow \alpha(1, \dots, n/s)$, $2 \rightarrow \alpha(n/s + 1, \dots, 2n/s)$, ..., $s \rightarrow \alpha((s-1)n/s + 1, \dots, n)$, where $\alpha(1, \dots, a)$ is a permutation of the

integers $1, \dots, a$. Figure 33.1b shows an orthogonal array-based LHS, constructed from an OA(9, 3^2 , 2). Notice the improved two-dimensional space filling compared with the randomly generated LHS. The two-dimensional projection properties of more general space-filling designs have also been considered by other authors [29], especially for *uniform* designs minimizing specific L^2 -discrepancies [38].

In addition to the orthogonal array-based LHS, there has been a variety of work on generating space-filling designs that directly minimize the correlation between columns of \mathbf{X}^n [47], including algorithmic [103] and analytic [117] construction methods. Such designs have good two-dimensional space-filling properties and also provide near-independent estimators of the β_i ($i = 1, \dots, d$) in Eq. (33.2), a desirable property for screening.

A maximin LHS [76] achieves a wide spread of design points across the design region by maximizing the minimum distance between pairs of design points within the class of LHS designs with n points and d variables. The Euclidean distance between two points $\mathbf{x} = (x_1, \dots, x_d)^\top$ and $\mathbf{x}' = (x'_1, \dots, x'_d)^\top$ is given by

$$\text{dist}(\mathbf{x}, \mathbf{x}') = \left\{ \sum_{j=1}^d (x_j - x'_j)^2 \right\}^{1/2}. \quad (33.14)$$

Rather than maximizing directly the minimum of (33.14), most authors [6, 76] find designs by minimization of

$$\phi(\mathbf{X}^n) = \left\{ \sum_{1 \leq i < j \leq n} \left[\text{dist}(\mathbf{x}_i^n, \mathbf{x}_j^n) \right]^{-q} \right\}^{1/q}, \quad (33.15)$$

where, for $q \rightarrow \infty$, minimization of (33.15) is equivalent to maximizing the minimum of (33.14) across all pairs of design points; see also [85]. Figure 33.1c shows a maximin LHS, found by this method with $q = 15$. This design displays better two-dimensional space filling than the random LHS and a more even distribution of the design points than the orthogonal array-based LHS.

Maximin LHS can be found using the R packages DiceDesign [40] and SLHD [5]. More general classes of distance-based space-filling designs, without the projection properties of the Latin hypercubes, can also be found [see 13, 50]. Studies of the numerical efficiencies of optimization algorithms for LHS designs are available [29, 49].

Construction of LHS designs is an active area of research, and many further extensions to the basic methods have been suggested. Recently, maximum projection space-filling designs have been found [54] that minimize

$$\psi(\mathbf{X}^n) = \left\{ \frac{1}{\binom{n}{2}} \sum_{1 \leq i < j \leq n} \frac{1}{\prod_{l=1}^d (x_i^{(l)} - x_j^{(l)})^2} \right\}. \quad (33.16)$$

Such a design promotes good space-filling properties, as measured by (33.15), in all projections of the design into subspaces of variables. Objective function (33.16) arises from the use of a weighted Euclidean distance; see also [13].

Another important recent development is *sliced* LHS designs [6, 88, 89], where the design can be partitioned into sets of runs or slices, each of which is an orthogonal or maximin LHS. The overall design, composed of the runs from all the slices, is also an LHS. Such designs may be used to study multiple numerical models having the same inputs where one slice is used to investigate each model, for example, to compare results from different model implementations. They are also useful for experiments on quantitative and qualitative variables when each slice is combined with one combination of levels of the qualitative variables. This latter application is the most important for screening where the resulting data may be used to estimate a surrogate linear model with dummy variables or a GP model with an appropriate correlation structure [90]. Supersaturated LHS designs, for $d \geq n$, have also been developed [21]. See *Maximin sliced Latin hypercube designs, with application to cross validating prediction error* for more on space-filling and Latin hypercube designs.

4.2 Sampling Plans for Estimating Elementary Effects (Morris' Method)

As an alternative to estimation of a surrogate model, Morris [74] suggested a model-free approach that uses the elementary effect (33.8) to measure the sensitivity of the response $Y(\mathbf{x})$ to a change in the i th variable at point \mathbf{x} . Each $\text{EE}_i(\mathbf{x})$ may be exactly or approximately (a) zero for all \mathbf{x} , implying a negligible influence of the i th variable on $Y(\mathbf{x})$; (b) a nonzero constant for all \mathbf{x} , implying a linear, additive effect; (c) a nonconstant function of x_i , implying nonlinearity; or (d) a nonconstant function of x_j for $j \neq i$, implying the presence of at least one interaction involving x_i .

In practice, active variables are usually selected using data from a relatively small experiment, and therefore it is not possible to reconstruct $\text{EE}_i(\mathbf{x})$ as a continuous function of \mathbf{x} . The use of r “trajectory vectors”, $\mathbf{x}_1, \dots, \mathbf{x}_r$, enables the following sensitivity indices to be defined for $i = 1, \dots, d$:

$$\mu_i = \frac{1}{r} \sum_{j=1}^r \text{EE}_i(\mathbf{x}_j) \quad (33.17)$$

and

$$\sigma_i = \sqrt{\sum_{j=1}^r \frac{(\text{EE}_i(\mathbf{x}_j) - \mu_i)^2}{r-1}}. \quad (33.18)$$

A large value of the mean μ_i suggests the i th input variable is active. Nonlinear and interaction effects are indicated by large values of σ_i . Plots of the sensitivity indices may be used to decide which variables are active and, among these variables, which have complex (nonadditive and nonlinear) effects.

In addition to (33.17) and (33.18), an additional measure [22] of the individual effect of the i th variable has been proposed that overcomes the possible cancellation of elementary effects in (33.17) due to non-monotonic variable effects, namely,

$$\mu_i^* = \frac{1}{r} \sum_{j=1}^r |\text{EE}_i(\mathbf{x}_j)|, \quad (33.19)$$

where $|\cdot|$ denotes the absolute value. Large values of both μ_i and μ_i^* suggest that the i th variable is active and has a linear effect on $Y(\mathbf{x})$; large values of μ_i^* and small values of μ_i indicate cancellation in (33.17) and a nonlinear effect for the i th variable.

Four examples of the types of effects which use of (33.17), (33.18) and (33.19) seeks to identify are shown in Fig. 33.2. These are linear, nonlinear, and interaction effects corresponding to nonzero values of (33.17) and (33.19) and both zero and nonzero values of (33.18). It is not possible to use these statistics to distinguish between nonlinear and interaction effects; see Fig. 33.2b, c.

The future development of a surrogate model can be simplified by separation of the active variables into two vectors, \mathbf{x}_{S_1} and \mathbf{x}_{S_2} , where the variables in \mathbf{x}_{S_1} have linear effects and the variables in \mathbf{x}_{S_2} have nonlinear effects or are involved in interactions [12]. For example, model (33.1) might be fitted in which $\mathbf{h}(\mathbf{x}_{S_1})$ consists of linear functions and $\varepsilon(\mathbf{x}_{S_2})$ is modeled via a Gaussian process with correlation structure dependent only on variables in \mathbf{x}_{S_2} .

In the elementary effect literature, the design region is assumed to be $\mathcal{X} = [0, 1]^d$, after any necessary scaling, and is usually approximated by a d -dimensional grid, \mathcal{X}_G , having f equally spaced values, $0, 1/(f - 1), \dots, 1$, for each input variable. The design of a screening experiment to allow the computation of the sample moments (33.17), (33.18) and (33.19) has three components: the trajectory vectors $\mathbf{x}_1, \dots, \mathbf{x}_r$, the m -run sub-design used to calculate $\text{EE}_i(\mathbf{x}_j)$ ($i = 1, \dots, d$) for each \mathbf{x}_j ($j = 1, \dots, r$), and stepsize Δ . Choices for these components are now discussed.

1. Morris [74] chose $\mathbf{x}_1, \dots, \mathbf{x}_r$ at random from \mathcal{X}_G , subject to the constraint that $\mathbf{x}_j + \Delta \mathbf{e}_{id} \in \mathcal{X}_G$ for $i = 1, \dots, d$; $j = 1, \dots, r$. Alternative suggestions include choosing the trajectory vectors as the r points of a space-filling design [22] found, for example, by minimizing (33.15). Larger values of r result in (33.17), (33.18) and (33.19) being more precise estimators of the corresponding moments of the elementary effect distribution. Morris used $r = 3$ or 4 ; more recently, other authors [22] have discussed the use of larger values ($r = 10\text{--}50$).
2. An OFAAT design with $m = d + 1$ runs may be used to calculate $\text{EE}_1(\mathbf{x}_j), \dots, \text{EE}_d(\mathbf{x}_j)$ for $j = 1, \dots, r$. The design matrix is

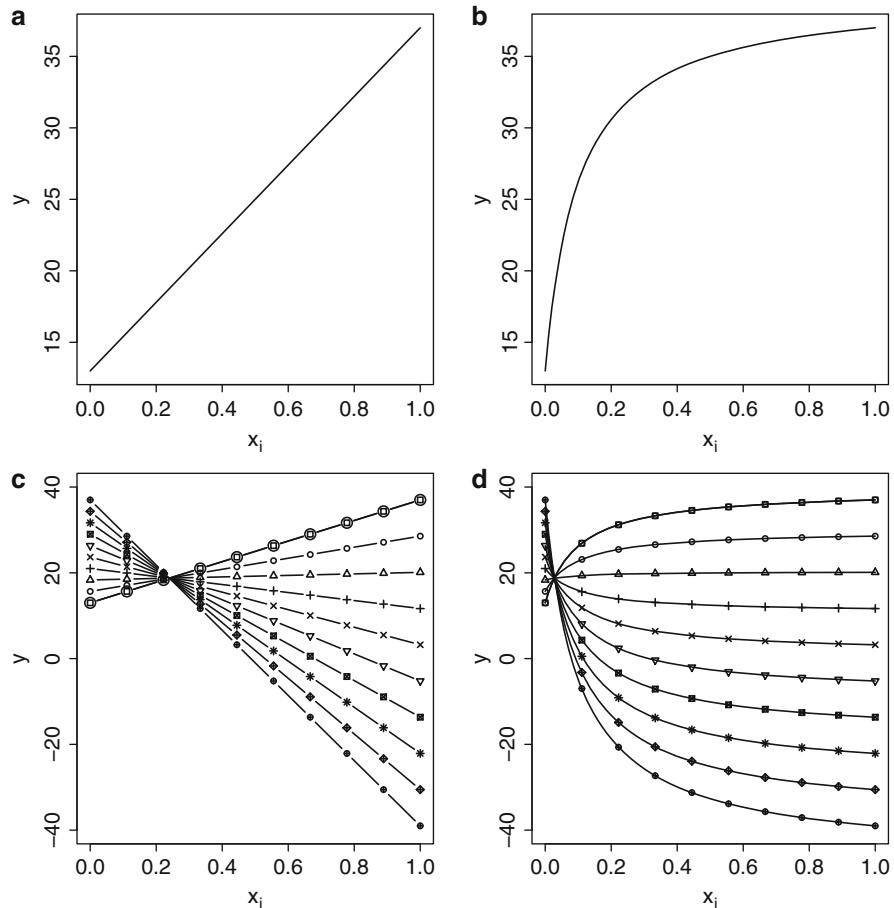

Fig. 33.2 Illustrative examples of effects for an active variable x_i with values of μ_i , μ_i^* , and σ_i . In plots (c) and (d), the plotting symbols correspond to the ten levels of a second variable. (a) Linear effect: $\mu_i > 0$, $\mu_i^* > 0$; $\sigma_i = 0$. (b) Nonlinear effect: $\mu_i^* > 0$; $\sigma_i > 0$. (c) Interaction: $\sigma_i > 0$. (d) Nonlinear effect and interaction: $\mu_i^* > 0$, $\sigma_i > 0$

$\mathbf{X}_j = \mathbf{1}_{d+1}\mathbf{x}_j + \Delta\mathbf{B}$, where $\mathbf{1}_m$ is a column m -vector with all entries equal to 1 and $\mathbf{B} = \sum_{l=2}^{d+1} \sum_{k=1}^{l-1} \mathbf{e}_{l(d+1)} \mathbf{e}_{k(d+1)}^T$. That is, \mathbf{B} is the $(d+1) \times d$ matrix

$$\mathbf{B} = \begin{pmatrix} 0 & 0 & 0 & \cdots & 0 \\ 1 & 0 & 0 & \cdots & 0 \\ 1 & 1 & 0 & \cdots & 0 \\ \vdots & \vdots & & & \vdots \\ 1 & 1 & 1 & \cdots & 1 \end{pmatrix}.$$

Designs are generated by swapping 0's and 1's at random within each column of \mathbf{B} and randomizing the column order. The overall design $\mathbf{X}^n = (\mathbf{X}_1^T, \dots, \mathbf{X}_r^T)^T$ then has $n = (d + 1)r$ runs. It can be shown that this choice of \mathbf{B} , combined with the randomization scheme, minimizes the variability in the number of times in \mathbf{X}^n that each variable takes each of the f possible values [74].

Such OFAAT designs have the disadvantage of poor projectivity onto subsets of (active) variables, compared with, for example, LHS designs. Projection of a d -dimensional OFAAT design into $d - 1$ dimensions reduces the number of distinct points from $d + 1$ to d . This is a particular issue when the projection of the screening design onto the active variables is used to estimate a detailed surrogate model. Better projection properties may be obtained by replacing an OFAAT design by a rotated simplex [86] at the cost of less precision in the estimators of the elementary effects.

3. The choice of the “stepsize” Δ in (33.8) is determined by the choice of design region \mathcal{X}_G . Recommended values are $f = 2g$ for some integer $g > 0$ and $\Delta = f/2(f - 1)$. This choice ensures that all $f^d/2$ elementary effects are equally likely to be selected for each variable when the trajectory vectors \mathbf{x} are selected at random from \mathcal{X}_G .

Further extensions of the elementary effect methodology include the application to group screening for numerical models with hundreds or thousands of input variables through the study of μ^* (33.19) [22], and a sequential experimentation strategy to reduce the number of runs of the numerical model required [12]. This latter approach performs r OFAAT experiments, one for each trajectory vector, in turn. For the j th experiment, elementary effects are calculated only for those variables that have not already been identified as having a nonlinear or interaction effect. That is, if $\sigma_i > \sigma_0$, for some threshold σ_0 , when σ_i is calculated from $r_1 < r$ trajectory vectors, the i th elementary effect is no longer calculated for $\mathbf{x}_{r_1+1}, \dots, \mathbf{x}_r$. The threshold σ_0 can be elicited directly from subject experts or by using prior knowledge about departures from linearity for the effect of each variable [12]. An obvious generalization of the elementary effect method is to compute sensitivity indices directly from the (averaged local) derivatives (see ▶ Chap. 33, “Design of Experiments for Screening”).

Methodology for the design and analysis of screening experiments using elementary effects is available in the R package `sensitivity` [87].

5 Model Selection Methods

The selection and estimation of a surrogate model (33.1) from an application of a design discussed in this paper generally requires advanced statistical methods. An exception is a regular fractional factorial design. For these designs, standard linear modeling methods can be used provided that only one effect from each alias string is included in the model and it is recognized that $\hat{\beta}$ may be biased. A brief description

is now given of variable selection methods for (a) linear models with nonregular and supersaturated designs and (b) Gaussian process models.

5.1 Variable Selection for Nonregular and Supersaturated Designs

For designs with complex partial aliasing such as supersaturated and nonregular fractional factorial designs, a wide range of model selection methods have been proposed. An early suggestion was forward stepwise selection [72], but this was shown to have low sensitivity in many situations [1, 67]. More recently, evidence has been provided for the effectiveness of shrinkage regression for the selection of active effects using data from these more complex designs [34, 67, 83], particularly use of the Dantzig selector [24]. For this method, estimators $\hat{\beta}$ of the parameters in model (33.1) are chosen to satisfy

$$\min_{\hat{\beta} \in \mathbb{R}^p} \sum_{u=1}^p |\hat{\beta}_u| \quad \text{subject to } \|\mathbf{H}^T(\mathbf{Y}^n - \mathbf{H}\hat{\beta})\|_\infty \leq s, \quad (33.20)$$

with s a tuning constant and $\|\mathbf{a}\|_\infty = \max |a_i|$, $\mathbf{a}^T = (a_1, \dots, a_p)$. This equation balances the desire for a parsimonious model with the need for models that adequately describe the data. The value of s can be chosen via an information criterion [20] (e.g., AIC, AICc, BIC). The solution to (33.20) may be obtained via linear programming; computationally efficient algorithms exist for calculating coefficient paths for varying s [48].

The Dantzig selector is applied to choose a subset of potentially active variables, and then standard least squares is used to fit a reduced linear model. The terms in this model whose coefficient estimates exceeded a threshold t , elicited from subject experts, are declared active. This procedure is known as the Gauss-Dantzig selector [24].

Other methods for variable selection that have been effective for these designs include Bayesian methods that use mixture prior distributions for the elements of β [26, 41] and the application of stochastic optimization algorithms [110].

5.2 Variable Selection for Gaussian Process Models

Screening for a Gaussian process model (33.1), with constant mean ($\mathbf{h}(\mathbf{x}) = 1$) and $\varepsilon(\mathbf{x}), \varepsilon(\mathbf{x})'$ having correlation (33.7), may be performed by deciding which θ_i in (33.7) are “large” using data obtained from an LHS or other space-filling design. Two approaches to this problem are outlined below: stepwise Gaussian process variable selection (SGPVS) [109] and reference distribution variable selection (RDVS) [63].

In the first method, screening is via stepwise selection of θ_i, α_i in (33.7), analogous to forward stepwise selection in linear regression models. The SGPVS

algorithm identifies those variables that differ from the majority in their impact on the response in the following steps:

- (i) Find the maximized log-likelihood for model (33.1) subject to $\theta_i = \theta$ and $\alpha_i = \alpha$ for all $i = 1, \dots, d$; denote this by l_0 .
- (ii) Set $\mathcal{E} = \{1, \dots, d\}$.
- (iii) For each $j \in \mathcal{E}$, find the maximized log-likelihood subject to $\theta_k = \theta$ and $\alpha_k = \alpha$ for all $k \in \mathcal{E} \setminus \{j\}$; denote the maximized log-likelihood by l_j .
- (iv) Let $j^* = \arg \max_{j \in \mathcal{E}} l_j$. If $l_{j^*} - l_0 > c$, set $\mathcal{E} = \mathcal{E} \setminus \{j^*\}$, $l_0 = l_{j^*}$ and go to step (iii). Otherwise, stop.

In step (iv), the value $c \approx 6$ (the 5% critical value for a χ_2 distribution) has been suggested [109].

The algorithm starts by assuming an isotropic correlation function, and, at each iteration, at most one variable is allocated individual correlation parameters. The initial model contains only four parameters and the largest model considered has $4d + 2$ parameters. However, factor sparsity suggests that the algorithm usually terminates before models of this size are considered. Hence, smaller experiments can be used than are normally employed for GP regression in d variables (e.g., $d = 20$ and $n = 40$ or 50 [109]). This approach essentially adds one variable at a time to the model. Hence, it has, potentially, similar issues as stepwise regression for linear models; in particular, the space of possible GP models is not very thoroughly explored.

The second method, RDVS, is a fully Bayesian approach to the GP variable selection problem. A Bayesian treatment of model (33.1) with correlation function (33.7) requires numerical methods, such as Markov Chain Monte Carlo (MCMC), to obtain an approximate joint posterior distribution of $\theta_1, \dots, \theta_d$ (in RDVS, $\alpha_i = 2$ for all i). Conjugate prior distributions can be used for β_0 and σ^2 to reduce the computational complexity of this approximation. In RDVS, a prior distribution, formed as a mixture of a standard uniform distribution on $[0, 1]$ and a point mass at 1, is assigned to $\rho_i = \exp(-0.25\theta_i)$. This reparameterization of θ_i aids the implementation of MCMC algorithms and provides an intuitive interpretation: small $0 < \rho_i \leq 1$ corresponds to an active variable with the response changing rapidly with respect to the i th variable.

To screen variables using RDVS, the design matrix \mathbf{X}^n for the experiment is augmented by a $(d + 1)$ th column corresponding to an inert variable (having no substantive effect on the response) whose values are set at random. The posterior median for the correlation parameter, θ_{d+1} , of the inert variable is computed for b different randomly generated design matrices, formed by sampling values for the inert variable, to obtain an empirical *reference distribution* for the median θ_{d+1} . The percentiles of this reference distribution can be used to assess the importance of the “real” variables via the size of the corresponding correlation parameters.

For methods that also incorporate variable selection into the Gaussian process mean function, i.e., incorporating the choice of functions in $\mathbf{h}(\mathbf{x})$, see [68, 80].

6 Examples and Comparisons

In this section, six combinations of the design and modeling strategies discussed in this paper are demonstrated and compared for variable screening using two test functions from the literature having $d = 20$ variables and $\mathcal{X} = [-1, 1]^d$. The functions differ in the number of active variables and the strength of influence of these variables on the output.

Example 1. A function used to demonstrate stepwise Gaussian process variable selection [109]:

$$\begin{aligned} Y(\mathbf{x}) = & \frac{5w_{12}}{1+w_1} + 5(w_4 - w_{20})^2 + w_5 + 40w_{19}^3 - 5w_{19} \\ & + 0.05w_2 + 0.08w_3 - 0.03w_6 + 0.03w_7 - 0.09w_9 - 0.01w_{10} \\ & - 0.07w_{11} + 0.25w_{13}^2 - 0.04w_{14} + 0.06w_{15} - 0.01w_{17} - 0.03w_{18}, \end{aligned} \quad (33.21)$$

where $w_i = 0.5x_i$ ($i = 1, \dots, 20$). There are six active variables, $x_1, x_4, x_5, x_{12}, x_{19}$, and x_{20} .

Example 2. A function used to demonstrate the elementary effect method [74]:

$$\begin{aligned} Y(\mathbf{x}) = & \beta_0 + \sum_{j=1}^{20} \beta_j v_j + \sum_{1 \leq j < k}^{20} \beta_{jk} v_j v_k + \sum_{1 \leq j < k < l}^{20} \beta_{jkl} v_j v_k v_l \\ & + \sum_{1 \leq j < k < l < u} \beta_{jklu} v_j v_k v_l v_u, \end{aligned} \quad (33.22)$$

where $v_i = x_i$ for $i \neq 3, 5, 7$ and $v_i = 11(x_i + 1)/(5x_i + 6) - 1$ otherwise; $\beta_j = 20$ ($j = 1, \dots, 10$), $\beta_{jk} = -15$ ($j, k = 1, \dots, 6$), $\beta_{jkl} = -10$ ($j, k, l = 1, \dots, 5$), and $\beta_{jklu} = 5$ ($j, k, l, u = 1, \dots, 4$). The remaining β_j and β_{jk} values are independently generated from a $N(0, 1)$ distribution, and these are used in all the analyses; all other coefficients are set to 0. There are ten active variables, x_1, \dots, x_{10} .

There are some important differences between these two examples: function (33.21) has a proportion of active variables (0.3) in line with factor sparsity, but the influence of many of these active variables on the response is only small; function (33.22) is not effect sparse (with 50% of the variables being active), but the active variables have much stronger influence on the response. This second function also contains many more interactions. Thus, the examples present different screening challenges. For these two deterministic functions, a single data set was generated for each design employed.

The screening strategies employ experiment sizes chosen to allow comparison of the different methods. They fall into three classes:

1. Methods using Gaussian processes and space-filling designs:
 - (a) Stepwise Gaussian process variable selection (SGPVS)
 - (b) Reference distribution variable selection (RDVS)

These two variable selection methods use $n = 16, 41, 84, 200$ runs, where $n = 200$ follows the standard guidelines of $n = 10d$ runs for estimating a Gaussian process model [66]. For each value of n , two designs are found: a maximin Latin hypercube sampling design and a maximum projection space-filling design. These designs were generated from the R packages `SLHD` [5] and `MaxPro` [7] using simulated annealing and quasi-Newton algorithms. For both methods, $\alpha_i = 2$ in (33.7) for all $i = 1, \dots, d$; that is, for SGPVS, stepwise selection is performed for θ_i only.
2. One-factor-at-a-time methods:
 - (a) Elementary effect (EE) method
 - (b) Systematic fractional replicate designs (SFRD)

The elementary effects were calculated using the R package `sensitivity` [87], with each variable taking $f = 4$ levels, $\Delta = 2/3$ and $r = 2, 4, 10$ randomly generated trajectory vectors $\mathbf{x}_1, \dots, \mathbf{x}_r$, giving design sizes of $n = 42, 84, 210$, respectively. An $n = 42$ -run SFRD was used to calculate the sensitivity indices $S(i)$, Eq. (33.13), for $i = 1, \dots, 20$.
3. Linear model methods:
 - (a) Supersaturated design (SSD)
 - (b) Definitive screening design (DSD)

The designs used are an SSD with $n = 16$ runs and a DSD with $n = 41$ runs. For each design, variable selection is performed using the Dantzig selector as implemented in the R package `f1are` [60] with shrinkage parameter s chosen using AICc. Note that these designs are tailored to screening in linear models and hence may not perform well when the output is inadequately described by a linear model.

Tables 33.6 and 33.7 summarize the results for Examples 1 and 2, respectively, and present the sensitivity (ϕ_s), type I error rate (ϕ_I), and false discovery rate (ϕ_{fdr}) for the five methods. The summaries reported in these tables use automatic selection of tuning parameters in each method; see below. More nuanced screening, for example, using graphical methods, may produce different trade-offs between sensitivity, type I error rate, and false discovery rate. In general, with the exception of the EE method, results are better for Example 1, which obeys factor sparsity, than for Example 2, which does not.

For the Gaussian process methods (SGPVS and RDVS), the assessments presented in Tables 33.6 and 33.7 are the better of the results obtained from the maximin Latin hypercube sampling design and the maximum projection space-filling design. In Example 1, for $n = 16, 41, 84$ the maximin LHS design gave the better performance, while for $n = 200$ the maximum projection design was preferred. In Example 2, the maximum projection design was preferred for $n = 16, 200$

^cSensitivity for a main effects only model

and the maximin LHS design for $n = 41, 84$. For Example 1, note that, rather counterintuitively, for correlation function (33.7) with $\alpha_i = 2$, SGPVS has lower sensitivity for $n = 200$ than for $n = 41$ or $n = 84$. A working hypothesis to explain this result is that larger designs, with points closer together in the design space, can present challenges in estimating the parameters $\theta_1, \dots, \theta_d$ when the correlation function is very smooth. Setting $\alpha_i = 1$, so that the correlation function is less smooth, resulted in better screening for $n = 200$. The choice of design for Gaussian process screening is an area for further research, as is the application to screening of extensions of the Gaussian process model to high-dimensional inputs [37, 43].

SGPVS and RDVS performed well when used with larger designs ($n = 84, 200$) for both examples. For Example 1, the effectiveness of SGPVS has already been demonstrated [109] for a Latin hypercube design with $n = 50$ runs. In the current study, the method was also effective when $n = 41$. Neither RDVS or SGPVS provided reliable screening when $n = 16$. Both methods found Example 2, with a greater proportion of active variables, more challenging; effective screening was only achieved when $n = 84, 200$.

For RVDS, recall that the empirical distribution of the posterior median of the correlation parameter for the inert variable is used as a reference distribution to assess the size of the correlation parameters for the actual variables. For the assessments in Tables 33.6 and 33.7, a variable was declared active if the posterior median of its correlation parameter exceeded the 90th percentile of the reference distribution. A graphical analysis can provide a more detailed assessment of the method. Figure 33.3 shows the reference distribution and the posterior median of the correlation parameter for each of the 20 variables. Variables declared active have their posterior medians in the right-hand tail of the reference distribution. For both examples, the greater effectiveness of RDVS for larger n is clear. It is interesting to note that choosing a smaller percentile as the threshold to declare a variable active, for example, 80%, would have resulted in considerably higher type I error and false discovery rates for $n = 16, 41$.

For the EE method, performance was assessed by visual inspection of plots of μ_i^* against σ_i ($i = 1, \dots, 20$); see Fig. 33.4. A number of different samples of trajectory vectors $\mathbf{x}_1, \dots, \mathbf{x}_r$ were used and similar results obtained for each. For Example 1, where active variables have a smaller influence on the response, the EE method struggled to identify all the active variables. Variable x_{19} was consistently declared active, having a nonlinear effect. For larger n , variables x_1, x_4, x_{12} , and x_{20} were also identified. For Example 2, with larger active effects, the performance was better. All active variables are identified when $n = 84$ (as also demonstrated by Morris [74]) and when $n = 200$. Performance was also strong for $n = 42$, with only x_3 and x_7 not identified.

For both examples, relatively effective screening was achieved through use of an SFRD to estimate sensitivity indices (33.13). These estimated indices are displayed in Fig. 33.5. Using a threshold of $S(i) > 0.05$ leads to a small number of active variables being missed (one in Example 1 and four in Example 2); the choice of the lower threshold of $S(i) > 0.01$ results in all active variables being identified in both examples and no type I errors being made.

A study of the two true functions provides some understanding of the strong performance of the SFRD. Both functions can be reasonably well approximated (via Taylor series expansions) by linear models involving main effect and interaction terms, with no cancellation of main effects with three-variable interactions or of two variable with four-variable interactions. It is not difficult to modify the two functions to achieve a substantial reduction in the effectiveness of the SFRD. In Example 1, replacement of the term $5(w_4 - w_{20})^2$ by $5w_4^2 - 5w_{20}^2$ produces a function which is highly nonlinear in w_4 and w_{20} . Screening for this function resulted in these two variables being no longer declared active when the SFRD was used. For Example 2,

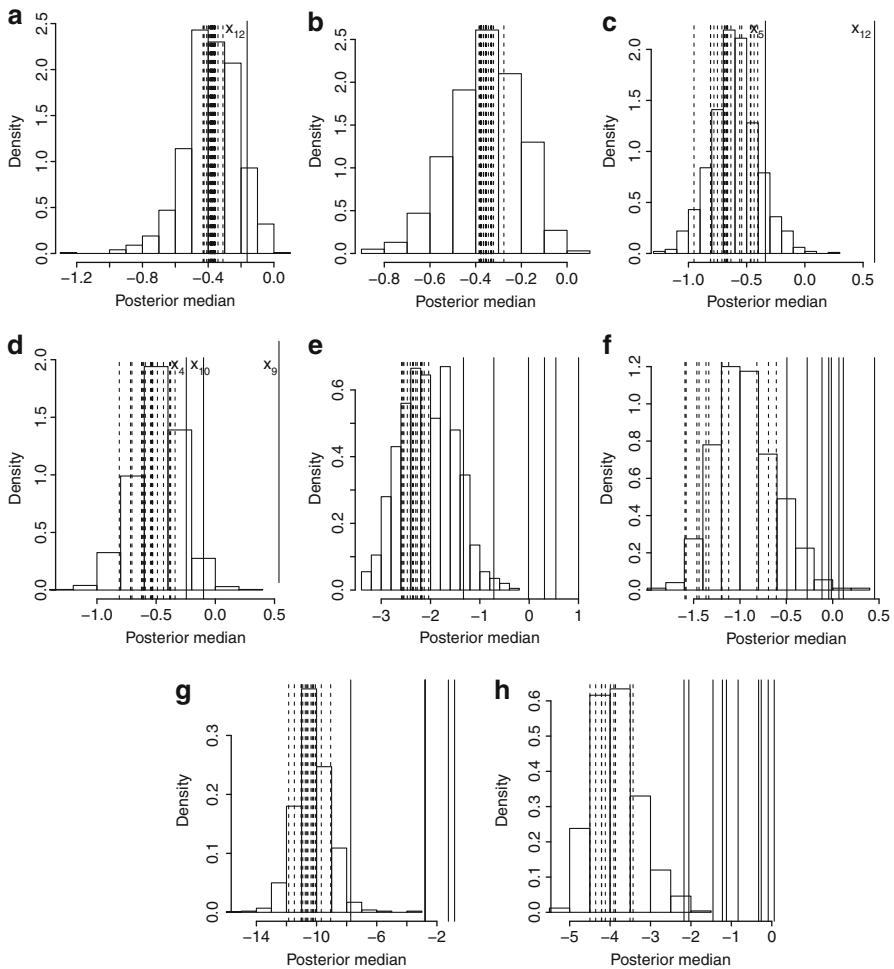

Fig. 33.3 RDVS results: histograms of the empirical distribution of the posterior median of the correlation parameter for 1000 randomly generated inert variables. The posterior medians of the correlation parameters for the 20 variables are marked as *vertical lines* (unbroken, declared active; broken, declared inactive). If there are fewer than five variables declared active, the variable names are also given. **(a)** Example 1: $n = 16$. **(b)** Example 2: $n = 16$. **(c)** Example 1: $n = 41$. **(d)** Example 2: $n = 41$. **(e)** Example 1: $n = 84$. **(f)** Example 2: $n = 84$. **(g)** Example 1: $n = 200$. **(h)** Example 2: $n = 200$

if $\beta_j = 20$ for $j = 1, \dots, 10$, $\beta_{jkl} = 0$ for $j, k, l = 1, \dots, 5$, and $\beta_{jkl} = -5$ for $jkl = 6, \dots, 10$, then use of an SFRD failed to detect variables $x_7 - x_{10}$, even when the threshold $S(i) > 0.01$ was applied, due to cancellation of main effects and three-variable interactions. The performance of the EE method for both these modified functions was the same as that achieved for the original functions.

(b) Example 2: $n = 42$. (c) Example 1: $n = 84$. (d) Example 2: $n = 84$. (e) Example 1: $n = 210$. (f) Example 2: $n = 210$

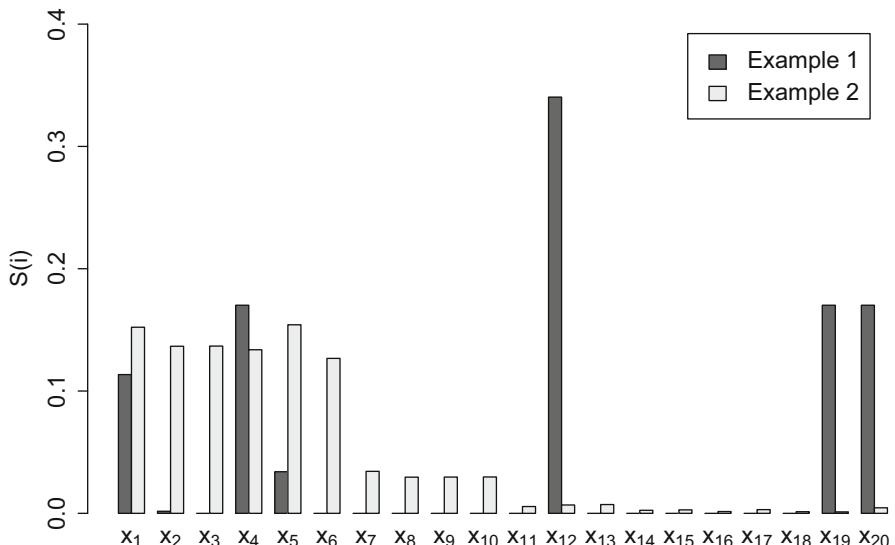

Fig. 33.5 Sensitivity indices (33.13) from the SFRD for Examples 1 and 2 for variables $x_1 - x_{20}$

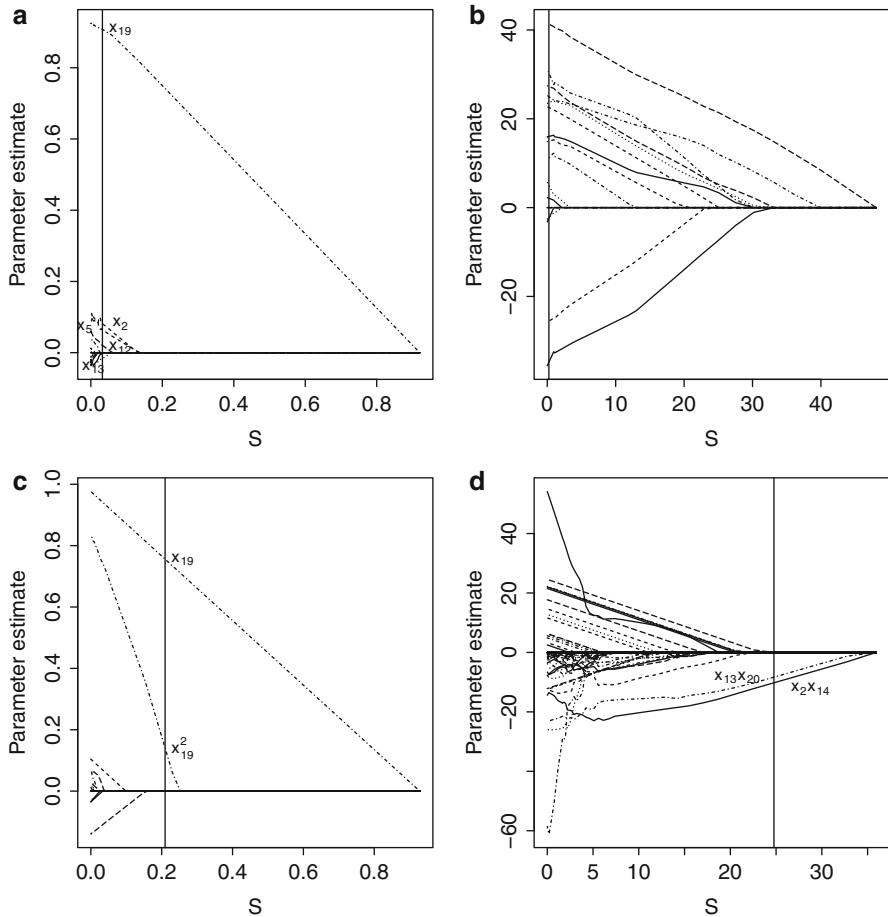

Fig. 33.6 Supersaturated (SSD) and definitive screening design (DSD) results: plots of penalty parameter s against parameter estimates. In each plot, the variables and effects declared active are labeled, with the exception of plot (b) where 15 variables are declared active. (a) Example 1: SSD $n = 16$. (b) Example 2: SSD $n = 16$. (c) Example 1: DSD $n = 41$. (d) Example 2: DSD $n = 41$

The nonregular designs (SSD and DSD) provide an interesting contrast to the other methods, all of which are tailored to, or have been suggested for, variable screening for nonlinear numerical models. For the SSD, only main effects are considered; for the DSD, the surrogate model can include main effects, two-variable interactions, and quadratic terms. Figure 33.6 gives shrinkage plots for each of the SSD and DSD which show the estimated model parameters against the shrinkage parameter s in (33.20). As $s \rightarrow 0$, the shrinkage of the estimated parameters is reduced; at $s = 0$, there would be no shrinkage which is not possible for designs with $n < p$. These plots may be used to choose the active variables, namely, those involved in at least one effect whose corresponding estimated model parameter is

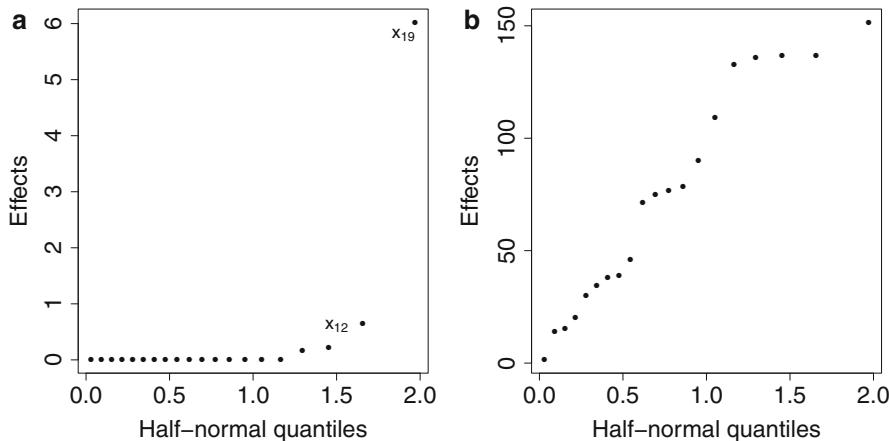

Fig. 33.7 Definitive screening design (DSD) results for main effects only: half-normal plots. (a) Example 1: DSD $n = 41$ (main effects). (b) Example 2: DSD $n = 41$ (main effects)

nonzero for larger values of s . In each plot, the value of s chosen by AICc is marked by a vertical line. Figure 33.6a, c shows shrinkage plots for Example 1 from which the dominant active variables are easily identified, although a number of smaller active variables are missed. For Example 2, Fig. 33.6b, d is much harder to interpret, because they have a number of moderately large estimated parameters. This reflects the larger number of active variables in Example 2. Clearly, the effectiveness of both methods for this second example is limited.

To provide a further comparison between the SSD and DSD, data from the latter design were also analyzed using a main effects only surrogate model (33.2). For these models, the DSD is an orthogonal design and hence standard linear model analyses are appropriate. To summarize the results, Fig. 33.7 gives half-normal plots [30] for each example. Here, the ordered absolute values of the estimated main effects are plotted against theoretical half-normal quantiles. Variables whose estimated main effects stand away from a straight line are declared active, such as x_{12} and x_{19} in Example 1; see Fig. 33.7a. No variables are identified as active for Example 2. These results agree with t-tests on the estimated model parameters.

7 Conclusions

Screening with numerical models is a challenging problem, due to the large number of input variables that are typically under investigation and the complex nonlinear relationships between these variables and the model outputs.

The results from the study in the previous section highlight these challenges and the dangers of attempting screening using experiments that are too small or are predicated on linear model methodology. For this study of $d = 20$ variables and six screening methods, a sample size of at least $n = 40$ was required for effective screening, with more runs needed when factor sparsity did not hold. The

EE method was the most effective and robust method for screening, with the highly resource-efficient SSD and DSD being the least effective here. Of course, these two nonregular designs were not developed for the purpose of screening variables in nonlinear functions; in contrast to the SFRD, neither explicitly incorporates higher-order interactions, and the SSD suffers from partial aliasing between main effects. The two Gaussian process methods, RDVS and SSD, required a greater number of runs to provide sensitive screening.

Methods that use Gaussian process models have the advantage of also providing predictive models for the response. Building such models with the EE or SFRD methods is likely to require additional experimentation. In common with screening via physical experiments, a sequential screening strategy, where possible, is likely to be more effective. Here, a small initial experiment could be run, for example, using the EE method, with more targeted follow-up experimentation and model building focused on a subset of variables using a Gaussian process modeling approach.

Weights and Importance in Composite Indicators: Mind the Gap

34

William Becker, Paolo Paruolo, Michaela Saisana, and Andrea Saltelli

Abstract

Multidimensional measures (often termed composite indicators) are popular tools in the public discourse for assessing the performance of countries on human development, perceived corruption, innovation, competitiveness, or other complex phenomena. These measures combine a set of variables using an aggregation formula, which is often a weighted arithmetic average. The values of the weights are usually meant to reflect the variables importance in the index. This paper uses measures drawn from global sensitivity analysis, specifically the Pearson correlation ratio, to discuss to what extent the importance of each variable coincides with the intentions of the developers. Two nonparametric regression approaches are used to provide alternative estimates of the correlation ratios, which are compared with linear measures. The relative advantages of different estimation procedures are discussed. Three case studies are investigated: the Resource Governance Index, the Good Country Index, and the Financial Secrecy Index.

Keywords

Composite indicators • Nonlinear regression • Sensitivity analysis

1 Introduction

Composite indicators are aggregations of observable variables (indicators) that aim to quantify underlying concepts that are not directly observable, such as competitiveness, freedom of press, or climate hazards. Composite indicators are employed for many purposes, including policy monitoring, and they are called in several different ways; for instance, they are also referred to as “performance indices.”

Hardly any newspaper can resist the temptation of commenting on an international country ranking. The popularity of rankings is due to two main reasons. First, their popularity: they provide a summary picture of the multiple facets or dimensions of complex, multidimensional phenomena in a way that facilitates evaluation and comparison. Second, rankings force institutions and governments to question their standards; rankings are drivers of behavior and of change [10].

Hence, it comes as no surprise that there has been a turbulent growth of performance indices over the past two decades. [3] provides a comprehensive inventory of over 400 country-level indices monitoring complex phenomena from economic progress to educational quality. Similarly, a more recent inventory by the United Nations [27] details 101 composite measures of human well-being and progress, covering a broad range of themes from happiness-adjusted income to environmentally adjusted income, from child development to information and communication technology development. Several of those indices have been cited online more than a million times.

The construction of a composite indicator requires several choices; it involves a number of steps in which the developer must make decisions regarding which variables to include in the composite index and how to aggregate them. These steps involve, first, developing a conceptual framework and then selecting and treating

data sets. Next, a multivariate analysis is often performed to identify principal components and correlations. The variables are then normalized, for example, by scaling onto the unit interval or adjusting by mean and variance.

The step discussed in this chapter is the aggregation step, where typically the variables are combined in a weighted average to give the resulting value of the composite indicator. Apart from the decision of which kind of weighted average to use (e.g., arithmetic, geometric), the developer must select values of weights to apply to each variable. The values of these weights can have a large impact on the subsequent rankings of the composite indicator. Understanding the impact of weights on the output composite indicator is hence important.

A possible misconception is that the weight assigned to a variable can be directly interpreted as a measure of importance of the variable to the resulting value of the composite indicator. However, this is true only under very restrictive assumptions; different variances and correlations among variables, for instance, prevent the weights from corresponding to the variables' importance.

A common practice in composite indicator construction is to set the weights of each input variable to be equal, with the intention to make each input variable contribute equally to the value of the composite indicator. This is usually done because choosing weights other than equal would impose questionable assumptions on the relative importance of each variable. However, as shown in this chapter, nominal weights rarely coincide with variable importance, because of dependence between input variables or – when the variables have not been standardized to have the same variance – simply because of variance differences among inputs.

In this chapter, tools from sensitivity analysis are applied to address the question: how dependent is the composite indicator, considered as an *output* variable, with respect to each single measured variable (the *input* variable) which is used to build it? This question concerns the relative importance of input variables in the composite indicator, where the terms *input* and *output* follow the terminology used in uncertainty and sensitivity analysis which is the wider subject of this book.

This chapter highlights how the relative importance of input variables should not be confused with the nominal weights that are used to construct the composite indicator. Other aspects that influence the issue of the importance of input variables are the dependence between variables and the possible nonlinear transformations applied to input variables in the aggregation. The chapter reviews an earlier proposal of some of the present authors (see [13]) to measure the relative importance with the Pearson correlation ratio between the composite indicator and the input variables. Indeed, this measure of importance differs from the nominal weights used in the aggregation.

The chosen measure of importance in this chapter is the Pearson's *correlation ratio*, which is a variance-based measure that accounts for (possibly nonlinear) dependence between input variables and the output. It is exactly equivalent to the *main effect index* or *first-order sensitivity index* (as it is more widely referred to), but is termed the correlation ratio here, first, to avoid confusion of the term "index" with composite indices and, second, to emphasize that it is used as a measure of

nonlinear dependence, rather than uncertainty. This distinction is explained in a little more detail below.

According to the authors' experience, the fact that weights are not measures of importance is rather counterintuitive at first sight. The proof of this fact is that most developers do indeed use weights with the intention to tune the importance of variables in the composite index. As shown in [13], a simple glance at the scatterplots of the composite indicator versus its input variables is sufficient to convince the reader that the relative importance of variables may be quite far from what the weights would imply. Denote the output of a composite indicator as y , which is a function of several input variables x_1, x_2, \dots . Now, consider an example in which inputs x_1 and x_2 are correlated with each other, but both independent from a third input x_3 . In this case, the scatterplots of y against each input variable would show (qualitatively) that – even if the three variables have equal weights and variances – the importance of x_1 and x_2 (in terms of the effect on y) would be larger than that of x_3 due to the dependence between x_1 and x_2 .

This example is important because, in general, the variables in a composite indicator are correlated; they need to be, as one assumes that they concur to describe a unique latent phenomenon. In spite of this rule, the reader is now asked to entertain the following thought experiment, where a composite indicator is built using just two uncorrelated variables (or pillars) with the same variance. The purpose of the experiment is to show the counterintuitiveness of the relation between weights and importance. As a rule, weights in a composite indicator are set by their developers to add up to one. Thus, if one wishes to have, for example, variable x_1 more important than x_2 , one could assign weight $w_1 = 0.9$ to x_1 and $w_2 = 0.1$ to the x_2 . This would imply that x_1 drives y much more than x_2 .

Would this translate into a quantitative statement such as " x_1 accounts for 90% of the variance of y , while x_2 accounts for 10%"? No, because if one decomposes the variance of y according its uncorrelated inputs, the fractional importance of a given variable x_i (i.e., the correlation ratio just mentioned) is $w_i^2 / \sum_i w_i^2$ for the case where all variables have the same variance (this is an exercise in the sensitivity analysis handbook [23]). In the case above, this implies fractional importance measures of x_1 and x_2 equal to 99% and 1%, respectively. Thus, in order for the weights to add up to one, and have target importance 90% and 10%, weights should in fact be equal to 3/4 and 1/4, respectively.

Further justification for using the correlation ratio as the right importance measure to use for variables importance is provided in the remainder of this chapter, where the idea of target fractional variance to be achieved is discussed by judicious assignment of weights for the realistic case where the variables are not independent.

The correlation ratio can be estimated noninvasively (i.e., with only a set of input values and corresponding output values and no explicit modeling of uncertainties as in [19]), using relatively simple, nonlinear regression tools; [13] proposed to use nonparametric, local linear, kernel regression. This method is similar to the one in [7], but does not require to use an independent sample from the marginal distribution of x to estimate the variance of the conditional expectation. In this chapter, the use of penalized splines is also reviewed in this context; see [17]. The relative merits of

different estimation methods for the conditional expectations are discussed. Results obtained for nonlinear regression are compared to with those obtained by linear regression, and the added value of nonlinearity is assessed in concrete cases studies.

The approach of this chapter lends itself to the possibility of selecting nominal weights which imply the intended importance (correlation ratios) of each input variable by searching through the “weight space” (for a short discussion on reverse engineering the weights, see [13]). An additional feature of this approach is that, as a by-product of the analysis, it provides an estimate of the conditional expectation of the composite indicator as a function of a single input variable. The local slope of this conditional expectation answers the related research question: “how much would the composite indicator increase for a marginal increase of the input variable (averaged over variations in other variables)?”. This question may be of interest when discussing alternative policy measures geared to influence different input variables.

The remainder of this chapter is organized as follows: the construction of composite indicators and some measures of variables’ importance are reviewed first, including the correlation ratio. A description is then given of linear and nonlinear approaches to estimation of the correlation ratio. Three case studies are used to illustrate the relative merits of each estimation approach: the Resource Governance Index, which aims to measure transparency and accountability in the oil, gas, and mining sectors; the Financial Secrecy Index, which measures secrecy and scope for abuse in the financial sector for each country; and the Good Country Index, which aims to measure to what extent a given country contributes to some preestablished normative “goods” for humanity. In these case studies, the relative strengths of the correlation ratio compared to linear measures of dependence are also discussed.

2 Measures of Importance and Transformations

2.1 Transformations and Weighting

Consider the case of a composite indicator y (output) calculated aggregating over d input variables x_i . The most common aggregation scheme is the weighted arithmetic average, i.e.:

$$y_j = \sum_{i=1}^d w_i x_{ji}, \quad j = 1, 2, \dots, n \quad (34.1)$$

where x_{ji} is the normalized score of individual j (e.g., country) based on the value X_{ji} of the i th raw variable $i = 1, \dots, d$ and w_i is the nominal weight assigned to the i th variable X_i or x_i . Input variables are usually normalized according to the min-max normalization method (see [3]):

$$x_{ji} = \frac{X_{ji} - X_{\min,i}}{X_{\max,i} - X_{\min,i}}, \quad (34.2)$$

where $X_{\max,i}$ and $X_{\min,i}$ are the upper and lower values, respectively, for the variable X_i ; in this case all scores x_{ji} vary in $[0, 1]$. $X_{\max,i}$ and $X_{\min,i}$ could be replaced by maximal and minimal values for the X_i that do not depend on the sample observations.

A popular alternative to the min-max normalization in (34.2) is given by the standardization:

$$x_{ji} = \frac{X_{ji} - \mathbb{E}(X_i)}{\sqrt{\mathbb{V}(X_i)}}, \quad (34.3)$$

where $\mathbb{E}(X_i)$ and $\mathbb{V}(X_i)$ are the mean and variances of the original variables X_i . Here $\mathbb{E}(X_i)$ and $\mathbb{V}(X_i)$ can be estimated by the sample mean and variance. Note that (34.3) guarantees equal variances, while transformation (34.2) does not.

In fact, transformation (34.2) scales each input variable onto $[0, 1]$, but allows for different means and variances. On the other hand, (34.3) transforms all variables such that they have a mean of zero and a variance of one. Importantly, however, both transformations do not affect the correlation structure of variables, because both are linear transformations of the original variables and correlations are invariant with respect to linear transformations.

The weight, w_i , attached to each variable, x_i , is usually chosen so as to reflect the importance of that variable with respect to the concept being measured. The ratios w_i/w_ℓ can be taken to be the “revealed target relative importance” of inputs i and ℓ because they measure the substitution effect between x_i and x_ℓ , i.e., how much x_ℓ must be increased to offset or balance a unit decrease in x_i (see [8]).

One of the central messages in this chapter is that the target importance does not usually coincide with the “true” importance of each variable, as defined by the correlation ratio, as shown above for the trivial case of two uncorrelated variables. In order to better understand the contribution of each input variable to the output of the composite indicator, measures of linear and nonlinear dependence may be used; these are reviewed in the following section.

2.2 Importance Measures

In the following, the sample index subscript j (usually representing the country or region) is dropped unless it is needed for clarity. Let also the expected value and variance of y be $\mathbb{E}(y) = \mu_y$ and $\mathbb{V}(y) = \sigma_y^2$. Similarly, the means and variances of each x_i are denoted as $\{\mu_i\}_{i=1}^d$ and $\{\sigma_i^2\}_{i=1}^d$, respectively.

For any given composite indicator, one can define measures of importance of each of the input variables with respect to the output values of the composite indicator. One approach for assessing the influence of each input variable x_i on the composite indicator is to measure the dependence of y on x_i , where, from here on, variables are assumed to be normalized – see Eqs. (34.2) and (34.3).

Assume that

$$y_j = f_i(x_{ji}) + \varepsilon_j \quad (34.4)$$

where $f_i(x_{j,i})$ is an appropriate function, possibly nonlinear, that models $E(y_j|x_i)$ – the conditional expectation of y given x_i – and ε_j is an error term. Dependence of y on x_i can be measured in a number of ways. The covariance and correlation between x_i and y , for example, are defined as

$$\text{cov}(y, x_i) := E[(y - \mu_y)(x_i - \mu_i)], \quad R_i := \text{corr}(y, x_i) := \frac{\text{cov}(y, x_i)}{\sigma_y \sigma_i}. \quad (34.5)$$

Remark here that $\text{corr}(y, x_i)$ is a standardized version of the covariance, called the *Pearson product-moment correlation coefficient*, which scales the covariance onto the interval $[-1, 1]$. In the case of a simple linear regression of y on x_i , the square of the correlation coefficient gives the well-known linear *coefficient of determination* R^2 , i.e., $R_i^2 := \text{corr}^2(y, x_i)$, which takes values in $[0, 1]$.

The coefficient of determination is used to measure the goodness of fit of an ordinary linear regression: as such R_i^2 is a measure of linear dependence. Because of (34.5), the covariance $\text{cov}(y, x_i)$, the correlation $\text{corr}(y, x_i)$, and the coefficient of determination R_i^2 are all related measures of linear dependence. In sample, the coefficient of determination R_i^2 can be computed as

$$SS_{\text{reg},i} / SS_{\text{tot}}, \quad (34.6)$$

where $SS_{\text{reg},i} = \sum_{j=1}^n (\hat{f}_i(x_{i,j}) - \bar{y})^2$ is the sum of squares explained by the linear regression, $\bar{y} := n^{-1} \sum_{j=1}^n y_j$ is the sample average, $\hat{f}_i(x_{i,j}) = \hat{\beta}_0 + \hat{\beta}_1 x_{i,j}$ is the linear fit for observation y_j , and $SS_{\text{tot}} = \sum_j (y_j - \bar{y})^2$ is the total sum of squares. R_i^2 can hence be seen as the ratio of the sum of squares explained by the linear regression of y on x_i and the total sum of squares of y .

If the relationship between y on x_i is nonlinear, R_i^2 may underestimate the degree of dependence. The proposed measure in this chapter is the *correlation ratio*, S_i , $i = 1, 2, \dots, d$ also widely known as the *first-order sensitivity index*, or *main effect index* (see ▶ Chap. 35, “[Variance-based Sensitivity Analysis: Theory and Estimation Algorithms](#)”). This measure is meant to measure the (possibly nonlinear) influence of each variable on the composite indicator. The correlation ratio can be interpreted as the expected variance reduction of the composite indicator, if a given variable were fixed. The correlation ratio is traditionally denoted as η_i^2 and was introduced by [14]; to follow the wider literature on sensitivity analysis, it is referred to here as S_i . Both the correlation ratio and the first-order sensitivity index are defined as

$$S_i \equiv \eta_i^2 := \frac{V_{x_i} (E_{x \sim i} (y | x_i))}{V(y)}, \quad (34.7)$$

where $x_{\sim i}$ is defined as the vector containing all the variables (x_1, \dots, x_d) except variable x_i and $E_{x \sim i} (y | x_i)$ denotes the conditional expectation of y given x_i , e.g., with x_i fixed at one value in its interval of variation. The notation employed here stresses that the expectation in $E_{x \sim i} (y | x_i)$ is computed with respect to the

distribution of $\mathbf{x}_{\sim i}$, i.e., with respect to all other input variables; while the subscript x_i used as the outer variance signifies that the variance is taken over all possible values of x_i . In the following the variance and expected value subscripts are dropped to economize on notation.

The conditional expectation $E(y | x_i)$ is known as the *main effect* of x_i on y , and it describes the expected value of y (the composite indicator) averaged over all input variables except x_i , keeping x_i fixed. As such, $E(y | x_i)$ is a function of x_i and is here denoted as $f_i(x_i)$. This function is not typically known; however, it can be estimated by performing a (nonlinear) regression of y on x_i . Various approaches for this problem are discussed in the following section; any of them delivers a fitted value $m_j := \hat{f}_i(x_{ij})$ corresponding to the prediction of y_j . The correlation ratio S_i can then be computed in sample as

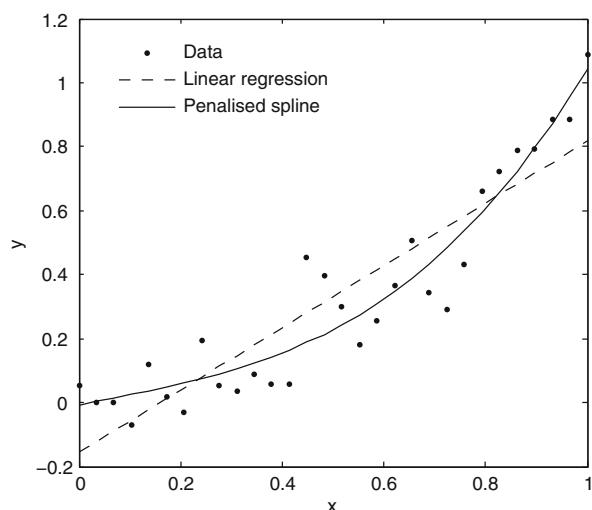

$$\sum_{j=1}^n (m_j - \bar{m})^2 / \sum_{j=1}^n (y_j - \bar{y})^2 \quad (34.8)$$

where $\bar{m} := n^{-1} \sum_{j=1}^n m_j$, $m_j := \hat{m}(x_{ij})$, and $\hat{m}(\cdot)$ is the estimate of $m(\cdot) := f_i(\cdot)$. Equation (34.8) mimics (34.6).

The correlation ratio S_i is closely connected with the measure R_i^2 of linear dependence discussed previously. More specifically, R_i^2 equals S_i when $f_i(x_i)$ is linear; note that the main effect is dependent on the functional form of the composite indicator *and* the dependence structure between variables. This shows that, in the linear case, S_i is also related to the covariance and correlation coefficients by the associations discussed earlier.

In order to illustrate why linear measures of importance would not be sufficient for nonlinear dependence, Fig. 34.1 plots data generated using the relationship

Fig. 34.1 Parabolic conditional mean with linear and penalized spline fits. Here $\text{corr}(x_1, y) = 0.91$, $R_i^2 = 0.82$, and $S_1 = 0.91$ (using the penalized spline estimate)

$y = 0.2 + x_1^2 + 0.1u$, with $u \sim \mathcal{N}(0, 1)$ independent of x_1 , which is generated drawing from a uniform distribution on $[0, 1]$. The conditional mean $E(y | x_1) = x_1^2$ is here nonlinear (a branch of a parabola). The linear regression through the data in Fig. 34.1 gives $R^2 = 0.82$, while the correlation ratio S_i is 0.91, as estimated by a nonlinear (penalized spline) regression.

In this case the strong dependency between y and x_1 would be underestimated by the linear measure R_i^2 , but it is captured by the correlation ratio S_i : about 91% of the variance in y is explained by the correlation ratio (using a nonlinear conditional mean specification), and about 9% of it would be missed by a linear regression model.

2.3 Relation to Sensitivity Analysis

The correlation ratio is widely used in the discipline of variance-based sensitivity analysis of computer models, typically under the name of “first-order sensitivity index,” “main effect index,” or “Sobol index.” It is important to recognize that sensitivity analysis, as it is commonly performed in physical sciences and engineering, is concerned with analyzing the effects of *uncertainty* in model input variables on the model output. Each input variable therefore has an associated probability distribution $p(x_i)$ which attempts to characterize the uncertainty in the value of x_i , either as a result of lack of knowledge or inherent variability. The “sensitivity analysis” described in this chapter, on the other hand, does not deal with uncertainty in the inputs of a composite indicator (although this is also an important area of research – see, e.g., [20]). Instead, it quantifies the contribution of each input to the composite indicator, as a result of the weight and aggregation of the indicator and the distribution and interdependence of each input variable, by measuring the nonlinear dependence of the composite indicator on each of its input variables. The distributions $p(x_i)$ of each input variable do not therefore characterize uncertainty in x_i – rather, they simply represent the distribution of entities (e.g., countries, institutions) in the variable x_i . Indeed, these distributions are often discrete: they represent a finite number of entities, such as countries or regions. It is therefore to emphasize that the application here is distinct from uncertainty analysis that the term “The correlation ratio is therefore used (as opposed to “first-order/main effect index,” which is more widely used elsewhere) to emphasize that the application here is distinct from uncertainty analysis.”

Usually in sensitivity analysis, as it is applied in physical models in science and engineering, one finds $\sum_{i=1}^d S_i \leq 1$ when studying a generic nonlinear output function with independent input variables; see [11, 21]. In this setting, the variance of the model output can be decomposed into portions that can be uniquely attributed to each variable and subset of variables. In the case of composite indicators, the input variables are almost certainly (positively) correlated, and it is usually the case that $\sum_{i=1}^d S_i > 1$. Furthermore, the correlation ratios here are not interpreted in terms of a variance decomposition – they are simply used as nonlinear measures of

correlation. However, even for the case of non-independent inputs, the S_i measure preserves its meaning of expected fractional reduction of the output variance that would be achieved if a variable could be fixed [22].

In order to estimate $f_i(x_i)$, a wide number of approaches are available. Two nonlinear regression approaches are discussed in the next section; both offer a flexible framework for estimating nonlinear main effects.

3 Estimating Main Effects

This section reviews the estimation of the conditional expectation $E(y | x_i)$ using polynomial (linear) regression, penalized splines, and nonparametric regression. There are many other ways of modeling $E(y | x_i)$, such as Gaussian processes [16]; see also [25]. The methods reviewed here are chosen for comparison purposes and because they have some attractive properties. Specifically, the linear regression model is considered here as the simplest model of the conditional expectation; kernel nonparametric regression is considered as the opposite polar leading example of nonlinear models for the conditional expectations; this method was employed in [13] in the context of composite indicators. As an additional method to estimate the nonlinear regression function, penalized splines are also investigated here, which share similar properties in smoothing nonlinear data with kernel nonparametric regression; moreover, they are computationally fast (and so can cope with large data sets). Note that in this section the variable subscript i is dropped, since the techniques here all refer to regression of y on a single variable x .

3.1 Polynomial Regression

Consider a set of bivariate data consisting of n pairs of observations $\{x_j, y_j\}$, $j = 1, 2, \dots, n$, an integer p (the degree of the polynomial), and the model

$$y_j = \beta_0 + \beta_1 x_j + \dots + \beta_p x_j^p + \epsilon_j \quad j = 1, 2, \dots, n \quad (34.9)$$

in which the β_h , $h = 0, \dots, p$ are coefficients and ϵ_j is an error term. This can be rewritten in matrix form using the $p + 1$ column vectors $\mathbf{x}_j = (1, x_j, x_j^2, \dots, x_j^p)^\top$ and $\boldsymbol{\beta} = (\beta_0, \beta_1, \dots, \beta_p)^\top$ and the n -dimensional column vectors $\mathbf{y} = (y_1, y_2, \dots, y_n)^\top$ and $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)^\top$. Next, one can define the $n \times (p + 1)$ design matrix $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_n)^\top$ so as to rewrite (34.9) as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}. \quad (34.10)$$

Minimizing the sum of squared residuals with respect to $\boldsymbol{\beta}$ gives the well-known expression

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{y}. \quad (34.11)$$

In case $p = 1$, (34.11) gives the linear regression coefficients $\hat{\beta}_0, \hat{\beta}_1$, which can be used to calculate R^2 . Note that in cases where $p > 1$, (34.10) is nonlinear with respect to x , but is still linear with respect to its parameters $\boldsymbol{\beta}$. Therefore, quadratic, cubic, and higher-order regressions (and indeed other basis functions that can be used with (34.10)) are often referred to as linear regression, depending on the context.

3.2 Penalized Splines

One approach to smoothing nonlinear data is the *penalized spline*. Penalized splines are also referred to as *semiparametric regression*, given that they are an extension of linear parametric regression (linear in the parameters), but also have the capabilities of nonparametric regression (i.e., local polynomial regression), such as the flexibility to accommodate nonlinear trends in the data [17].

The basis function which is the heart of the spline model is given by $(x - \kappa_h)_+^p$, where the “+” subscript denotes the positive part; in other words, for any number u , $u_+ = u$ if u is positive and equals zero otherwise. The κ_h parameter is called the “knot” of the basis function; it is a value of x at which the spline is “split.” Splines are constructed by using a number $h = 0, 1, 2, \dots, H$ of spline basis functions with different knots κ_h . Specifically, the polynomial $\beta_0 + \beta_1 x_j + \dots + \beta_p x_j^p$ in (34.9) is extended to give

$$\beta_0 + \beta_1 x + \dots + \beta_p x^p + \sum_{k=1}^K \beta_{pk} (x - \kappa_k)_+^p \quad (34.12)$$

where again β are coefficients to be estimated.

Since the model is linear with respect to its coefficients, it is possible to write it in the same form as (34.9) replacing $\mathbf{x}_j = (1, x_j, x_j^2, \dots, x_j^p)^\top$ with $\mathbf{x}_j = (1, x_j, x_j^2, \dots, x_j^p, (x_j - \kappa_1)_+^p, \dots, (x_j - \kappa_K)_+^p)^\top$ and $\boldsymbol{\beta} = (\beta_0, \beta_1, \dots, \beta_p)^\top$ with $\boldsymbol{\beta} = (\beta_0, \beta_1, \dots, \beta_p, \beta_{p1}, \dots, \beta_{pK})^\top$. When $p = 1$, this is known as a *linear spline*. In practice, quadratic or cubic splines are normally used (corresponding to $p = 2$ or 3, respectively), because they result in a smooth fit to the data. In the applications here, a value of $p = 3$ is used.

The coefficients may be directly estimated by using (34.11); however, this tends to result in a fit which is too “rough” – in other words, it fluctuates too much and is drawn too much to individual data points rather than following the smoother underlying trend. This is known as overfitting. To overcome this problem, the estimator (34.11) can be constrained to limit the influence of the spline basis terms, resulting in a smoother fit.

This results in what is known as *penalized splines*. To do this, $\boldsymbol{\beta}$ is chosen to minimize the sum of squared residuals, under the constraint that $\sum_{h=1}^H \beta_{ph}^2 = \boldsymbol{\beta}^\top \mathbf{D} \boldsymbol{\beta} < C$, where C is a positive constant and $\mathbf{D} = \text{diag}(\mathbf{0}_{(p+1) \times (p+1)}, \mathbf{I}_H)$. The

constraint reduces the influence of the last additional H terms $\sum_{h=1}^H \beta_{ph}(x - \kappa_h)_+^p$ in (34.12) to avoid overfitting the data and results in the *penalized spline* model. The constraining of regression parameters shares similarities with other approaches such as *ridge regression* (see, e.g., [9]) and *LASSO* [26].

The constrained minimization problem is solved by

$$\hat{\boldsymbol{\beta}}_\lambda = (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{D})^{-1} \mathbf{X}^\top \mathbf{y} \quad (34.13)$$

where λ plays the role of a Lagrange multiplier for the penalization. High λ values result in a very smooth fit, whereas low values give a rough fit which is closer to interpolating the data points. The smoothing parameter λ needs to be optimized, and this is done using a cross-validation approach, in which a search algorithm is used to find the value of λ that minimizes the average squared error resulting from removing a point from the set of training data and predicting at that point. The fact that penalized splines are only a short step from linear regression means that they can exploit well-known properties to give fast order- n algorithms for the calculation of cross-validation measures; therefore, the fitting of a penalized spline can be very fast. More details on this can be found in [17] Section 5.3.

The spline model requires the specification of the knots κ_h ; here they are placed at equally spaced quantiles of the unique x_i values, and the number of knots is chosen from a set of candidate H values, as the number of knots which results in the best fit according to a measure of cross-validation. This procedure is described in more detail in [17] Section 5.5.

In the applications in this chapter, the spline models are deliberately constrained to be quite simple fits to the data. To do this, the spline is allowed to have $K = 0, 1, 2, 3, 4$ knots, where the optimal number is chosen as that which minimizes the cross-validation measure. In the case of $H = 0$, the spline is reduced to the polynomial model, which in this work is cubic, since p is set to 3.

Finally, note that in the following work, “penalized splines” will sometimes be referred to simply as “splines.” All splines used in this investigation are penalized cubic splines.

3.3 Local Polynomial Regression

Another approach to nonlinear regression is *local polynomial regression*, also referred to as *kernel smoothing* – see, e.g., [4]. Kernel smoothing works by averaging a number of weighted polynomial regressions, centered at different values of x . The regression $\hat{f}(x)$ is chosen here to be *local linear*, and the estimation is performed minimizing the weighted sum of squares, where weights are proportional to a kernel function with bandwidth b . The kernel function gives the strongest weight to squared residuals corresponding to points close to x_j for observation j , which reflects the belief that the closer two points are to each other in x , the more likely they are to have similar values in y .

A commonly used kernel function is the Gaussian density function with standard deviation b . Local-linear regression is used here (as opposed to, e.g., local mean regression) since it is generally regarded as a good choice, due to its good properties near the edges of the data cloud. The smoothing parameter b can be optimized by cross-validation; this is the method that is adopted in the applications in this chapter. The local polynomial approach is used by [7] for estimation of first-order sensitivity indices of uncertainty for models with correlated inputs.

3.4 Remarks

The choice of whether to use penalized splines, kernel regression, linear regression, or another nonlinear regression approach entirely is a working decision of the analyst. By construction, linear regression (i.e., linear with respect to x) only reveals linear dependencies between variables and so should be used with this caveat in mind. Higher-order polynomial regression or other basis functions within a linear regression might improve the fit, but also risk overfitting. The penalized splines and local-linear regression allow for nonlinearities when they are present in the data, but can also model near-linear data when required. In most applications, these two latter approaches are expected to give comparable results. However, in the presence of highly skewed and/or heteroskedastic data, the two fits may be quite different.

While the fits are likely to be similar, splines may have a slight advantage over local-linear regression in some other respects. First, they are less computationally demanding than kernel regression, due to the fast computation of cross-validation measures discussed previously. While the difference is small enough to be negligible for running a few regressions on small data sets, the difference may be sizable if one wants to attempt an optimization of weights or if a very large number of regressions need to be run. Large data sets of the order of thousands or millions of points are common in environmental science. A second advantage of splines is that the computation of their derivatives is just as easy.

In any case, a prudent strategy would be to run both analyses with splines and kernel regression and compare the results – this is the approach taken in the following examples where both methods are applied and compared.

4 Case Studies

This section delves into the conceptual and statistical properties of three composite indicators selected for their interesting structure as well as for their popularity. These examples allow a practical demonstration of the methods described in previous sections, as well as providing an interesting analysis of three well-known composite indicators. The case studies are chosen because:

- They are transparent – namely, the values of each input variable are publicly available, and the index can be reproduced given the methodological notes provided by the developers.

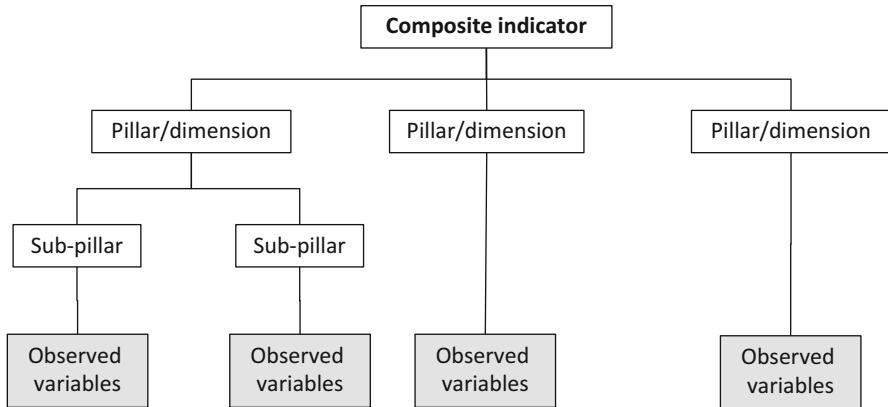

Fig. 34.2 A (fictional) example of the hierarchy of a composite indicator

- They use three different aggregation formulas, which allows the effect of the different measures of importance described here, and estimation methods, to be assessed.
- They deal with issues of governance and accountability and hence offer interesting narratives on the misconception of what matters when developing an index.

Often, composite indicators are built on a number of hierarchical “levels.” Rather than having d measured variables x_1, x_2, \dots, x_d as direct inputs to the composite indicator, variables (indicators) are usually put together into groups, known as “pillars” or “dimensions,” which share similar conceptual characteristics (see Fig. 34.2). Variables in each pillar are aggregated in a weighted sum, such that each pillar is itself a composite indicator characterizing one aspect of the greater theme. The composite values of each pillar are then used as the inputs of the composite indicator itself. Indeed, pillars may also consist of sub-pillars if the developers deem it appropriate. For simplicity however, and to be consistent with the sensitivity analysis literature and previous sections, the direct inputs to the composite indicators here are referred to as “variables” in the analytical parts of the following section, even though they might represent pillars.

4.1 Resource Governance Index (RGI)

4.1.1 Aim

The Resource Governance Index (RGI) is developed by the Revenue Watch Institute in order to measure the transparency and accountability in the oil, gas, and mining sectors in 58 countries [15]. These nations produce 85% of the world’s petroleum, 90% of diamonds, and 80% of copper, generating trillions of dollars in annual profits. The future of these countries depends on how well they manage their natural resources.

4.1.2 Sources

To evaluate the quality of governance in the extractive sector, the Resource Governance Index employs a 173-item questionnaire that is based on the standards put forward by the International Monetary Fund's 2007 *Guide on Resource Revenue Transparency* and the Extractive Industries Transparency Initiative, among others. The answers to the 173 questions are grouped into 45 indicators that are then mapped into three (of the four) RGI dimensions: Institutional and Legal Setting, Reporting Practices, and Safeguards and Quality Controls. The fourth dimension, Enabling Environment, consists of five additional indicators that describe a country's broader governance environment; it uses data compiled from over 30 external sources by the Economist Intelligence Unit, International Budget Partnership, Transparency International, and Worldwide Governance Indicators. The Index is therefore a hybrid, with three dimensions based on the questionnaire specifically assessing the extractive sector, and the fourth rating the country's overall governance.

4.1.3 Main Dimensions

The RGI's four dimensions cover the following topics:

1. Institutional and Legal Setting (20% weight): ten indicators that assess whether the laws, regulations, and institutional practices enable comprehensive disclosures, open and fair competition, and accountability.
2. Reporting Practices (40% weight): 20 indicators that evaluate the actual disclosure of information and reporting practices by government agencies.
3. Safeguards and Quality Controls (20% weight): 15 indicators that measure the checks and oversight mechanisms that guard against conflicts of interest and undue discretion, such as audits.
4. Enabling Environment (20% weight): five indicators of the broader governance environment generated using over 30 external measures of accountability, government effectiveness, rule of law, corruption, and democracy.

The RGI score is a weighted arithmetic average of the four dimensions, i.e., of the form of (34.1), where the dimensions here are treated as the x_1, x_2, x_3, x_4 input variables.

Because actual disclosure constitutes the core of transparency, developers assigned a greater weight to the Reporting Practices dimension. This choice also reflects a belief that without reporting information, rules and safeguards ring hollow. Therefore, Reporting Practices are assigned a weight equal to 40% of the final country score, and the other three dimensions (Institutional and Legal Setting, Safeguards and Quality Controls, and Enabling Environment) account for 20% each.

On the inclusion of the Enabling Environment dimension, there have been arguments for and against. Against its inclusion, the arguments are:

1. The Enabling Environment dimension dilutes the focus of the index on the oil, gas, and mining sector by incorporating measures of overall governance.

2. The Enabling Environment dimension can have an undue effect on the index scores, driving scores up or down, inflating or depressing performances beyond what countries actually show in their extractive sector.

In favor of its inclusion, the arguments are:

1. External governance indicators reflect the influence of the broader country environment on the quality of natural resource governance. When considering the quality of transparency and accountability in a certain area, it does matter whether a country also has an authoritarian regime, a high risk of corruption, or respect for basic freedoms.
2. As an expert-based index, the accuracy and consistency of its findings suffer from the bias introduced by researchers and by peer and Research Watch Institute reviewers. Including this dimension as an external measure reduces this margin of error.

Given these last two arguments, the developers chose to include the Enabling Environment dimension and to allocate a 20% weight to this dimension. As part of the Index website, the developers provide a tool that allows users to change the weights for the different dimensions, creating different composite scores that reflect their own sense of prioritization. This is a direct example of how weights are often (erroneously) interpreted as measures of importance.

4.1.4 Results

Before examining the relationships between each variable (dimension/pillar) and the output of the composite indicator, a basic analysis of the structure of the data was performed. There are no outliers (absolute skewness is less than 0.63) in the four dimensions' distributions that could bias the subsequent interpretations of the correlation structure. The four dimensions of the Resource Governance Index have moderate to high correlations that range from 0.41 (between Institutional and Legal Setting and Enabling Environment) to 0.82 (between Reporting Practices and Safeguards and Quality Controls) and an overall good average bivariate correlation of 0.65. Principal component analysis suggests that there is indeed a single latent phenomenon underlying the four index dimensions. This first principal component captures 74% of the variation in the four dimensions.

Moving now to the importance measures, Table 34.1 shows the estimates of the correlation ratios obtained both with penalized splines and local-linear (LL) regression, as well linear correlations, for the four input variables of the index. The correlation ratios S_i (penalized splines and LL approach) and the Pearson correlation coefficients R_i^2 confirm that the Reporting Practices component has indeed the highest impact on the index. This was the intention of the RGI developers on the grounds that actual disclosure constitutes the core of transparency. This choice also reflects a belief that without reporting information, rules and safeguards are inconsequential. In fact, the correlation between Reporting Practices and Safeguards and Quality Control is very high (0.82, the highest among the

Table 34.1 Measures of dependence of the Resource Governance Index on its input variables: $R_i = \text{corr}(x_i, y)$ (correlation), $S_{i,\text{spl}}$ (correlation ratio, penalized spline), $S_{i,\text{LL}}$ (correlation ratio, local linear)

Resource Governance Index ($n = 58$)	x_i	w_i	R_i	R_i^2	$S_{i,\text{spl}}$	$S_{i,\text{LL}}$
Institutional and legal setting	x_1	0.2	0.79	0.63	0.65	0.67
Reporting practices	x_2	0.4	0.95	0.90	0.90	0.94
Safeguards and quality controls	x_3	0.2	0.91	0.82	0.83	0.83
Enabling Environment	x_4	0.2	0.77	0.59	0.65	0.70

components). If one could fix the Reporting Practices variable, the variance of the RGI scores across the 58 countries would on average be reduced by 94% (local-linear estimate). It is worth noting that despite the equal weights assigned to the other three components, their impact on the RGI variation differs: by fixing any of the other variables, the variance reduction would be 83% for Safeguards and Quality Control, 70% for Enabling Environment, and 67% for Institutional and Legal Setting, using the estimates of the local-linear regression.

As per the developers intention to have Reporting Practices twice as important as any of the other three dimensions, i.e. Institutional and Legal Setting, Safeguards and Quality Controls, and Enabling Environment, it is easy to see that this was not achieved. The strong correlation of Reporting Practices with Safeguards and Quality Controls results in these two pillars being almost equally important (0.90 and 0.82), while the importance of Reporting Practices relative to the remaining two pillars is of about 3/2 rather than 2.

Aside from the implications of this analysis from the point of view of the RGI, it is interesting to look at the differences between the measures of importance in Table 34.1. The linear R_i^2 measure consistently gives the lowest estimates of importance, the LL estimate of correlation ratio is the highest, and the penalized spline estimate of correlation ratio is somewhere in between. To see in a little more detail what is happening, Fig. 34.3 shows the scatterplots of the four input variables and the simple linear, penalized spline and local-linear estimations of main effects. For the Institutional and Legal Setting variable, the two nonlinear fits are significantly different to the linear fit, but fairly similar to each other. However, the structure of the data is such that the gradient of the linear fit (and the overall trend of the nonlinear fits) is not very steep, resulting in relatively low importance estimates compared to other variables. The Reporting Practices variable shows quite similar fits between all three methods, although the local-linear curve has a slightly higher variance. Safeguards and Quality gives a near-linear fit for both nonlinear regression approaches, showing a strong agreement in measures of importance. The Enabling Environment variable is the most interesting here from a regression point of view: the penalized spline fits a roughly cubic model, whereas the local-linear curve fluctuates more strongly with the data. Whether the more parsimonious penalized spline curve or the more variable local-linear curve is a better estimate of $E(y|x_i)$ is not intuitively clear from visual inspection.

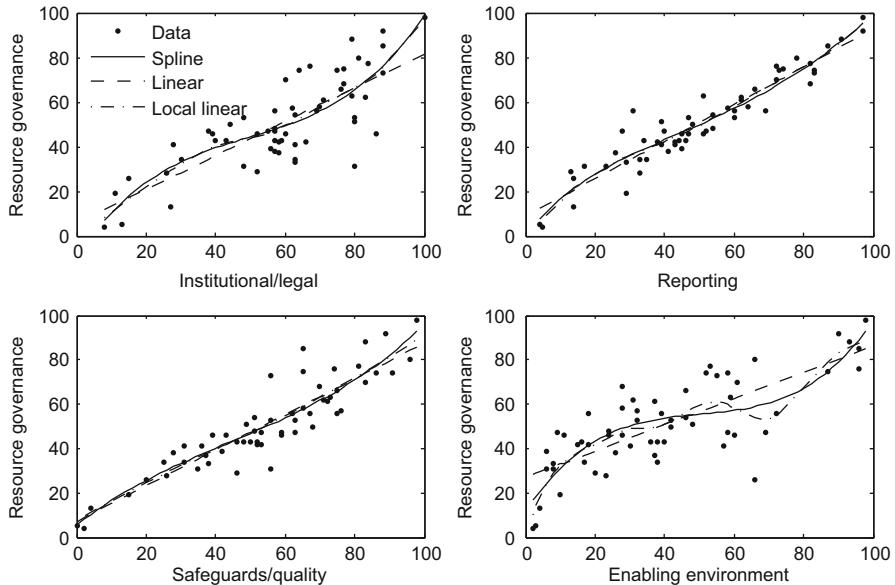

Fig. 34.3 Penalized spline, local linear, and linear fits to the Resource Governance Index

As a further analysis of the effect of each variable, Fig. 34.4 shows the first derivatives of $E(y|x_i)$ with respect to each input variable, as estimated by the penalized splines. First, the nonlinearities of the spline fits are evident from the nonconstant derivatives. The derivative plots also have implications for the index itself – they effectively summarize the expected change in the RGI that a country would achieve if it moved a given amount in each variable. Two example countries, Libya and India, have their scores in each indicator marked as dotted vertical lines. In the case of Libya, it is clear that to move up the rankings in the RGI, it would be better to invest efforts in improving the Institutional and Legal Setting, and Enabling Environment dimensions, whereas gains in Reporting and Safeguards and Quality would yield lesser gains. India, a country ranked overall 12th in the RGI, would on the other hand stand to gain very little from small improvements in Enabling Environment, and immediate efforts would be better directed toward either Reporting or Safeguards and Quality.

4.2 Financial Secrecy Index (FSI)

4.2.1 Aim

The Financial Secrecy Index (FSI) is developed by the Tax Justice Network (TJN) and aims to measure the contribution to the global problem of financial secrecy in 80 jurisdictions worldwide [5]. In other words, the Index attempts to provide an answer to the question: by providing offshore financial services in combination

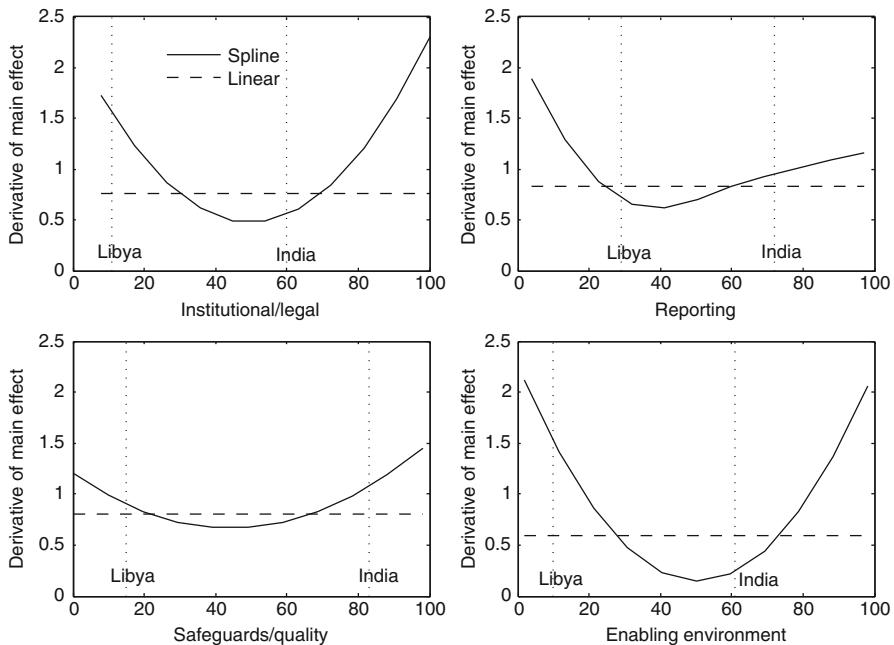

Fig. 34.4 Derivatives $d[E(y|x_i)]/dx_i$ using penalized splines and linear regression fits to the Resource Governance Index. Indicator values of Libya and India marked as *vertical dotted lines*

with a lack of transparency, how much damage is each secrecy jurisdiction actually responsible for?

To give an example of what this implies, the home page of the FSI informs us that because of capital flights dwarfing the inflow of aid money, Africa is in fact a net creditor to the rest of the world since the seventies. As per the money stashed away, the TJN informs us that “those assets are in the hands of a few wealthy people, protected by offshore secrecy, while the debts are shouldered by broad African populations.”

4.2.2 Sources

The index combines qualitative data and quantitative data. Qualitative data are based on laws, regulations, cooperation with information exchange processes, and other verifiable data sources and are used to calculate a secrecy score for each jurisdiction. Secrecy jurisdictions with the highest secrecy scores are more opaque in the operations they host, less engaged in information sharing with other national authorities, and less compliant with international norms relating to combating money laundering. Lack of transparency and unwillingness to engage in effective information exchange makes a secrecy jurisdiction a more attractive location for routing illicit financial flows and for concealing criminal and corrupt activities.

Quantitative data is used to create a global scale score, for each jurisdiction, according to its share of offshore financial service activity in the global total.

Publicly available data about the trade in international financial services of each jurisdiction are used. Where necessary because of missing data, the developers follow International Monetary Fund methodology to extrapolate from stock measures to generate flow estimates. Jurisdictions with the largest weightings are those that play the biggest role in the market for financial services offered to nonresidents.

4.2.3 Main Dimensions

The first dimension of the FSI is the Financial Secrecy score, which is calculated from a set of fifteen qualitative key financial secrecy indicators that assess the degree to which the legal and regulatory systems (or their absence) of a country contribute to the secrecy that enables illicit financial flows. These indicators can be grouped around four dimensions of secrecy: 1) knowledge of beneficial ownership (3 indicators), 2) corporate transparency (3 indicators), 3) efficiency of tax and financial regulation (4 indicators), and 4) international standards and cooperation (5 indicators). Taken together, these indicators result in one aggregate secrecy score for each jurisdiction.

The second dimension of the FSI is the Global Scale score, which is calculated based on quantitative data (publicly available) about the trade in international financial services, and captures the potential for a jurisdiction to contribute to the global problem of financial secrecy. Data on international trade in financial services come from the IMF's Balance of Payments statistics. Data on stocks of portfolio assets and liabilities are taken from two IMF sources: the Coordinated Portfolio Investment Survey and the International Investment Position statistics.

At the final step, the Financial Secrecy score is cubed and the Global Scale is cube rooted before being multiplied to produce the FSI scores for each j th jurisdiction, i.e.:

$$FSI_j = \text{Secrecy}_j^3 \cdot \sqrt[3]{\text{GlobalScale}_j}.$$

Critics have argued that the Global Scale dimension unfairly points to large financial centers. However, the developers' response is that "to dispense with the scale risks ignoring the big elephants in the room." While large players may be slightly less secretive than other jurisdictions, the extraordinary size of their financial sectors offers far more opportunities for illicit financial flows to hide. Therefore, the larger an international financial sector becomes, the better its regulations and transparency ought to be. This logic is reflected in the FSI which aims to avoid the conceptual pitfalls of the "usual suspects" – lists of tax havens which are often remote islands whose overall share in global financial markets is tiny. In the FSI a jurisdiction with a larger share of the offshore finance market, and a moderate degree of opacity, may receive the same overall ranking as a smaller but more secretive jurisdiction.

Due to a significantly greater skew in the Global Scale scores compared to the Financial Secrecy scores, the developers transform the two to generate series that are more evenly distributed. The choice of the transformation has been guided by the 90/10% and the 75/25% quantile ratios in each of the two series. In the original

Table 34.2 Importance measures of the variables of the Financial Secrecy Index. $R_i = \text{corr}(x_i, y)$ (correlation), $S_{i,\text{spl}}$ (correlation ratio, penalized spline), $S_{i,\text{LL}}$ (correlation ratio, local linear)

Financial Secrecy Index (n=80)	x_i	w_i	R_i	R_i^2	$S_{i,\text{spl}}$	$S_{i,\text{LL}}$
Global Scale	x_1	0.5	0.57	0.32	0.63	0.79
Financial Secrecy	x_2	0.5	0.09	0.01	0.13	0.09

series, the 90/10% ratio is more than five thousand times higher for the Global Scale than the Secrecy variable, the 75/25 ratio nearly a hundred times higher. If one squares the Secrecy Score and takes the square root of the Global Scale, these ratios fall to below 26 and 6, respectively; and if one cubes the Secrecy Score and takes the cube root of the Global Scale, they fall below 3 and 2, respectively. Finally, looking at fourth and fifth roots and powers, the variation of the Global Scale series becomes disproportionately small. Hence, the cube root/cube combination was adopted by the developers on the grounds that “these transformations are sufficient to ensure that neither secrecy nor scale alone determine the FSI” – see [6].

4.2.4 Results

Despite the intentions of the developers, and the reasoning based on the quantiles, the correlation ratios S_i (splines and LL approach) and the Pearson correlation coefficients reveal a notably unbalanced impact of the two components on the FSI (see Table 34.2). The greatest difference between the estimates is in the correlation ratios provided by the local-linear regression, in which the values are 0.79 for Global Scale and 0.09 for Secrecy. This is in stark contrast to the intended influence, which should be roughly equal for both variables. Examining the scatterplots in Fig. 34.5 however, the data looks quite challenging to smooth, and the three regression approaches have markedly different fits. In particular, the local-linear regression of the Global Scale variable has a large spike in the fit at a value of around 7, which does not appear to be justified by the data. Therefore, the LL importance estimates ought to be treated with caution. The spline fit is slightly more convincing, but seems to be quite heavily biased by the outlying points above a score of around 5. However, given that even the linear fit yields a far higher importance measure for the Global Scale variable than the Secrecy variable (0.32 and 0.01, respectively), the evidence seems fairly compelling that the Global scale variable dominates the FSI by a significant margin. The analysis illustrates vividly that the cube root/cube transformation of the FSI components and the equal weights assigned to the two components are not a sufficient condition to ensure equal importance, at least according to the correlation ratio measure.

The Global scale scores are particularly skewed (skewness = 4.6 and kurtosis = 23). Yet, after considering the cube root, the distribution is no longer problematic (skewness = 1.7 and kurtosis = 3.0). Nevertheless, what remains problematic is the strong negative association between the cubed distribution of the Financial Secrecy scores and the cube-rooted distribution of the Global Scale scores ($\text{corr} = -.536$).

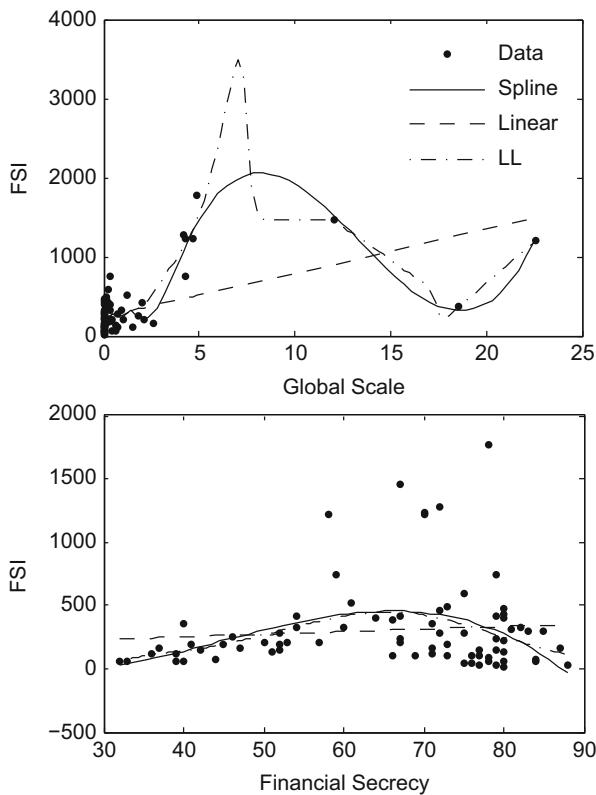

Fig. 34.5 Scatter plots of Financial Secrecy Index versus its components

Table 34.3 Importance measures of the variables of the Financial Secrecy Index with the N_{trim} points with the highest Global Scale scores removed. $R_i = \text{corr}(x_i, y)$ (correlation), $S_{i,\text{spl}}$ (correlation ratio, spline), $S_{i,\text{LL}}$ (correlation ratio, local-linear)

N_{trim}	Financial Secrecy Index (n=50)	R_i^2	$S_{i,\text{spl}}$	$S_{i,\text{LL}}$
3	Global Scale	0.616	0.798	0.754
	Financial Secrecy	0.017	0.112	0.074
8	Global Scale	0.028	0.310	0.077
	Financial Secrecy	0.015	0.119	0.093

If the points with the highest Global Scale scores are treated as outliers, the problem lessens somewhat but does not disappear. Table 34.3 shows the results of rerunning the analysis, trimming the points with three highest or eight highest Global Scale values. By visual inspection, these seem to be two possible reasonable definitions of outliers depending on where the cutoff value is set. Trimming the top three points, the disparity is very similar, with the Global Scale correlation ratios far higher than the Secrecy values. After trimming the top eight points, the importance

scores are much closer; however, in the linear and spline estimates, the importance of the Global Scale variable is still at least twice that of the Secrecy variable. In the case of the LL regression, the Secrecy variable is now rated as slightly more influential than the Global Scale, but given that this is the only (mild) contradiction to an otherwise compelling trend, the conclusion that the variables are not equally influential appears to stand.

In defense of the developers, one may note that this gross unbalance refers to a specific definition of importance (how much the variance of the index would be reduced on average if one could fix one dimension), and this definition appears to condemn the FSI as problematic. One might argue however that the use of variance of the main effect $E(y|x_i)$ as a measure of importance might not tell the whole story and that interactions between the two variables should also be accounted for. Following this line of thought, a useful tool might be the “total effect index” S_{Ti} , which is defined as $E_{\mathbf{x}_{\sim i}}[V_{x_i}(y | \mathbf{x}_{\sim i})]/V(y)$, where $\mathbf{x}_{\sim i}$ denotes the vector of all variables but x_i . This measure also accounts for variance due to interactions. In fact the scatterplot of Financial Secrecy in Fig. 34.5 looks like a textbook example of a variable with a low S_i and a high S_{Ti} , with the points displaying a rather constant mean and an increasing variance while moving over the horizontal axis.

An investigation using this measure in the context of composite indicators is outside of the scope of this work, but further information can be found in the section on Variance-Based Sensitivity Analysis: Theory and Applications.

4.3 Good Country Index

4.3.1 Aim

The Good Country Index (GCI) is developed by the Good Country Party with a view to measure what a country contributes to the common good of humanity, and what it takes away [1], following its developers’ normative framework and world view. In total, 125 countries are included in the Index. In contrast to the majority of similar composite indicators, the Good Country Index does not measure what countries do at home; rather, it aims to start a global discussion about how countries can balance their duty to their own citizens with their responsibility to the wider world.

This reflects the consideration that the biggest challenges facing humanity today are global and borderless: problems such as climate change, economic crisis, terrorism, drug trafficking, slavery, pandemics, poverty and inequality, population growth, food and water shortages, energy, species loss, human rights, and migration.

All of these problems stretch across national borders, so they can be properly tackled through international efforts. Hence, the concept of the “Good Country” is about encouraging populations and their governments to be more outward looking and to consider the international consequences of their national behavior.

4.3.2 Sources

The GCI builds upon 35 indicators that are produced by the United Nations and other international agencies and a few by NGOs and other organizations. Most of

the indicators used are direct measurements of world-friendly or world-unfriendly behavior (such as signing of international treaties, pollution, acts of terrorism, wars) and some are rather indirect (such as Nobel prizes, exports of scientific journals). By adding them up, the developers aim to get a reasonable picture of whether each country is effectively a net creditor to the rest of humanity in each of the seven categories or whether it is a “freeloader” on the global system and ought to be recognized as such.

4.3.3 Main Dimensions

The 35 indicators are split in seven groups of five indicators each. These seven dimensions, which closely mirror the dimensions of the United Nations Charter, are:

1. Science, Technology, and Knowledge, which includes foreign students studying in the country; exports of periodicals, scientific journals, and newspapers; articles published in international journals; Nobel prize winners; and International Patent Cooperation Treaty applications.
2. Culture, which measures exports and imports of creative goods; UNESCO dues in arrears (a negative indicator); countries and territories that citizens can enter without a visa; and freedom of the press (based on the mean score of the Reporters without Borders and Freedom House indices as a negative indicator).
3. International Peace and Security, which aggregates peacekeeping troops sent overseas; dues in arrears to financial contribution to UN peacekeeping missions (negative indicator); casualties of international organized violence (negative indicator); exports of weapons and ammunition (negative indicator); and the Global Cyber Security Index (negative indicator).
4. World Order, which measures population that gives to charity as proxy for cosmopolitan attitude; refugees hosted; refugees overseas (negative indicator); population growth rate (negative indicator); and treaties signed as proxy for diplomatic action and peaceful conflict resolution.
5. Planet and Climate, which measures the National Footprint Accounts Biocapacity reserve; exports of hazardous waste (negative indicator); organic water pollutant emissions (negative indicator); CO₂ emissions (negative indicator); and methane + nitrous oxide + other greenhouse gases (HFC, PFC, and SF6) emissions (negative indicator).
6. Prosperity and Equality, which aggregates trading across borders; aid workers and volunteers sent overseas; fair trade market size; foreign direct investment outflow; and development cooperation contributions (aid).
7. Health and Wellbeing, which includes wheat-tonne-equivalent food aid shipments; exports of pharmaceuticals; voluntary excess contributions to the World Health Organization; humanitarian aid contributions; and drug seizures.

A ranking is calculated for each of the seven dimensions. The Good Country Index is then calculated by taking the arithmetic average of the seven ranks in Science, Technology, and Knowledge; Culture; International Peace and Security;

World Order; Planet and Climate; Prosperity and Equality; and, finally, Health and Wellbeing. This aggregation scheme has been selected by the developers because of its simplicity and relative robustness to outliers. Beyond what is stated by the developers, a further argument in favor of this aggregation scheme would be the “imperfect substitutability across all seven index components,” i.e., the reduction of the fully compensatory nature of an arithmetic average of the seven scores.

4.3.4 Results

Before looking at the correlation ratios describing the importance of each variable to the output, it is useful to look at the correlations between input variables, as it is good practice in the construction/evaluation of composite indicators. Six of the seven dimensions of the Good Country Index have low to moderate correlations that range from 0.20 (between several pairs of dimensions, mostly those involving Prosperity and Equality) to 0.78 (between Science and Technology and Culture) and an overall moderate average bivariate correlation of 0.37. Principal component analysis suggests that there is indeed a single latent phenomenon underlying the six dimensions and that the first principal component captures almost 50% of the variation in these dimensions. However, the International Peace and Security dimension has a negative correlation to both the Science and Technology and to the Culture variables (-0.48) and almost random correlation to all remaining dimensions. This point is a strong concern for the validity of the GCI. The negative correlations between International Peace and Security on one hand and either Science and Technology or Culture or Health and Wellbeing on the other are undesirable in a composite indicator context, as they suggest the presence of trade-offs, and are a reminder of the danger of compensability between components.

Turning now to the correlation coefficients, Table 34.4 shows that, unlike the equal weighting scheme of the seven components would suggest, the impact of the seven components on the index is uneven. Three of the seven components, namely, Culture, World Order, and Science and Technology, account for over 50% of the variation in the index scores (up to 63% for Culture). Instead, by fixing either of the three components – Health and Wellbeing, Planet and Climate, and Prosperity and Equality – the variance reduction would be between 25–37%. What is striking

Table 34.4 $R_i = \text{corr}(x_{i,}, y)$ (correlation), $S_{i,\text{spl}}$ (correlation ratio, spline), $S_{i,\text{ker}}$ (correlation ratio, local linear)

Good Country Index (n=125)	x_i	w_i	R_i	R_i^2	$S_{i,\text{spl}}$	$S_{i,\text{LL}}$
Science and Technology	x_1	1/7	0.71	0.50	0.50	0.50
Culture	x_2	1/7	0.79	0.63	0.63	0.66
International Peace and Security	x_3	1/7	-0.17	0.03	0.05	0.03
World Order	x_4	1/7	0.78	0.62	0.64	0.63
Planet and Climate	x_5	1/7	0.57	0.32	0.34	0.33
Prosperity and Equality	x_6	1/7	0.49	0.24	0.27	0.25
Health and Wellbeing	x_7	1/7	0.55	0.30	0.35	0.37

is that the International Peace and Security component is practically cosmetic in the framework: by fixing this component, the index variance would be reduced by merely 3%. Moreover, it actually has a negative correlation with the GCI output, meaning that countries that rank low in International Peace and Security, on average, actually stand out as “good countries,” with a higher GCI score. This effect, likely due to the negative correlations with other variables, suggests a weakness in the GCI which ought to be addressed.

This conclusion can be of value in a general sense because it indicates that, aside from the choice of weights and aggregation formulas based on subjective considerations, the impact of components on the variance of the index is driven by the statistical properties of the components, and this latter fact is often overlooked during the index development process.

5 Discussion on Estimation Approaches

The tables showing correlation ratios and correlation coefficients from the case studies in the previous section (i.e., Tables 34.1, 34.2, and 34.4) help to understand the relative merits of the measures used in this study. The correlation coefficient R_i and the coefficient of determination R_i^2 give the linear correlation of the composite indicator with each of its inputs. The R_i^2 measure can be interpreted as the fraction of variance accounted for by the linear regression (similar to S_i), but it is also useful to see the R_i value in order to understand whether the relation is positive or negative. As shown in the Good Country Index (Table 34.4), this measure revealed that one of the input indicators is in fact negatively correlated with the composite indicator – this is an undesirable property as discussed previously, at least in the context of linearly or geometrically aggregated composite indicators.

The spline and local-linear estimates of S_i are all higher than or equal to the R_i^2 values. In most cases the difference is small – this reflects the fact that the main effects are close to linear. In these cases (see, e.g., the “Reporting Practices” variable of the Resource Governance Index in Table 34.1), the spline and LL regression fits are very close to straight lines. However, in some cases, such as the Enabling Environment pillar (also from the Resource Governance Index), S_i estimates are significantly higher than R_i^2 – this is due to the nonlinear main effect, which is captured by the spline and LL regression, but missed by the linear regression. In this instance, $R^2 = 0.59$ and S_i is estimated as 0.65 or 0.70 by the spline and LL regression, respectively. Looking at all three tables, one can see that in the majority of cases, R_i^2 would be a sufficient approximation of the effect of each variable, but there are several exceptions. This shows the added value of nonlinear regression – it can approximate linear and near-linear main effects, which appear in the majority of cases, but can generalize to nonlinear fits when required.

An obvious question at this point is to ask whether splines or LL regression provides a better estimate of S_i , given that the fits are slightly different in some cases. The short answer is that there is no way to know which is better, given that we do not know the “true” values of S_i or the “true” main effects. The three tables

show however that in the majority of cases, the estimates are very similar and in the cases where the estimates differ, neither the splines nor the LL regression has a tendency to provide higher estimates than the other overall.

It is tempting to think that higher estimates might be better estimates, given that they “capture” more of the total variance. However, both the splines and the LL regression could be easily adjusted to capture 100% of the variance; this would result in interpolation rather than smoothing. But this does not in general provide a good approximation of the main effects and results in *overfitting*. Instead, the aim of nonlinear regression is to find a balance between interpolation and simplicity – this is known as the “bias-variance tradeoff” in machine learning; see, e.g., [9].

Given then that neither splines nor local-linear regression provides consistently higher or lower estimates than the other, the best strategy would be to estimate main effects using both methods and then compare the results. It can also be helpful to visually examine the fits – for example, in Fig. 34.5, the Global Scale variable of the Financial Secrecy Index gives a data set that results in very different main effect estimates between the linear, spline, and local-linear approaches. Although none of the fits seem extremely convincing (the data is strongly skewed and heteroskedastic), the LL fit in particular has a strange “spike” that does not appear to be justified by the data – in this case one might treat the estimate of the local-linear regression with caution. A clear avenue of research here would be to incorporate confidence intervals into the estimates of main effects and subsequently into the estimates of S_i . Some approaches to doing this within the context of splines can be found in [17]. An alternative tool might be to use a Bayesian implementation of a Gaussian process, which would formally propagate uncertainties in main effect estimation to estimates of correlation ratios.

Aside from the fitting of the data, splines may offer some small advantages over LL regression. The first is that, being closely related to linear regression, they can provide fast analytic estimates of derivatives. This property is used in Fig. 34.4, to illustrate the gain in Resource Governance Index that a country or entity would achieve if its value of a given variable changed by a given amount along its axis. Furthermore, splines are able to exploit properties of linear regression (such as calculation of the cross-validation measures) to allow very fast fitting to a given data set. In the examples here, which feature relatively small data sets, computational time is not an issue. However, some composite indicators based on physical maps measure concepts such as ecosystem service indices at resolutions as high as 1km, over the whole of Europe [12]. In such cases, the data set may feature millions of points, and splines offer a significant advantage over the slower local-linear regression.

6 Conclusions

The leitmotif of the present chapter is to “mind the gap” between the two stories which can be told about the weights of composite indicators. On one hand weights appear to “belong” to developers, who are entitled to set them by analysis and

negotiation based on their norms and values. On the other hand, most forms of aggregation – and notably all linear aggregations – are particularly inept at translating these weights into “effects.” The proposal here is to look at the problem by choosing a statistically defensible definition of importance, one that derives from the theory of global sensitivity analysis, which in turn originates from the theory of experimental design and of analysis of variance (ANOVA-like decomposition). It is therefore possible to compare the importance of different variables against what their weights would purport them to be. The discussion of the Financial Secrecy Index makes it clear that all inferences made here are conditional on the definition of “importance.” There is nothing surprising in this. The same holds in sensitivity analysis. In fact “in sensitivity analysis [an] analyst [must] specify what is meant by “factor’s importance” for a particular application. Leaving instead the concept of importance undefined could result in several tests being thrown at the problem and in several rankings of factor importance being obtained, without a basis to decide which one to believe” [24]. The situation is similar in the analysis of the coherence of the weights with the behavior of the index.

Still, within the limits of this analysis, it is perhaps possible to say something useful to the developers. As far as the Resource Governance Index is concerned, it can be said that developers were successful in making Reporting Practices the most important dimension. They were less successful in making the other three dimensions equally important (Table 34.1). Further, in the intention of the developers, each of these three dimensions, “Institutional and Legal Setting,” “Safeguards and Quality Controls,” and “Enabling Environment,” was supposed to be half important as “Reporting Practices.” The correlation structure of the problem did not allow this to happen, at least with the selected weights.

For the Financial Secrecy Index, the measures of importance point to a problematic property of the index, whereby one dimension, “Global Scale,” apparently far more important than the other, “Financial Secrecy” (with the exact ratio varying somewhat between various estimates), while the two are intended to be equally important. At the same time, the aggregation formula chosen generates an important interaction term in the index. This challenges the correlation ratio as a sufficient measure of importance for this particular application. More analysis is needed on this challenging test case.

In the case of the Good Country Index, it is clear that the ambition to capture several dimensions normatively labeled as equally important was not rewarded by the results. Not only are the dimensions unequal, but one important dimension, “International Peace and Security,” has a very small influence on the index score and in fact has a negative correlation with the output.

Note that the approach presented in this chapter can be used to actually improve the indices by tuning the weights as to obtain the desired importance [13]. The approach has been implemented in two important indices: the INSEAD-WIPO Global Innovation Index [18] and the Environmental Performance Index developed by Yale University [2].

Variance-Based Sensitivity Analysis: Theory and Estimation Algorithms

35

Clémentine Prieur and Stefano Tarantola

Abstract

This section aims at presenting an overview of variance-based approaches for global sensitivity analysis. Starting from functional ANOVA, Sobol' indices are first defined and then estimation algorithms are provided. The performance of these algorithms is theoretically and practically discussed. The review includes recent results on the topic.

1 Introduction

Many mathematical models involve input parameters and variables (simply named inputs from now on), which are not precisely known. Global sensitivity analysis aims to identify the inputs whose uncertainty has the largest impact on the variability of a quantity of interest (output of the model). One of the statistical tools used to quantify the influence of each input on the output are the Sobol' sensitivity indices. These indices measure the part of the output's variance due to one or more inputs. To define the so-called Sobol' sensitivity indices, a first step is the decomposition of the model, as a d -variate function $G(x)$ into a finite hierarchical expansion of component functions in terms of the input $x = (x_1, x_2, \dots, x_d)$. A way to do that is the functional ANOVA (FANOVA) decomposition also known as the high-dimensional model representation (HDMR) technique.

2 General Definition of FANOVA Representation

Consider a numerical model $G(x)$, depending on d inputs x_1, \dots, x_d , which may be scalar or vectorial: for any $j \in \{1, \dots, d\}$, $x_j \in \mathbb{R}^{k_j}$, where $k_j \in \mathbb{Z}_{>0}$, where $\mathbb{Z}_{>0}$ denotes the set of positive integers. In the global sensitivity analysis framework, the uncertainty of the inputs is modeled by random vectors. More precisely, the uncertainty of the inputs is modeled by the random vector $\mathbf{X} = (X_1, \dots, X_d)$ whose distribution is a product distribution $P_{\mathbf{X}} = P_{X_1} \otimes \dots \otimes P_{X_d}$, with P_{X_j} a probability measure on \mathbb{R}^{k_j} whose support is denoted by $I_j \subset \mathbb{R}^{k_j}$. It means that the random vectors X_j , $j = 1, \dots, d$ are mutually independent. Note that no further assumption is made on the dependence structure of each random vector X_j , $j = 1, \dots, d$.

Definition 1 (FANOVA decomposition; see, e.g., [9, 37, 48]). Let $\mathbf{x} = (x_1, \dots, x_d) \in I_1 \times \dots \times I_d$. Let $G \in \mathbb{L}_{\mathbb{R}}^2(P_{\mathbf{X}}) = \{f : I_1 \times \dots \times I_d \rightarrow \mathbb{R} \mid \int f^2(\mathbf{x}) P_{\mathbf{X}}(d\mathbf{x}) < +\infty\}$. One can decompose $G(\mathbf{x}) = G(x_1, \dots, x_d)$ as the sum of increasing dimension functions:

$$\begin{aligned} G(\mathbf{x}) &= G_{\emptyset} + \sum_{j=1}^d G_j(x_j) + \sum_{1 \leq j < k \leq d} G_{j,k}(x_j, x_k) + \dots + G_{1,\dots,d}(\mathbf{x}) \\ &= \sum_{\mathbf{u} \in \mathcal{P}(\{1, \dots, d\})} G_{\mathbf{u}}(\mathbf{x}_{\mathbf{u}}), \end{aligned}$$

with $\mathbf{x}_\mathbf{u} = (x_j, j \in \mathbf{u})$. This expansion exists and is unique under the constraint

$$\int G_\mathbf{u}(\mathbf{x}_\mathbf{u}) P_{X_j}(dx_j) = 0 \quad \forall j \in \mathbf{u}, \quad \forall \mathbf{u} \in \mathcal{P}(\{1, \dots, d\}).$$

Remark. A consequence of Definition 1 is that for any $\mathbf{u} \neq \mathbf{v} \in \mathcal{P}(\{1, \dots, d\})$, $\int G_\mathbf{u}(\mathbf{x}_\mathbf{u}) G_\mathbf{v}(\mathbf{x}_\mathbf{v}) P_{\mathbf{X}}(d\mathbf{x}) = 0$.

From Definition 1, the following corollary follows:

Corollary 1. *From the FANOVA decomposition of G , one gets*

$$\begin{aligned} \text{Var}(G(\mathbf{X})) &= \sum_{j=1}^d \text{Var}(G_j(X_j)) \\ &\quad + \sum_{1 \leq j < k \leq d} \text{Var}(G_{j,k}(X_j, X_k)) + \dots + \text{Var}(G_{1,\dots,d}(\mathbf{X})) \\ &= \sum_{\mathbf{u} \in \mathcal{P}(\{1, \dots, d\})} \text{Var}(G_\mathbf{u}(\mathbf{X}_\mathbf{u})). \end{aligned}$$

Proof. The FANOVA decomposition defined in Definition 1 is applied to the random vector \mathbf{X} , and the expectation of the square

$$\mathbb{E}(G(\mathbf{X}) - G_\emptyset)^2 = \mathbb{E}\left(\sum_{\mathbf{u} \in \mathcal{P}(\{1, \dots, d\})} G_\mathbf{u}(\mathbf{X}_\mathbf{u})\right)^2$$

is considered. From the orthogonality of the $G_\mathbf{u}$, $\mathbf{u} \in \mathcal{P}(\{1, \dots, d\})$ (see the remark just below Definition 1), one can deduce:

$$\mathbb{E}(G(\mathbf{X}) - G_\emptyset)^2 = \sum_{\mathbf{u} \in \mathcal{P}(\{1, \dots, d\})} \mathbb{E}(G_\mathbf{u}(\mathbf{X}_\mathbf{u}))^2.$$

Then, under the constraints in Definition 1, one gets that $G_\emptyset = \mathbb{E}(G(\mathbf{X}))$ and that the $G_\mathbf{u}(\mathbf{X}_\mathbf{u})$ are centered. Thus, $\mathbb{E}(G(\mathbf{X}) - G_\emptyset)^2 = \text{Var}(G(\mathbf{X}))$ and $\mathbb{E}(G_\mathbf{u}(\mathbf{X}_\mathbf{u}))^2 = \text{Var}(G_\mathbf{u}(\mathbf{X}_\mathbf{u}))$. This concludes the proof of Corollary 1. \square

Remark. The elements of the decomposition can be computed recursively with the formula

$$G_\mathbf{u}(\mathbf{X}_\mathbf{u}) = \sum_{\mathbf{v} \subset \mathbf{u}} (-1)^{|\mathbf{u}| - |\mathbf{v}|} \mathbb{E}(G(\mathbf{X}) | \mathbf{X}_\mathbf{i}, \mathbf{i} \in \mathbf{v}).$$

3 Definition of Sobol' Sensitivity Indices

Following [48], Sobol' sensitivity indices are defined based on the functional ANOVA decomposition introduced in the previous section.

Definition 2. For any $\mathbf{u} \in \mathcal{P}(\{1, \dots, d\})$, if $G \in \mathbb{L}_{\mathbb{R}}^2(P_{\mathbf{X}})$ and $\text{Var}(G(\mathbf{X})) \neq 0$, define

- the Sobol' index associated to \mathbf{u} : $S_{\mathbf{u}} = \frac{\text{Var } G_{\mathbf{u}}(\mathbf{X}_{\mathbf{u}})}{\text{Var } G(\mathbf{X})}$.
- the closed Sobol' index associated to \mathbf{u} : $S_{\mathbf{u}}^{\text{clo}} = \frac{\text{Var } (\mathbb{E}(G(\mathbf{X})|X_j, j \in \mathbf{u}))}{\text{Var } G(\mathbf{X})}$.
- the total Sobol' index associated to \mathbf{u} : $S_{\mathbf{u}}^{\text{tot}} = 1 - \frac{\text{Var } (\mathbb{E}(G(\mathbf{X})|X_j, j \notin \mathbf{u}))}{\text{Var } G(\mathbf{X})}$.

From Corollary 1, one gets

$$1 = \sum_{\mathbf{u} \in \mathcal{P}(\{1, \dots, d\}), \mathbf{u} \neq \emptyset} S_{\mathbf{u}}.$$

Interpretation. An intuitive interpretation of these indices is given in the case where $\mathbf{u} = \{j\}$ or $\{j, k\}$, $1 \leq j \neq k \leq d$.

- The first-order Sobol' index $S_{\{j\}}$, also denoted by S_j , measures the main effect of the group of inputs $X_j \in \mathbb{R}^{k_j}$. The second-order Sobol' index $S_{\{j,k\}}$ measures the effect due to the second-order interaction between groups X_j and X_k , once the main effect of each group has been removed.
- The closed second-order Sobol' index $S_{\{j,k\}}^{\text{clo}}$ measures the effect due to both groups X_j and X_k . One has $S_{\{j,k\}}^{\text{clo}} = S_{\{j,k\}} + S_{\{j\}} + S_{\{k\}}$. Moreover, $S_{\{j\}}^{\text{clo}} = S_{\{j\}}$.
- At last, the total Sobol' index $S_{\{j\}}^{\text{tot}}$ measures the effect due to X_j and its interactions with all the other X_k , $k = 1, \dots, j-1, j+1, \dots, d$ [15]. One has $S_{\{j\}}^{\text{tot}} = \sum_{\mathbf{u} \in \mathcal{P}(\{1, \dots, d\}), j \in \mathbf{u}} S_{\mathbf{u}}$. Note that $S_{\{j\}}^{\text{tot}} = 1 - S_{-j}^{\text{clo}}$ where $-j = \{1, \dots, j-1, j+1, \dots, d\}$.

Remark.

- The origin of Sobol' indices probably goes back to the correlation ratio [39]. In the seminal paper [48], the X_j are assumed to be uniformly distributed on $[0, 1]$. However, the definitions in [48] easily generalize to the ones proposed in Definition 2.
- The generalization of the total Sobol' index $S_{\mathbf{u}}^{\text{tot}}$, for any $\mathbf{u} \in \mathcal{P}(\{1, \dots, d\})$, is also known as total variation associated with input set \mathbf{u} (see, e.g., [45]). It is also possible to consider the importance superset measure of the group of variables

$\mathbf{X}_{\mathbf{u}}$, as introduced in [31] for uniform distributions: $\sum_{\mathbf{u} \subset \mathbf{v}} S_{\mathbf{v}}$. This last measure was also investigated in the data-mining framework by [16], and in the case where \mathbf{u} represents a pair of inputs, it was used for screening purposes in [11]. In these last papers, the authors work with the unnormalized versions of the indices, that is, they consider the above indices multiplied by the overall variance $\text{Var } G(\mathbf{X})$.

4 Available Estimation Techniques

4.1 Monte Carlo-Based Techniques

4.1.1 Derivation of the MC-Type Estimators

The evaluation of the sensitivity indices defined above is usually based on Monte Carlo integrations. Several approaches have been proposed in the literature to numerically compute such sensitivity indices [15, 19, 44, 48]. This work present the most efficient formulas available today, as recommended by [44]. For the sake of clarity in the presentation, it is assumed that for any $j = 1, \dots, d$, X_j is a one-dimensional random vector, that is, $k_j = 1$. However, the estimation techniques presented below can easily be generalized to the estimation of the general indices defined in Definition 2.

The closed Sobol' index associated to \mathbf{u} , $S_{\mathbf{u}}^{\text{clo}}$, is derived by expressing its numerator as

$$\text{Var} [\mathbb{E}(G(\mathbf{X})|\mathbf{X}_{\mathbf{u}})] = \int \mathbb{E}^2(G(\mathbf{X})|\mathbf{x}_{\mathbf{u}}) P_{\mathbf{X}_{\mathbf{u}}}(d\mathbf{x}_{\mathbf{u}}) - \left(\int \mathbb{E}(G(\mathbf{X})|\mathbf{x}_{\mathbf{u}}) P_{\mathbf{X}_{\mathbf{u}}}(d\mathbf{x}_{\mathbf{u}}) \right)^2 \quad (35.1)$$

The second term in (35.1) reduces to $\mathbb{E}^2(G(\mathbf{X}))$ since $\mathbb{E}[\mathbb{E}(G(\mathbf{X})|\mathbf{X}_{\mathbf{u}})] = \mathbb{E}(G(\mathbf{X}))$, whereas the first term can be written as

$$\begin{aligned} \int \mathbb{E}^2(G(\mathbf{X})|\mathbf{x}_{\mathbf{u}}) P_{\mathbf{X}_{\mathbf{u}}}(d\mathbf{x}_{\mathbf{u}}) &= \int \mathbb{E}(G(\mathbf{X})|\mathbf{x}_{\mathbf{u}}) \mathbb{E}(G(\mathbf{X})|\mathbf{x}_{\mathbf{u}}) P_{\mathbf{X}_{\mathbf{u}}}(d\mathbf{x}_{\mathbf{u}}) \\ &= \int \left(\int \int G(\mathbf{x}_{\bar{\mathbf{u}}}, \mathbf{x}_{\mathbf{u}}) G(\mathbf{x}'_{\bar{\mathbf{u}}}, \mathbf{x}_{\mathbf{u}}) P_{\mathbf{X}_{\bar{\mathbf{u}}}}(d\mathbf{x}_{\bar{\mathbf{u}}}) P_{\mathbf{X}_{\bar{\mathbf{u}}}}(d\mathbf{x}'_{\bar{\mathbf{u}}}) \right) P_{\mathbf{X}_{\mathbf{u}}}(d\mathbf{x}_{\mathbf{u}}) \\ &= \int \int G(\mathbf{x}_{\bar{\mathbf{u}}}, \mathbf{x}_{\mathbf{u}}) G(\mathbf{x}'_{\bar{\mathbf{u}}}, \mathbf{x}_{\mathbf{u}}) P_{\mathbf{X}}(d\mathbf{x}) P_{\mathbf{X}'_{\bar{\mathbf{u}}}}(d\mathbf{x}'_{\bar{\mathbf{u}}}) \end{aligned} \quad (35.2)$$

where $\mathbf{X}_{\bar{\mathbf{u}}}$ denotes the input variables complementary to $\mathbf{X}_{\mathbf{u}}$ and \mathbf{X}' is an independent copy of \mathbf{X} . Writing $\mathbb{E}^2(G(\mathbf{X}))$ as

$$\mathbb{E}^2(G(\mathbf{X})) = \mathbb{E}(G(\mathbf{X})) \mathbb{E}(G(\mathbf{X}')) \quad (35.3)$$

and replacing (35.2) and (35.3) into (35.1), one obtains

$$\text{Var} [\mathbb{E}(G(\mathbf{X})|\mathbf{X}_{\mathbf{u}})] = \int G(\mathbf{x}) \left(G(\mathbf{x}'_{\bar{\mathbf{u}}}, \mathbf{x}_{\mathbf{u}}) - G(\mathbf{x}') \right) P_{\mathbf{X}}(d\mathbf{x}) P_{\mathbf{X}'_{\bar{\mathbf{u}}}}(d\mathbf{x}'). \quad (35.4)$$

Now, if \mathbf{C} denotes a $N \times d$ sampling matrix, $G(\mathbf{C})$ is the N -dimensional vector whose i th coordinate $G(\mathbf{C})^{(i)}$ is the evaluation of G on the i th row of \mathbf{C} .

Then, the integral in the right-hand side of (35.4) can be computed numerically by Monte Carlo:

$$S_{\mathbf{u}}^{\text{clo}} \cdot \text{Var } G(\mathbf{X}) = \frac{1}{N} \sum_{i=1}^N G(\mathbf{B})^{(i)} (G(\mathbf{A}_{\mathbf{B}(\mathbf{u})}^{(i)}) - G(\mathbf{A})^{(i)}) \quad (35.5)$$

where N is the sample size (typically of the order of 500–1,000, although larger values might be needed to achieve stable estimates of sensitivity for more complex $G(\mathbf{X})$); \mathbf{A} and \mathbf{B} are two independent $N \times d$ sampling matrices where each row of the matrix is a sample point in the d -dimensional space of the inputs. In (35.5), $\mathbf{A}_{\mathbf{B}(\mathbf{u})}$ is a resampled matrix, where columns \mathbf{u} come from matrix \mathbf{B} and all other $d - \text{card}(\mathbf{u})$ columns come from matrix \mathbf{A} . Here, $\text{card}(\mathbf{u})$ is the cardinality of subset \mathbf{u} . The term $\text{Var } G(\mathbf{X})$ can be computed efficiently using $2N$ sample points, i.e., the N rows of matrix \mathbf{A} and the N rows of matrix \mathbf{B} :

$$\text{Var}(G(\mathbf{X})) = \frac{1}{2N} \sum_{i=1}^N [(G(\mathbf{A})^{(i)} - \mu(\mathbf{A}))^2 + (G(\mathbf{B})^{(i)} - \mu(\mathbf{B}))^2] \quad (35.6)$$

where $\mu(\mathbf{A}) = \frac{1}{N} \sum_{i=1}^N G(\mathbf{A})^{(i)}$ and $\mu(\mathbf{B}) = \frac{1}{N} \sum_{i=1}^N G(\mathbf{B})^{(i)}$.

In the particular case where $\mathbf{u} = \{j\}$, (35.5) reduces to (35.7a), i.e., to the first-order Sobol' index for a single input:

$$S_j \cdot \text{Var } G(\mathbf{X}) = \frac{1}{N} \sum_{i=1}^N G(\mathbf{B})^{(i)} (G(\mathbf{A}_{\mathbf{B}(\{j\})})^{(i)} - G(\mathbf{A})^{(i)}). \quad (35.7a)$$

4.1.2 An Alternative to Formulas (35.6) and (35.7a)

An alternative to formulas (35.6) and (35.7a) was proposed in [36]. For $i = 1, \dots, N$ and $j = 1, \dots, d$, define

$$Y^{(i)} = G(\mathbf{B})^{(i)} \text{ and } Y_j^{(i)} = G(\mathbf{A}_{\mathbf{B}(\{j\})})^{(i)}.$$

$\text{Var}(G(\mathbf{X}))$ is estimated by

$$\frac{1}{N} \sum_{i=1}^N Y^{(i)} Y_j^{(i)} - \left(\frac{1}{N} \sum_{i=1}^N \frac{Y^{(i)} + Y_j^{(i)}}{2} \right)^2 \quad (35.7b)$$

and define $S_j \cdot \text{Var } G(\mathbf{X})$ by

$$\frac{1}{N} \sum_{i=1}^N \frac{(Y^{(i)})^2 + (Y_j^{(i)})^2}{2} - \left(\frac{1}{N} \sum_{i=1}^N \frac{Y^{(i)} + Y_j^{(i)}}{2} \right)^2. \quad (35.7c)$$

Remark. It was proven in [18] that the estimator based on (35.7b) and (35.7c) is asymptotically efficient, in the sense that it has an optimal asymptotic variance among a given class of estimators containing, e.g., the estimator defined by formulas (35.6) and (35.7a). However, in the form of (35.7b) and (35.7c), the numerical stability is far from being guaranteed. In Remark 1.4 of [18], the authors propose mathematically equivalent formulas to (35.7b) and (35.7c) which enable greater numerical stability (i.e., less error due to roundoffs).

Remark. Formulas (35.7b) and (35.7c) can be extended for the estimation of closed Sobol' indices of any order as well (see [18] for more details).

Remark. Owen [38] extends (35.5) by drawing points from a third $N \times d$ sample matrix obtaining more accurate estimates of small sensitivity indices. However, no additional evaluations are necessary when applying the strategy of simultaneous estimation of all indices described in [43], Theorem 1 (see also the comments after Theorem 1).

4.1.3 Estimation of Total Sobol' Indices

The Monte Carlo formula for the total Sobol' index S_j^{tot} was derived by [20]

$$S_j^{\text{tot}} \cdot \text{Var } G(\mathbf{X}) = \frac{1}{2N} \sum_{i=1}^N (G(\mathbf{A})^{(i)} - G(\mathbf{A}_{\mathbf{B}(\{j\})})^{(i)})^2. \quad (35.7d)$$

Remark. The total number of model runs required to compute $S_j^{\text{tot}}, j = 1, 2, \dots, d$ (see (35.7d)) is $N_T = N(d + 1)$, while if $S_j, j = 1, 2, \dots, d$ are also computed (see (35.7a)), the total cost increases up to $N_T = N(d + 2)$, due to the extra runs corresponding to the elements of the matrix \mathbf{B} . Likewise, in [38] the cost of the analysis is $N(3d + 2)$ model runs, with a good accuracy for the estimation of small indices. The cost for estimating $S_{\mathbf{u}}^{\text{clo}}, \mathbf{u} \in \mathcal{P}(\{1, \dots, d\})$ (see 35.5) is much larger as there are $2^d - 1$ possible measures of closed Sobol' indices. Therefore, $S_{\mathbf{u}}^{\text{clo}}$ are rarely estimated as the number of model runs could be prohibitive. When used, $S_{\mathbf{u}}^{\text{clo}}$ are generally estimated only for pairs of input variables, i.e., $\text{card}(\mathbf{u}) = 2$. However, in that case, the approach by Saltelli [43] is preferred, which is based on a tricky combinatoric argument.

4.1.4 A Tricky Combinatoric Argument Introduced in [43]

Theorem 1 (Theorem 2 in [43]). *Allowing for $N_T = N \times (2d + 2)$ model evaluations, one can obtain:*

- (1) double estimates for each S_j and S_j^{tot} index
- (2) double estimates for all $\binom{d}{2}$ indices $S_{j_1 j_2}^{\text{clo}}$
- (3) double estimates for all $\binom{d}{2}$ indices $S_{-\{j_1, j_2\}}^{\text{clo}}$

where $\{j_1, j_2\} \subset \{1, \dots, d\}$ and $-\{j_1, j_2\}$ means all variables except $\{j_1, j_2\}$.

Another theorem (Theorem 1 in [43]) shows that one can obtain single estimates of all first-order, second-order, and total sensitivity indices using $N_T = N \times (d + 2)$ model evaluations.

To explain the procedure yielding to Theorem 1 above, an illustration in dimension $d = 4$ is given. The following notation is used:

$$\begin{aligned} U_{\mathbf{u}} &= \mathbb{E}^2(G(\mathbf{X})|\mathbf{X}_{\mathbf{u}}), \\ V_{\mathbf{u}} &= \text{Var}[\mathbb{E}(G(\mathbf{X})|\mathbf{X}_{\mathbf{u}})] = U_{\mathbf{u}} - \mathbb{E}^2(G(\mathbf{X})). \end{aligned}$$

One then has

$$\begin{aligned} S_j &= \frac{U_j - \mathbb{E}^2(G(\mathbf{X}))}{\text{Var } G(\mathbf{X})}, \\ S_j^{\text{tot}} &= \frac{U_{-j} - \mathbb{E}^2(G(\mathbf{X}))}{\text{Var } G(\mathbf{X})}, \\ S_{j_1 j_2}^{\text{clo}} &= \frac{U_{j_1 j_2} - U_{j_1} - U_{j_2} + \mathbb{E}^2(G(\mathbf{X}))}{\text{Var } G(\mathbf{X})}. \end{aligned}$$

Let $\mathbf{a} = \mathbf{A}$, $\mathbf{b} = \mathbf{B}$, and $\mathbf{b}_{\mathbf{u}} = \mathbf{B}_{\mathbf{A}(\mathbf{u})}$.

Saltelli [43] suggests to estimate $\mathbb{E}^2(G(\mathbf{X}))$ by $\frac{1}{N} \sum_{i=1}^N G(\mathbf{b})^{(i)} G(\mathbf{a})^{(i)}$. The following table shows how the terms $U_{\mathbf{u}}$, $\mathbf{u} \subset \{1, \dots, d\}$ can be estimated.

One can see that only $N_T = N \times (2d + 2) = 10N$ model evaluations are needed to estimate twice all indices: S_j , S_j^{tot} , $j = 1, 2, 3, 4$, $S_{j_1 j_2}^{\text{clo}}$, $S_{-\{j_1, j_2\}}^{\text{clo}}$, $1 \leq j_1 \neq j_2 \leq 4$. This combinatoric trick can be applied to 35.5, 35.7a, and 35.7d to obtain double estimates of $S_{\mathbf{u}}$, $S_{\mathbf{u}}^{\text{tot}}$, $S_{\mathbf{u}}^{\text{clo}}$, and $S_{-\mathbf{u}}^{\text{clo}}$ indices with $\mathbf{u} = \{j_1, j_2\} \subset \{1, \dots, d\}$.

4.1.5 Sampling Strategies

There exist various ways to generate the matrices \mathbf{A} and \mathbf{B} . Some of the designs proposed in the following are also discussed in the paper ▶ Chap. 33, “Design of Experiments for Screening” of the present chapter. The more classical sampling scheme is to generate \mathbf{A} and \mathbf{B} from two *i.i.d.* (independent and identically distributed) $N \times d$ samples.

However, particularly in the case where N is small, one should prefer a “space-filling” sampling strategy.

The sampling matrices \mathbf{A} and \mathbf{B} can be generated from quasi-random (also called *low-discrepancy*) sequences. Indeed, quasi-Monte Carlo (QMC) can speed up the convergence rate of sensitivity estimates. Loosely speaking, the estimation of Sobol’ indices can be summarized by a problem of approximating multidimensional integrals. The efficiency of QMC approximations of integrals can be measured by the QMC error bound (see, e.g., [25, 56] for more details on the QMC error

	\mathbf{b}	$\mathbf{b}_{\{1\}}$	$\mathbf{b}_{\{2\}}$	$\mathbf{b}_{\{3\}}$	$\mathbf{b}_{\{4\}}$	$\mathbf{b}_{\{2,3,4\}}$	$\mathbf{b}_{\{1,3,4\}}$	$\mathbf{b}_{\{1,2,4\}}$	$\mathbf{b}_{\{1,2,3\}}$	$\mathbf{b}_{\{1,2,3,4\}}$

Fig. 35.1 Illustration in dimension $d = 4$ of all possible combinations of \mathbf{b}_u to obtain double estimates of S_j , S_j^{tot} , $S_{j_1 j_2}^{\text{clo}}$, and $S_{-\{j_1, j_2\}}^{\text{clo}}$ indices

bound). If the model has some regularity, in the sense that it has bounded Hardy-Krause variation, the Koksma-Hlawka inequality gives an upper bound for the QMC integration error. The rate of convergence is then in $\mathcal{O}\left(\frac{\log^d(N)}{N}\right)$ where N is the sample size and d the dimension. However, this bound is a weak bound for the integration error, as in practice it was proved that QMC may outperform MC even for large dimension d . Indeed, the key parameter is not the model nominal dimension but rather its effective dimension [2]. The effective dimension in the truncation sense d_T roughly speaking is equal to the number of important factors in the model, while a model has the effective dimension in the superposition sense d_S if it is almost a sum of s -dimensional components, with $s \leq d_S$, in the FANOVA decomposition. These dimensions d_T and d_S have a much more important impact on the rate of convergence of QMC than the nominal dimension d . This property will be illustrated on numerical experiments later in the chapter.

There exist two main families of constructions for low-discrepancy point sets and sequences: lattices and digital nets/sequences (see [28] for more details on these constructions and their properties). It is usual to use Sobol' sequences [21] as particular cases of *quasi-random* (or *low-discrepancy*) sequences of size (N, d) . The low-discrepancy properties of Sobol' sequences deteriorate with increasing dimension of the input space. If the important inputs are located in the last components of X , then the rate of convergence is negatively affected. Therefore, if a preliminary ranking of inputs in order of importance is available, the convergence

of sensitivity estimates could benefit by sampling the inputs in decreasing order of importance. The interested reader is referred to Chapter 5 in [28] for other low-discrepancy sequences, such as Halton, Faure, or Niederreiter sequences.

Some analysts prefer generating matrices \mathbf{A} and \mathbf{B} using Latin hypercube sampling (LHS) (see, e.g., [24]).

Both Sobol' quasi-random sequences and LHS allow additional sample points to be added to matrices \mathbf{A} and \mathbf{B} (i.e., increasing the number of rows N), and equations (35.7a) and (35.7d) can be updated until a desired target accuracy is achieved. Refer to [42] for the presentation of nested LHS. For LHS, at each update, the size of the sample is at least doubled, whereas Sobol' sequences can be updated point by point. Note that Sobol' sequences and LHS can be generated using freely available packages (e.g., the package DiceDesign [51] available on CRAN or the link [22] for MATLAB codes).

4.1.6 A Trick to Reduce the Cost: The Use of Replicated Designs

It is possible to reduce the cost of estimation, in terms of number of model evaluations, for the estimation of first-order Sobol' indices. The trick was first introduced in [32] and then further investigated in [55].

One starts as previously by constructing a $N \times d$ sampling matrix \mathbf{A} . The sampling matrix \mathbf{B} , of size $N \times d$ also, is then constructed from \mathbf{A} by applying a random permutation π_j to each column of \mathbf{A} , $j = 1, \dots, d$. For any $j = 1, \dots, d$, one then constructs a new $N \times d$ array by reordering the lines in \mathbf{B} in such a way that the j th column in this new array $\tilde{\mathbf{B}}_j$ coincides with the j th column of \mathbf{A} .

For each $j = 1, \dots, d$, one then estimates S_j with formula (35.7a) by replacing the design matrix $\mathbf{A}_{\mathbf{B}(\{j\})}$ with $\tilde{\mathbf{B}}_j$. It is important to note that the sampling matrices \mathbf{B} and $\tilde{\mathbf{B}}_j$, $j = 1, \dots, d$ are identical when considered as a set of N points in \mathbb{R}^d , by construction. Thus, the estimation of all first-order Sobol' indices only requires $2N$ model evaluations.

This approach can be extended to the estimation of closed second-order indices, using randomized orthogonal arrays (see [55]), but not to the estimation of total indices.

4.1.7 Estimating Sensitivity Indices Without a Specific Sampling Design or Given Data Estimators

Within the realm of Monte Carlo-based techniques, it is possible to estimate the first-order indices S_j (i.e., $S_{\mathbf{u}}$ when $\mathbf{u} = \{j\}$) without the need to use the sampling design proposed above. This approach is very simple because it uses the definition of S_j . However, the approach is not applicable in practice for the computation of $S_{\mathbf{u}}^{\text{clo}}$ and $S_{\mathbf{u}}^{\text{tot}}$. The starting point can either be a generic random sample of N points of the input \mathbf{X} , on which one can evaluate the model output $\mathbf{G}(\mathbf{X})$, or a precomputed set of model output $(\mathbf{X}^{(i)}, G(\mathbf{X})^{(i)})$, $i = 1, \dots, N$. From the N pairs $(\mathbf{X}^{(i)}, G(\mathbf{X})^{(i)})$, $i = 1, \dots, N$, the quantity $G_j(X_j)$, $j = 1, \dots, d$ can be estimated by partitioning the values of X_j into classes \mathcal{C}_m , $m = 1, \dots, M$ and computing the expectation of $G(\mathbf{X})$ conditional on all the values of X_j that belong to each class.

Finally, the variance of all such conditional expectations yields the numerator of S_j , $\text{Var } G_j(X_j)$. Although several partition strategies are possible, an effective way is to form classes of nearly the same size $N_m = (N/M)$. A de-biased formula has been proposed by [41]

$$S_j = \frac{\sum_{m=1}^M N_m (\bar{G}_m - \bar{G})^2}{\sum_{i=1}^N (G(\mathbf{X})^{(i)} - \bar{G})^2} \quad (35.8)$$

where

$$\bar{G}_m = \frac{1}{N_m} \sum_{i:X_j^{(i)} \in C_m} G(\mathbf{X})^{(i)}$$

and

$$\bar{G} = \frac{1}{N} \sum_{i=1}^N G(\mathbf{X})^{(i)}.$$

Remark. Numerical experiments have shown that increasing such equally sized partitions beyond 50 classes has negligible effect on the estimation accuracy [41].

Remark. The form of the estimate in (35.8) is very close to the one proposed by McKay [34] (see also [35]) based on permuted column sampling. However, the one described here is more general as it allows using any sampling design.

4.2 Spectral Approaches

In case the model G has some regularity, one might prefer spectral approaches rather than Monte Carlo approaches to estimate Sobol' indices.

4.2.1 Notation, Definitions

For this purpose, consider, for all $j = 1, \dots, d$, an orthonormal Hilbert basis of $\mathbb{L}_{\mathbb{R}}^2(P_{X_j})$, denoted by $(\Phi_{j,k}, k \in \mathbb{Z})$ such that $\Phi_{j,0} \equiv 1$.

Remark. Considering that $\mathbb{L}_{\mathbb{R}}^2(P_{X_j}) \subset \mathbb{L}_{\mathbb{C}}^2(P_{X_j})$, one can also replace the basis $(\Phi_{j,k}, k \in \mathbb{Z})$ by a Hilbert basis of $\mathbb{L}_{\mathbb{C}}^2(P_{X_j})$. It will have a practical interest when considering, e.g., the Fourier basis.

Consider the tensorized basis of $\mathbb{L}_{\mathbb{K}}^2(P_{\mathbf{X}})$, $\mathbb{K} = \mathbb{R}$, or \mathbb{C} , whose elements are indexed by $\mathbf{k} = (k_1, \dots, k_d) \in \mathbb{Z}^d$ and defined as the products $\Phi_{1,k_1}(\cdot) \times \dots \times \Phi_{d,k_d}(\cdot)$. $G(\mathbf{X})$ can be decomposed as follows:

$$Y = G(\mathbf{X}) = \sum_{\mathbf{k} \in \mathbb{Z}^d} c_{\mathbf{k}}(G) \Phi_{1,k_1}(X_1) \dots \Phi_{d,k_d}(X_d).$$

Now define

$$\begin{aligned}\mathbb{Z}_{\mathbf{u}, \neq 0} &:= \{\mathbf{k} \in \mathbb{Z}^d \mid \forall j \in \mathbf{u}, k_j \in \mathbb{Z}_{\neq 0} \text{ and } \forall j \notin \mathbf{u}, k_j = 0\} \\ \text{and } (\mathbb{Z}^d)_{\neq 0} &= \{\mathbf{k} \in \mathbb{Z}^d \mid \mathbf{k} \neq (0, \dots, 0)\}.\end{aligned}$$

Thanks to the orthonormality of the bases $(\Phi_{j,k}, k \in \mathbb{Z})$, it is possible to identify the components in the FANOVA decomposition as

$$G_{\mathbf{u}}(\mathbf{X}_{\mathbf{u}}) = \sum_{\mathbf{k} \in \mathbb{Z}_{\mathbf{u}, \neq 0}} c_{\mathbf{k}}(G) \Phi_{1,k_1}(X_1) \dots \Phi_{d,k_d}(X_d). \quad (35.9)$$

Proposition 1. Assume that $G \in \mathbb{L}_{\mathbb{K}}^2(P_{\mathbf{X}})$ and that $\text{Var}(G(\mathbf{X})) \neq 0$. Then, for any nonempty subset $\mathbf{u} \subset \{1, \dots, d\}$,

$$S_{\mathbf{u}} = \frac{\sum_{\mathbf{k} \in \mathbb{Z}_{\mathbf{u}, \neq 0}} |c_{\mathbf{k}}(G)|^2}{\text{Var}(G(\mathbf{X}))}. \quad (35.10)$$

Proof. Endow the space $\mathbb{L}_{\mathbb{K}}^2(P_{\mathbf{X}})$ with the scalar product associated to $P_{\mathbf{X}}$: $\langle f, g \rangle = \int f(\mathbf{x}) \overline{g(\mathbf{x})} P_{\mathbf{X}}(d\mathbf{x})$. Equality (35.10) is a straightforward consequence of the identification equality (35.9) and of Parseval's identity. \square

Recall that for all $j = 1, \dots, d$, I_j is the support of the probability distribution of X_j . For $n \in \mathbb{Z}_{>0}$, let $D = \{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ be any finite subset of n points in $I_1 \times \dots \times I_d$. Let $\mathbf{p} = (p_1, \dots, p_n) \in (\mathbb{R}_{\geq 0})^n$ such that $\sum_{i=1}^n p_i = 1$. In the following, integrals in (35.10) are approximated by quadrature formulas associated to the set of nodes D and to the weights \mathbf{p} . $c_{\mathbf{k}}(G) = \langle G, \Phi_{\mathbf{k}} \rangle$ can be approximated by

$$\hat{c}_{\mathbf{k}}(G, D, \mathbf{p}) = \sum_{i=1}^n G(\mathbf{x}_i) \overline{\Phi_{\mathbf{k}}(\mathbf{x}_i)} p_i$$

and $\text{Var}(G(\mathbf{X}))$ by

$$\widehat{V}(D, \mathbf{p}) = \sum_{i=1}^n \left(G(\mathbf{x}_i) - \sum_{j=1}^n G(\mathbf{x}_j) p_j \right)^2 p_i.$$

Let now $K_{\mathbf{u}}$ be any finite subset of $\mathbb{Z}_{\mathbf{u}, \neq 0}$ and define the following intuitive estimator for $S_{\mathbf{u}}$:

$$\widehat{S}_{\mathbf{u}}(K_{\mathbf{u}}, D, \mathbf{p}) = \frac{\sum_{\mathbf{k} \in K_{\mathbf{u}}} \hat{c}_{\mathbf{k}}(G, D, \mathbf{p})}{\widehat{V}(D, \mathbf{p})}. \quad (35.11)$$

Remark. As the infinite set $\mathbb{Z}_{\mathbf{u}, \neq 0}$ is truncated, an important requirement under this way of estimating Sobol' indices is the fast decrease of the coefficients $c_{\mathbf{k}}(G)$. This is why spectral approaches are particularly well suited for regular models G , for which they outperform Monte Carlo-type approaches. However, the choice of the truncation set $K_{\mathbf{u}}$ is very important. Applying a too drastic truncation may lead to nonconvergent estimates.

4.2.2 FAST and RBD Particular Cases

Consider the particular case where $\forall j \in \{1, \dots, d\}$, X_j is uniformly distributed on $[0, 1]$. A possible choice for the basis is then the Fourier basis: $\mathbf{x} \mapsto e^{i\mathbf{k}\cdot\mathbf{x}}$, $\mathbf{k} \in \mathbb{Z}^d$, with $\mathbf{k}\cdot\mathbf{x} = \sum_{j=1}^d k_j x_j$. For any $p \in \mathbb{Z}_{>0}$, let

$$\begin{cases} r_p : [0, 1] \longrightarrow [0, 1] \\ x \longmapsto \begin{cases} 2\{px\} & \text{if } 0 \leq \{px\} < \frac{1}{2} \\ 2 - 2\{px\} & \text{if } \frac{1}{2} \leq \{px\} \leq 1 \end{cases} \end{cases}$$

and for any $\varphi \in [0, 2\pi)$, let

$$\begin{cases} t_{\varphi} : [0, 1] \longrightarrow [0, 1] \\ x \longmapsto \{x + \tilde{\varphi}\} \quad \text{with } \tilde{\varphi} = \frac{1}{4} + \frac{\varphi}{2\pi}, \end{cases}$$

with for any real number z , $\{z\} = z - \lfloor z \rfloor$, the fractional part of $z \in \mathbb{R}$ and $\lfloor \cdot \rfloor$ the floor function.

Then, define the linear operators \mathcal{R}_p and \mathcal{T}_{φ} on $L^2_{\mathbb{C}}([0, 1]^d)$ (see Fig. 35.2 below) such that for all $\mathbf{x} \in [0, 1]^d$,

$$\mathcal{R}_p G(\mathbf{x}) = G(r_p(x_1), \dots, r_p(x_d)) \quad \text{and} \quad \mathcal{T}_{\varphi} G(\mathbf{x}) = G(t_{\varphi_1}(x_1), \dots, t_{\varphi_d}(x_d)).$$

with $\mathcal{R}_p = \underbrace{\mathcal{R}_1 \circ \cdots \circ \mathcal{R}_1}_{p \text{ times}}$.

Lemma 1 (Lemma 1 in [54]). *For any $p \in \mathbb{N}^*$ and any $\varphi \in [0, 2\pi)^d$, the variance decomposition is \mathcal{R}_p and \mathcal{T}_{φ} -invariant on $L^2_{\mathbb{C}}([0, 1]^d)$.*

Proof. The interested reader is referred to Appendix A.3 in [54] for a detailed proof of Lemma 1. \square

Two classical designs of experiments are introduced. For any $\omega \in (\mathbb{Z}_{>0})^d$, denote

$$\mathcal{G}(\omega) = \left\{ \left(\left\{ \frac{i}{n} \omega_1 \right\}, \dots, \left\{ \frac{i}{n} \omega_d \right\} \right), i \in \{0, \dots, n-1\} \right\}.$$

The cyclic subgroup – of order $n/gcd(\omega_1, \dots, \omega_d, n)$ – of the torus $\mathbb{T}^d = (\mathbb{R}/\mathbb{Z})^d \simeq [0, 1]^d$ is generated by $(\{\frac{\omega_1}{n}\}, \dots, \{\frac{\omega_d}{n}\})$.

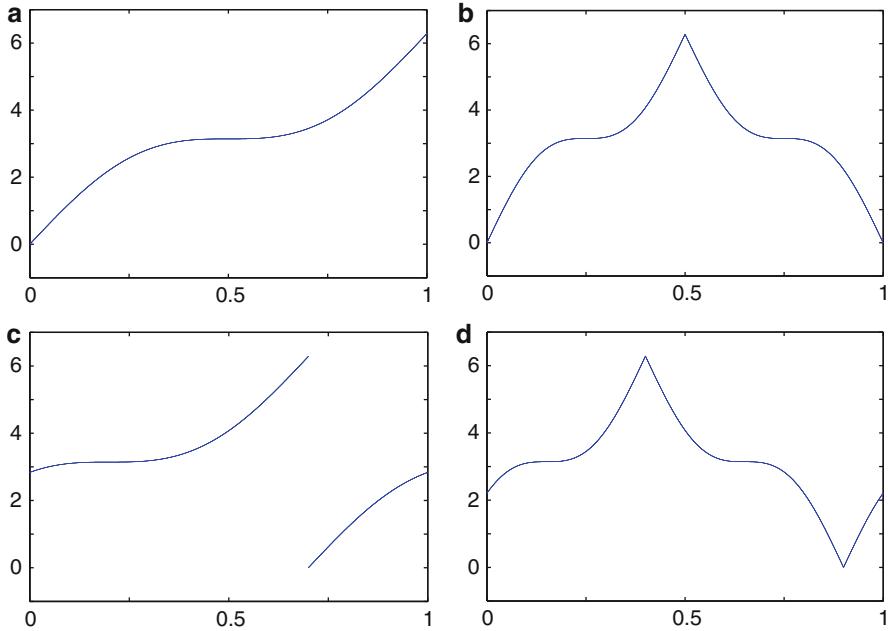

Fig. 35.2 Examples of operators \mathcal{R}_p and \mathcal{T}_φ in dimension 1. (a) Plot of $f : x \mapsto x + \sin(x)$. (b) Plot of $\mathcal{R}_1 f$. (c) Plot of $\mathcal{T}_{\frac{\pi}{10}} f$. (d) Plot of $(\mathcal{T}_{\frac{\pi}{30}} \circ \mathcal{R}_1) f$

Let $\sigma_1, \dots, \sigma_d$ be random permutations on $\{0, \dots, n - 1\}$ and \mathfrak{S} denote the set of all possible $\sigma = (\sigma_1, \dots, \sigma_d)$. For any $\sigma \in \mathfrak{S}$, denote with

$$A(\sigma) = \left\{ \left(\frac{\sigma_1(i)}{n}, \dots, \frac{\sigma_d(i)}{n} \right), i \in \{0, \dots, n - 1\} \right\}$$

the orthogonal array of strength 1 and index unity with elements taken from $\{0, \frac{1}{n}, \dots, \frac{n-1}{n}\}$ and based on the permutation σ .

Let \mathbf{p}_0 be the set of weights defined by $\mathbf{p}_0 = (\underbrace{n^{-1}, \dots, n^{-1}}_{n \text{ times}})$.

Fourier amplitude sensitivity test (FAST) and random balance design (RBD) methods for estimating Sobol' indices are then defined by Definition 3.

Definition 3. For any nonempty subset $\mathbf{u} \subset \{1, \dots, d\}$, and any finite subset $K_{\mathbf{u}} \subset \mathbb{Z}_{\mathbf{u}, \neq 0}$, for any $\varphi \in [0, 2\pi]^d$ and any $\omega \in (\mathbb{Z}_{>0})^d$, one has

$$\hat{S}_{\mathbf{u}}^{\text{FAST}}(G, K_{\mathbf{u}}, \mathbf{x}^*) = \hat{S}_{\mathbf{u}}((\mathcal{T}_\varphi \circ \mathcal{R}_1)G, K_{\mathbf{u}}, \mathcal{G}(\omega), \mathbf{p}_0).$$

For any nonempty subset $\mathbf{u} \subset \{1, \dots, d\}$, and any finite subset $K_{\mathbf{u}} \subset \mathbb{Z}_{\mathbf{u}, \neq 0}$, for any $\sigma \in \mathfrak{S}$ and any $\omega \in \mathbb{Z}_{>0}$, one has

$$\hat{S}_{\mathbf{u}}^{\text{RBD}}(G, K_{\{\mathbf{u}\}}, \mathbf{x}^*) = \hat{S}_{\mathbf{u}}((\mathcal{T}_\omega \circ \mathcal{R}_\omega)G, \omega K_{\{\mathbf{u}\}}, A(\sigma), \mathbf{p}_0)$$

where $\tilde{\omega} = \left(\frac{(1-\omega)\pi}{2\omega}, \dots, \frac{(1-\omega)\pi}{2\omega} \right)$ and $\omega K_{\{u\}} = \{(\omega k_1, \dots, \omega k_d), \mathbf{k} \in K_{\{u\}}\}$.

Remark. Note that the linear operator \mathcal{R}_p “regularizes” the function G in the sense that the coefficients $c_{\mathbf{k}}(\mathcal{R}_p G)$ decrease faster to zero than the coefficients $c_{\mathbf{k}}(G)$ as $\sum_{j=1}^d |k_j|$ tends to infinity. The other operator \mathcal{T}_{φ} essentially allows to define randomized estimators in FAST.

Remark. FAST was introduced in [6–8] and RBD for first-order Sobol’ indices in [50] and for higher-order Sobol’ indices in [57]. Both methods were revisited recently in [54], leading to Definition 3. Under regularity assumptions, the estimators in RBD are asymptotically unbiased.

Remark. A variant of RBD called quasi-random balance design (QRBD) has recently been proposed to increase the precision and accuracy of first-order indices. The method differs from RBD in the way the sample is created. QRBD uses multidimensional quasi-random sequences to construct the permutations which are used to create the realizations of the inputs. A working paper describing the methodology is being prepared by Plischke, Tarantola, and Mara.

4.2.3 Choice of Parameters ω and n in FAST

There exist various criteria for the choice of these parameters. Refer to [54] for a recent review. In [47], the authors propose a criterion which aims at choosing $\omega_1, \dots, \omega_d$ free of interferences up to order $M \in \mathbb{Z}_{>0}$:

$$(\mathbf{k} - \mathbf{k}') \cdot \omega \neq 0 \text{ for all } \mathbf{k}, \mathbf{k}' \in \mathbb{Z}^d, \mathbf{k} \neq \mathbf{k}', \text{ s.t. } \sum_{i=1}^d |k_i - k'_i| \leq M + 1 \quad (35.12)$$

and n sufficiently large

$$n \approx M \max(\omega_1, \dots, \omega_d).$$

More recently, referring to the classical information theory, the authors in [46] suggest to replace the previous formula with Nyquist-Shannon sampling theorem

$$n > 2M \max(\omega_1, \dots, \omega_d).$$

Choosing $K_u = \mathbb{Z}_u \cap (-M, M]^d$, it seems more natural to replace (35.12) by

$$(\mathbf{k} - \mathbf{k}') \cdot \omega \neq 0 \text{ for all } \mathbf{k}, \mathbf{k}' \in \mathbb{Z}^d, \mathbf{k} \neq \mathbf{k}', \text{ s.t. } \sum_{i=1}^d |k_i| \leq M \text{ and } \sum_{i=1}^d |k'_i| \leq M.$$

Remark. In the RBD method, the parameter ω is usually set equal to 1. The RBD approach is known to be biased (even if asymptotically unbiased), and recently a partial correction of the bias was proposed in [53] and generalized in [54].

4.2.4 The EASI Method

An effective algorithm for computing sensitivity indices (EASI) has been proposed in [40] where first-order sensitivity indices are estimated from a set of precomputed model evaluations $(\mathbf{X}^{(i)}, G(\mathbf{X})^{(i)}), i = 1, \dots, N$ using the fast Fourier transform. The article also discusses ideas for the estimation of higher-order sensitivity indices. The sampled values of the j th input $X_j^{(i)}, i = 1, \dots, N$ are ordered increasingly. Then, the sampled values that correspond to all odd indices i are ordered increasingly followed by all even indices in decreasing order. With this sorting and shuffling procedure, one obtains a reordered input that is triangular shaped and can be thought of as a periodic curve with frequency 1. By permuting the output values according to this rule, one looks out for resonances of period 1 and its higher harmonics in the power spectrum of the permuted output using the standard procedure implemented in both FAST and RBD. By repeating the sorting and shuffling of X_j for all other j on the same set of N sampled values, one obtains all the other first-order sensitivity indices. Estimates produced by EASI are biased with respect to the maximal number of harmonics M , defined in Eq. (35.12). A bias correction formula, derived in [23], is proposed in [40].

4.2.5 Polynomial Chaos Expansion

Consider the case where the vector $\mathbf{X} = (X_1, \dots, X_d)$ is d -dimensional with independent components. A pertinent choice for the basis $(\Phi_{j,k}, k \in \mathbb{Z})$ is then a basis of orthogonal polynomials, e.g., the Legendre basis if X_j is uniformly distributed on $[0, 1]$ or the Hermite polynomials if X_j is normally distributed. There exists a wide literature on PC expansions (see, e.g., [1, 49]).

5 Test Functions

5.1 The g -Sobol' Function and Effective Dimension

The first test case is the g -Sobol' function. It is a classical test case, which is parameter dependent. Depending on the choice of the parameter, the effective dimension of this model can be varied. Moreover, an analytical expression for Sobol' indices is available.

5.1.1 Model

$Y = f_1(X_1) \times \dots \times f_d(X_d)$ with $(X_1, \dots, X_d) \sim \mathcal{U}([0, 1]^d)$ and

$$f_j(X_j) = \frac{|4X_j - 2| + a_j}{1 + a_j}, \quad a_j \geq 0, \quad j = 1, \dots, d.$$

The example provided in [43] with $a = (0, 0.5, 3, 9, 99, 99)$ has been chosen in dimension $d = 6$.

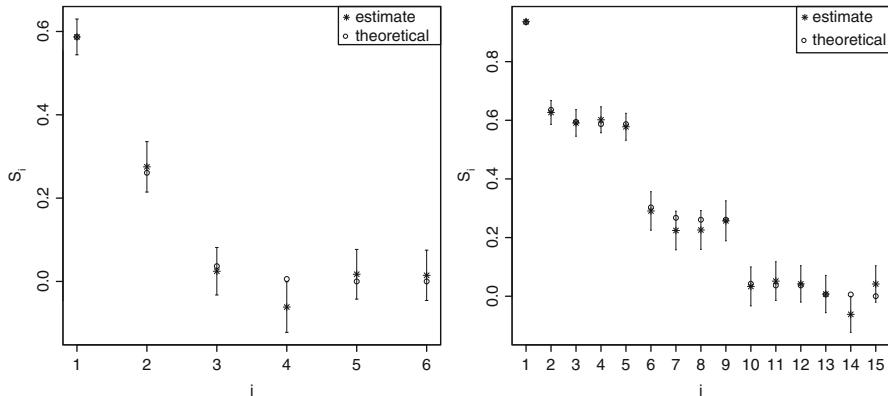

Fig. 35.3 Estimation of (left) first-order and (right) closed second-order indices for the g-Sobol' function with $a = (0, 0.5, 3, 9, 99, 99)$, using replicated designs and formulas (35.7b) and (35.7c), with replicated LHS (left) of level 1024 and replicated randomized orthogonal arrays (right) of level 31. The confidence bounds are provided by the asymptotic central limit theorem stated in [18]

The estimation of first-order Sobol' indices is given below using replicated designs [32, 55]. Closed second-order Sobol' indices are also provided using the extension of formulas (35.7b) and (35.7c) given in [18].

$N = 1024$ has been chosen. The number of model evaluations for the estimation of all d first-order Sobol' indices is $N_T = 2 \times N = 2048$, and the cost to estimate all closed second-order Sobol' indices is $N'_T = 2 \times 31^2 = 1922$. This number is explained hereafter. Replicated designs for the estimation of closed second-order indices are based on the construction of an orthogonal array of strength 2. To construct this orthogonal array, a prime number has to be chosen for the level. The largest prime number p such that $p^2 \leq 1024$ was chosen; thus, $p = 31$.

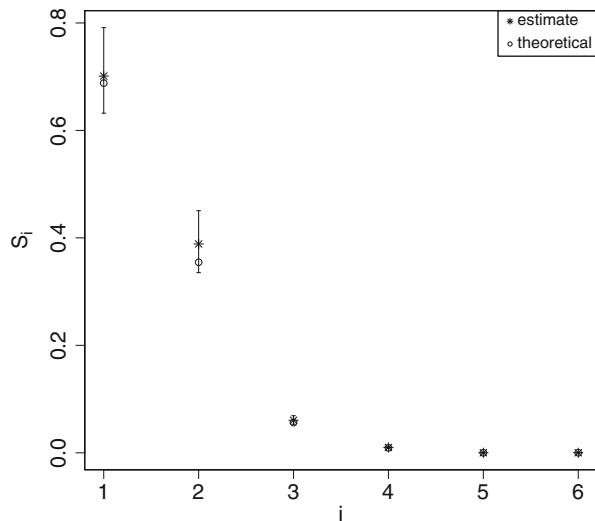

The results are presented in Fig. 35.3. Closed second-order Sobol' indices are labeled from 1 to 15 from $S_{\{1,2\}}^{\text{clo}}$ to $S_{\{5,6\}}^{\text{clo}}$.

Note that the confidence bounds are small enough at this sample size. The estimation is better for influential factors. However, the replicated approach does not allow one to estimate total indices. If needed, and if a budget for that is available, one can use the estimator defined by formula (35.7d) and initially derived by [20]. The results are presented in Fig. 35.4. Again, $N = 1024$ has been chosen; thus, the number of model evaluations which are required for the estimation of all d total Sobol' indices is $N_T = (d + 2) \times N = 8192$.

If one is interested in estimating first-order, second-order and total sensitivity indices altogether, the combinatoric trick proposed by [43] is suggested, as it requires $N_T = N(d + 2)$ model evaluations (see Theorem 1 in [43]).

The numerical tests above have been performed by using the package `sensitivity` [52] available on CRAN.

Fig. 35.4 Estimation of total Sobol' indices for the g -Sobol' function with $a = (0, 0.5, 3, 9, 99, 99)$, using random sampling and formula (35.7d). The confidence bounds are computed with $B = 100$ bootstrap replications. The number of model evaluations is $N = (d + 2) \times 1024 = 8192$

5.2 A Discontinuous Test Function

The test function in d dimensions is defined as follows:

$$G(\mathbf{X}) = \sum_{i=1}^d X_i - \gamma/2$$

where

$$\begin{aligned}\gamma &= 1 \text{ if } \exists X_i : 0 \leq X_i < 1/2, \\ \gamma &= 2 \text{ if } \exists i \neq j \exists X_i, X_j : \{0 \leq X_i < 1/2, 0 \leq X_j < 1/2\}, \\ \gamma &= 3 \text{ if } \exists i, j, k \text{ distinct } \exists X_i, X_j, X_k : \{0 \leq X_i < 1/2, 0 \leq X_j < 1/2, 0 \leq X_k < 1/2\},\end{aligned}$$

and so on until $\gamma = d$.

Table 35.1 contains the results of applying the Sobol' method and all the spectral methods described in this chapter, for the estimation of first-order indices to the discontinuous function defined above in two dimensions. Table 35.1 shows quite interesting results. Firstly, the Sobol' method provides very accurate estimates even at $N = 32$, although the precision of such estimates (expressed by the standard deviation over the 100 replicates) is quite weak and becomes comparable to that of the other techniques only at $N = 512$. Secondly, RBD is biased at small sample size, although this bias tends to disappear as N increases. At small N , the de-biased version of RBD is very accurate, but its precision is lower than that of RBD. QRBD is both accurate and precise even at small N . However, its de-biased version underestimates the true values. This is because the assumption of white noise

Table 35.1 First-order indices obtained by the method of Sobol'; de-biased and non-de-biased versions of RBD, QRBD, and EASI; as well as the definition of first-order index with "no specific design." The tests have been made on the discontinuous function, defined above, in the case of two inputs. The analytic first-order indices are 0.5 and 0.5, for the symmetric nature of the test function. N indicates the total sample size. The analysis is replicated 100 times. In each cell, the average sensitivity indices and the standard deviations are shown. The "no specific design" approach uses simple random sample with 16 equally sized bins. In these tests, 16 bins allow the estimation of sensitivity indices only for sample sizes 128, 256, and 512. At lower sample size, estimations are not possible due to few empty bins

N	32	64	128	256	512

Table 35.2 First-order indices obtained using the de-noised version of the EASI method for different values of frequency truncation; see Equation (35.12). The tests have been made on the discontinuous function, defined above, in the case of two inputs. Each analytic first-order index is 0.5, due to the symmetric nature of the test function. The total sample size $N = 10,000$ is chosen sufficiently large so as to minimize sampling error and highlight the underestimation error due to the truncation of the Fourier coefficients. The analysis is replicated 100 times. In each cell, the average sensitivity indices over the 100 replicates are shown. The standard deviations across the 100 replicates are all equal to 0.005. As one can see, the negative bias is progressively reduced as the truncation parameter increases

Truncation	S_1	S_2
4	.4870	.4865
6	.4925	.4915
8	.4942	.4942
10	.4951	.4953
20	.4978	.4981
50	.4985	.4987
100	.4993	.4998

underlying the de-biasing algorithm does not hold for quasi-random permutations. Therefore, it is recommended not to use this procedure. Finally, the EASI technique, which does not require a specific design but works for any given input dataset, is very precise even at $N = 32$, although less accurate. However, at large sample size, its estimates are very accurate. The de-biased version of EASI proves very effective in both accuracy and precision (Table 35.1).

6 Conclusions

This section provides an overview of variance-based sensitivity measures. Conceptually, the variance of the output of a computer model is decomposed into parts (called partial variances) representing the fraction of the output's variance that is accounted for by each input to the model. Such partial variances provide a measure of relative importance of the model inputs, either taken singularly or considered by groups. The section introduces first-order, higher-order, and total sensitivity measures. Of these, the analyst is generally interested in first-order, second-order, and total indices, as higher-order indices require too many runs of the model and hence too much computational time. The section splits the available estimation techniques in two classes, those based on Monte Carlo and those based on spectral approaches. After illustrating their properties, the described techniques are tested on few functions for which the true sensitivity measures can be calculated analytically, so as to compare their relative performances. Monte Carlo-type approaches are particularly flexible in the sense that no regularity assumption on the model is required. For first- and second-order indices, replicated designs seem particularly well suited. However, if one wishes to compute total indices, one has to pay a price which is linear in the dimension, and the recommended estimator is given by Saltelli [43] which allows to get simultaneously first-order, second-order, and total indices. However, in case the model has some regularity, spectral approaches perform very well and particularly the EASI approach.

Scalar (and independent sets of) inputs as well as univariate outputs have been considered in the present section. Sometimes, this is not the case.

- Various approaches have been proposed to handle the case of correlated inputs. The interested reader is referred to [3–5, 26, 29, 33] (see also **Introduction** of the present chapter).
- In many instances, one has to deal with multivariate outputs. Two interesting approaches are described in [13, 27]. The reader can also refer to [14] for an overview of different approaches to the analysis of multivariate output.
- It is also possible to generalize global sensitivity analysis to computer codes with functional inputs. In [17, 30], or [10], the authors propose approaches which result in one sensitivity index for each functional input as a whole. More recently, the authors in [12] proposed a method which provides insight into the sensitivity with respect to changes at specific intervals of the functional domain (see also the paper ► [Chap. 39, “Sensitivity Analysis of Spatial and/or Temporal Phenomena”](#) of the present chapter which presents a review on sensitivity analysis for functional inputs and/or functional outputs).

Abstract

The method of derivative-based global sensitivity measures (DGSM) has recently become popular among practitioners. It has a strong link with the Morris screening method and Sobol' sensitivity indices and has several advantages over them. DGSM are very easy to implement and evaluate numerically. The computational time required for numerical evaluation of DGSM is generally much lower than that for estimation of Sobol' sensitivity indices. This paper presents a survey of recent advances in DGSM concerning lower and upper bounds on the values of Sobol' total sensitivity indices S_i^{tot} . Using these bounds it is possible in most cases to get a good practical estimation of the values of S_i^{tot} . Several examples are used to illustrate an application of DGSM.

1 Introduction

Global sensitivity analysis (SA) offers a comprehensive approach to the model analysis. Unlike local SA, global SA methods evaluate the effect of a factor while all other factors are varied as well, and thus they account for interactions between variables and do not depend on the choice of a nominal point. Reviews of different global SA methods can be found in [30] and [37]. The method of global sensitivity indices suggested by [33, 34] and then further developed by [11] is one of the most efficient and popular global SA techniques. It belongs to the class of variance-based methods. These methods provide information on the importance of different subsets of input variables to the output variance. There are two types of Sobol' sensitivity indices: the main effect indices, which estimate the individual contribution of each input parameter to the output variance, and the total sensitivity indices, which measure the total contribution of a single input factor or a group of inputs. The total sensitivity indices are used to identify non-important variables which can then be fixed at their nominal values to reduce model complexity. This approach is known as “factors' fixing setting” [30]. For high-dimensional models, the direct application of variance-based global SA measures can be extremely time-consuming and impractical.

A number of alternative SA techniques have been proposed. One of them is the screening method by [21]. It can be regarded as global as the final measure is obtained by averaging local measures (the elementary effects). This method is considerably cheaper than the variance-based methods in terms of computational time. The Morris method can be used for identifying unimportant variables. However, the Morris method has two main drawbacks. Firstly, it uses random sampling of points from the fixed grid (levels) for averaging elementary effects which are calculated as finite differences with the increment delta comparable with the range of uncertainty. For this reason it cannot correctly account for the effects

with characteristic dimensions much less than delta. Secondly, it lacks the ability of the Sobol' method to provide information about main effects (contribution of individual variables to uncertainty), and it cannot distinguish between low- and high-order interactions.

This paper presents a survey of derivative-based global sensitivity measures (DGSM) and their link with Sobol' sensitivity indices. DGSM are based on averaging local derivatives using Monte Carlo or quasi-Monte Carlo sampling methods. This technique is much more accurate than the Morris method as the elementary effects are evaluated as strict local derivatives with small increments compared to the variable uncertainty ranges. Local derivatives are evaluated at randomly or quasi-randomly selected points in the whole range of uncertainty and not at the points from a fixed grid.

The so-called alternative global sensitivity estimator defined as a normalized integral of partial derivatives was firstly introduced by [36]. Kucherenko et al. [17] introduced some other DGSM and coined the acronym DGSM. They showed that DGSM can be seen as the generalization of the Morris method [21]. Kucherenko et al. [17] also established empirically the link between DGSM and Sobol' sensitivity indices. They showed that the computational cost of numerical evaluation of DGSM can be much lower than that for estimation of Sobol' sensitivity indices.

Sobol and Kucherenko [38] proved theoretically that, in the cases of uniformly and normally distributed input variables, there is a link between DGSM and the Sobol' total sensitivity index S_i^{tot} for the same input. They showed that DGSM can be used as an upper bound on total sensitivity index S_i^{tot} . Small values of DGSM imply small S_i^{tot} and hence unessential factors x_i . However, ranking influential factors using DGSM can be similar to that based on S_i^{tot} only for the case of linear and quasi-linear models. For highly nonlinear models, two rankings can be very different. They also introduced modified DGSM which can be used for both a single input and groups of inputs [39]. From DGSM, [16] have also derived lower bounds on total sensitivity index. Lamboni et al. [19] extended results of Sobol' and Kucherenko for models with input variables belonging to the general class of continuous probability distributions. In the same framework, [28] have defined crossed-DGSM, based on second-order derivatives of model output, in order to bound the total Sobol' indices of an interaction between two inputs.

All these DGSM can be applied for problems with a high number of input variables to reduce the computational time. Indeed, the numerical efficiency of the DGSM method can be improved by using the automatic differentiation algorithm for calculation DGSM as was shown in [15]. However, the number of required function evaluations still remains to be proportional to the number of inputs. This dependence can be greatly reduced using an approach based on algorithmic differentiation in the adjoint or reverse mode [9] (see ▶ Chap. 32, “Variational Methods”). It allows estimating all derivatives at a cost at most 4–6 times of that for evaluating the original function [13].

This paper is organized as follows: the Morris method and DGSM are firstly described in the following section. Sobol' global sensitivity indices and useful relationships are then introduced. Therefore, DGSM-based lower and upper bounds

on total Sobol' sensitivity indices for uniformly and normally distributed random variables are presented, followed by DGSM for groups of variables and their link with total Sobol' sensitivity indices. Another section presents the upper bound results in the general case of variables with continuous probability distributions. Then, computational costs are considered, followed by some test cases which illustrate an application of DGSM and their links with total Sobol' sensitivity indices. Finally, conclusions are presented in the last section.

2 From Morris Method to DGSM

2.1 Basics of the Morris Method

The Morris method is traditionally used as a screening method for problems with a high number of variables for which function evaluations can be CPU time-consuming (see ▶ Chap. 33, “Design of Experiments for Screening”). It is composed of individually randomized “one-factor-at-a-time” (OAT) experiments. Each input factor may assume a discrete number of values, called levels, which are chosen within the factor range of variation.

The sensitivity measures proposed in the original work of [21] are based on what is called an elementary effect. It is defined as follows. The range of each input variable is divided into p levels. Then the elementary effect (incremental ratio) of the i -th input factor is defined as

$$EE_i(\mathbf{x}^*) = \frac{[G(x_1^*, \dots, x_{i-1}^*, x_i^* + \Delta, x_{i+1}^*, \dots, x_d^*) - G(\mathbf{x}^*)]}{\Delta}, \quad (36.1)$$

where Δ is a predetermined multiple of $1/(p-1)$ and point $\mathbf{x}^* = (x_1^*, \dots, x_d^*) \in H^d$ is such that $x_i^* + \Delta \leq 1$. One can see that the elementary effects are finite difference approximations of the model derivative with respect to x_i and using a large perturbation step Δ .

The distribution of elementary effects EE_i is obtained by randomly sampling R points from H^d . Two sensitivity measures are evaluated for each factor: μ_i an estimate of the mean of the distribution EE_i , and σ_i an estimate of the standard deviation of EE_i . A high value of μ_i indicates an input variable with an important overall influence on the output. A high value of σ_i indicates a factor involved in interaction with other factors or whose effect is nonlinear. The computational cost of the Morris method is $N_F = R(d+1)$.

The revised version of the $EE_i(\mathbf{x}^*)$ measure and a more effective sampling strategy, which allows a better exploration of the space of the uncertain input factors, were proposed by [3]. To avoid the canceling effect which appears in non-monotonic functions, [3] introduced another sensitivity measure μ_i^* based on the absolute value of $EE_i(\mathbf{x}^*)$: $|EE_i(\mathbf{x}^*)|$. It was also noticed that μ_i^* has similarities with the total sensitivity index S_i^{tot} in that it can give a ranking of the variables similar to that based on the S_i^{tot} , but no formal proof of the link between μ_i^* and S_i^{tot} was given [3].

Finally, other extensions of the initial Morris method have been introduced for the second-order effects' analysis [2, 4, 6], for the estimation of Morris measures with any type of design [26, 32], and for building some 3D Morris graph [26].

2.2 The Local Sensitivity Measure

Consider a differentiable function $G(\mathbf{x})$, where $\mathbf{x} = (x_1, \dots, x_d)$ is a vector of input variables defined in the unit hypercube H^d ($0 \leq x_i \leq 1$, $i = 1, \dots, d$). Local sensitivity measures are based on partial derivatives

$$E_i(\mathbf{x}^*) = \frac{\partial G(\mathbf{x}^*)}{\partial x_i}. \quad (36.2)$$

This measure E_i is the limit version of the elementary effect EE_i defined in (36.2) when Δ tends to zero. It is its generalization in this sense. In SA, using the partial derivative $\partial G / \partial x_i$ is well known as a local method (see ▶ Chap. 32, “Variational Methods”). In this paper, the goal is to take advantage of this information in global SA.

The local sensitivity measure $E_i(\mathbf{x}^*)$ depends on a nominal point \mathbf{x}^* , and it changes with a change of \mathbf{x}^* . This deficiency can be overcome by averaging $E_i(\mathbf{x}^*)$ over the parameter space H^d . This is done just below, allowing to define new sensitivity measures, called DGSM for derivative-based global sensitivity measures.

2.3 DGSM for Uniformly Distributed Variables

Assume that $\partial G / \partial x_i \in L_2$. Three different DGSM are defined:

$$v_i = \int_{H^d} \left(\frac{\partial G(\mathbf{x})}{\partial x_i} \right)^2 d\mathbf{x}, \quad (36.3)$$

$$w_i^{(m)} = \int_{H^d} x_i^m \frac{\partial G(\mathbf{x})}{\partial x_i} d\mathbf{x}, \quad (36.4)$$

where $m > 0$ is a constant, and

$$\varsigma_i = \frac{1}{2} \int_{H^d} x_i(1 - x_i) \left(\frac{\partial G(\mathbf{x})}{\partial x_i} \right)^2 d\mathbf{x}. \quad (36.5)$$

2.4 DGSM for Randomly Distributed Variables

Consider a function $G(X_1, \dots, X_d)$, where X_1, \dots, X_d are independent random variables, defined in the Euclidian space R^d , with cumulative density functions (cdfs) $F_1(x_1), \dots, F_d(x_d)$. The following DGSM was introduced in [38]:

$$v_i = \int_{R^d} \left(\frac{\partial G(\mathbf{x})}{\partial x_i} \right)^2 dF(\mathbf{x}) = \mathbb{E} \left[\left(\frac{\partial G(\mathbf{x})}{\partial x_i} \right)^2 \right], \quad (36.6)$$

with F the joint cdf. A new measure is also introduced:

$$w_i = \int_{R^d} \frac{\partial G(\mathbf{x})}{\partial x_i} dF(\mathbf{x}) = \mathbb{E} \left(\frac{\partial G(\mathbf{x})}{\partial x_i} \right). \quad (36.7)$$

In (36.3) and (36.6), v_i is in fact the mean value of $(\partial G / \partial x_i)^2$. In the following and in practice, it will be the most useful DGSM.

3 Sobol' Global Sensitivity Indices

3.1 Definitions

The method of global sensitivity indices developed by Sobol' (see ► Chap. 35, “Variance-Based Sensitivity Analysis: Theory and Estimation Algorithms”) is based on ANOVA decomposition [32, 33]. Consider a square integrable function $G(\mathbf{x})$ defined in the unit hypercube H^d . It can be expanded in the following form:

$$G(\mathbf{x}) = g_0 + \sum_i g_i(x_i) + \sum_{i < j} g_{ij}(x_i, x_j) + \dots + g_{12\dots d}(x_1, x_2, \dots, x_d). \quad (36.8)$$

This decomposition is unique if conditions $\int_0^1 g_{i_1\dots i_s} dx_{i_k} = 0$ for $1 \leq k \leq s$ are satisfied. Here $1 \leq i_1 < \dots < i_s \leq d$.

The variances of the terms in the ANOVA decomposition add up to the total variance of the function

$$V = \sum_{s=1}^d \sum_{i_1 < \dots < i_s} V_{i_1\dots i_s},$$

where $V_{i_1\dots i_s} = \int_0^1 g_{i_1\dots i_s}^2(x_{i_1}, \dots, x_{i_s}) dx_{i_1}, \dots, x_{i_s}$ are called partial variances.

Sobol' defined the global sensitivity indices as the ratios

$$S_{i_1\dots i_s} = V_{i_1\dots i_s} / V.$$

All $S_{i_1\dots i_s}$ are nonnegative and add up to one:

$$\sum_{i=1}^d S_i + \sum_i \sum_j S_{ij} + \sum_i \sum_j \sum_k S_{ijk} \dots + S_{1,2,\dots,d} = 1.$$

Sobol' also defined sensitivity indices for subsets of variables. Consider two complementary subsets of variables y and z :

$$\mathbf{x} = (y, z).$$

Let $y = (x_{i_1}, \dots, x_{i_m})$, $1 \leq i_1 < \dots < i_m \leq d$, $K = (i_1, \dots, i_m)$. The variance corresponding to the set y is defined as

$$V_y = \sum_{s=1}^m \sum_{(i_1 < \dots < i_s) \in K} V_{i_1 \dots i_s}.$$

V_y includes all partial variances V_{i_1} , V_{i_2}, \dots , $V_{i_1 \dots i_s}$ such that their subsets of indices $(i_1, \dots, i_s) \in K$.

The total sensitivity indices were introduced by [11]. The total variance V_y^{tot} is defined as

$$V_y^{\text{tot}} = V - V_z.$$

V_y^{tot} consists of all $V_{i_1 \dots i_s}$ such that at least one index $i_p \in K$ while the remaining indices can belong to the complimentary K set \bar{K} . The corresponding global sensitivity indices are defined as

$$\begin{aligned} S_y &= V_y/V, \\ S_y^{\text{tot}} &= V_y^{\text{tot}}/V. \end{aligned} \quad (36.9)$$

The important indices in practice are S_i and S_i^{tot} , $i = 1, \dots, d$:

$$\begin{aligned} S_i &= V_i/V, \\ S_i^{\text{tot}} &= V_i^{\text{tot}}/V. \end{aligned} \quad (36.10)$$

Their values in most cases provide sufficient information to determine the sensitivity of the analyzed function to individual input variables. Variance-based methods generally require a large number of function evaluations (see Variance-Based Methods: Theory and Algorithms) to achieve reasonable convergence and can become impractical for large engineering problems.

3.2 Useful Relationships

To present further results on lower and upper bounds of S_i^{tot} , new notations and useful relationships have to be firstly presented. Denote $u_i(\mathbf{x})$ the sum of all terms in the ANOVA decomposition (36.8) that depend on x_i :

$$u_i(\mathbf{x}) = g_i(x_i) + \sum_{j=1, j \neq i}^d g_{ij}(x_i, x_j) + \dots + g_{12 \dots d}(x_1, \dots, x_d). \quad (36.11)$$

From the definition of ANOVA decomposition, it follows that

$$\int_{H^d} u_i(\mathbf{x}) d\mathbf{x} = 0. \quad (36.12)$$

It is obvious that

$$\frac{\partial G}{\partial x_i} = \frac{\partial u_i}{\partial x_i}. \quad (36.13)$$

Denote $\mathbf{z} = (x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_d)$ the vector of all variables but x_i , then $\mathbf{x} \equiv (x_i, \mathbf{z})$ and $G(\mathbf{x}) \equiv G(x_i, \mathbf{z})$. The ANOVA decomposition of $G(\mathbf{x})$ (36.8) can be presented in the following form:

$$G(\mathbf{x}) = u_i(x_i, \mathbf{z}) + v(\mathbf{z}),$$

where $v(\mathbf{z})$ is the sum of terms independent of x_i . Because of (36.12) it is easy to show that $v(\mathbf{z}) = \int_0^1 G(\mathbf{x}) dx_i$. Hence

$$u_i(x_i, \mathbf{z}) = G(\mathbf{x}) - \int_0^1 G(\mathbf{x}) dx_i. \quad (36.14)$$

This equation can be found in [18]. The total partial variance V_i^{tot} can be computed as

$$V_i^{\text{tot}} = \int_{H^d} u_i^2(\mathbf{x}) d\mathbf{x} = \int_{H^d} u_i^2(x_i, z) dx_i d\mathbf{z}.$$

Then the total sensitivity index S_i^{tot} (36.10) is equal to

$$S_i^{\text{tot}} = \frac{1}{V} \int_{H^d} u_i^2(\mathbf{x}) d\mathbf{x}. \quad (36.15)$$

3.3 A First Direct Link Between Total Sobol' Sensitivity Indices and Partial Derivatives

Consider continuously differentiable function $G(\mathbf{x})$ defined in the unit hypercube $H^d = [0, 1]^d$. This section presents a theorem that establishes links between the index S_i^{tot} and the limiting values of $|\partial G / \partial x_i|$.

In the case when $\mathbf{y} = (x_i)$, Sobol'-Jansen formula [14, 31, 35] for D_i^{tot} can be rewritten as

$$D_i^{\text{tot}} = \frac{1}{2} \int_{H^d} \int_0^1 \left[G(\mathbf{x}) - G(\overset{\circ}{\mathbf{x}}) \right]^2 d\mathbf{x} dx'_i, \quad (36.16)$$

where $\overset{\circ}{\mathbf{x}} = (x_1, \dots, x_{i-1}, x'_i, x_{i+1}, \dots, x_n)$.

Theorem 1. Assuming that $c \leq \left| \frac{\partial G}{\partial x_i} \right| \leq C$, then

$$\frac{c^2}{12V} \leq S_i^{\text{tot}} \leq \frac{C^2}{12V}. \quad (36.17)$$

Proof. Consider the increment of $G(\mathbf{x})$ in (36.16):

$$G(\mathbf{x}) - G\left(\overset{\circ}{\mathbf{x}}\right) = \frac{\partial G(\hat{\mathbf{x}})}{\partial x_i} (x_i - x'_i), \quad (36.18)$$

where $\hat{\mathbf{x}}$ is a point between \mathbf{x} and $\overset{\circ}{\mathbf{x}}$. Substituting (36.18) into (36.16) leads to

$$V_i^{\text{tot}} = \frac{1}{2} \int_{H^d} \int_0^1 \left(\frac{\partial G(\hat{\mathbf{x}})}{\partial x_i} \right)^2 (x_i - x'_i)^2 d\mathbf{x} dx'_i. \quad (36.19)$$

In (36.19) $c^2 \leq (\partial G / \partial x_i)^2 \leq C^2$, while the remaining integral is

$$\int_0^1 \int_0^1 (x'_i - x_i)^2 dx'_i dx_i = \frac{1}{6}.$$

Thus obtained inequalities are equivalent to (36.17). Consider the function $G = g_0 + c(x_i - 1/2)$. In this case $C = c$, $V = 1/12$, and $S_i^{\text{tot}} = 1$ and the inequalities in (36.17) become equalities.

4 DGSM-Based Bounds for Uniformly and Normally Distributed Variables

In this section, several theorems are listed in order to define useful lower and upper bounds of the total Sobol' indices. The proofs of these theorems come from previous works and papers and are not recalled here. Two cases are considered: variables \mathbf{x} following uniform distributions and variables \mathbf{x} following Gaussian distributions. The general case will be seen in a subsequent section.

4.1 Uniformly Distributed Variables

4.1.1 Lower Bounds on S_i^{tot}

Theorem 2. There exists the following lower bound between DGSM (36.3) and the Sobol' total sensitivity index:

$$\frac{\left(\int_{H^d} [G(1, \mathbf{z}) - G(0, \mathbf{z})] [G(1, \mathbf{z}) + G(0, \mathbf{z}) - 2G(\mathbf{x})] d\mathbf{x} \right)^2}{4v_i V} < S_i^{\text{tot}} \quad (36.20)$$

Proof. The proof of this theorem is given in [16] and is based on Eq. (36.15) and a Cauchy-Schwarz inequality applied on $\int_{H^d} u_i(\mathbf{x}) \frac{\partial u_i(\mathbf{x})}{\partial x_i} d\mathbf{x}$.

The lower bound number one (LB1) is defined as

$$\frac{\left(\int_{H^d} [G(1, \mathbf{z}) - G(0, \mathbf{z})] [G(1, \mathbf{z}) + G(0, \mathbf{z}) - 2G(\mathbf{x})] d\mathbf{x} \right)^2}{4v_i V}.$$

Theorem 3. *There exists the following lower bound, denoted $\gamma(m)$, between DGSM (36.4) and the Sobol' total sensitivity index:*

$$\gamma(m) = \frac{(2m+1) \left[\int_{H^d} (G(1, \mathbf{z}) - G(\mathbf{x})) d\mathbf{x} - w_i^{(m+1)} \right]^2}{(m+1)^2 V} < S_i^{\text{tot}}. \quad (36.21)$$

Proof. The proof of this theorem is given in [16] and is based on Eq. (36.15) and a Cauchy-Schwarz inequality applied on $\int_{H^d} x_i^m u_i(\mathbf{x}) d\mathbf{x}$.

In fact, Theorem 3 gives a set of lower bounds depending on parameter m . The value of m at which $\gamma(m)$ attains its maximum is of particular interest. Further, star (*) is used to denote such a value m : $m^* = \arg \max(\gamma(m))$. $\gamma(m^*)$ is called the lower bound number two (LB2):

$$\gamma(m^*) = \frac{(2m^*+1) \left[\int_{H^d} (G(1, \mathbf{z}) - G(\mathbf{x})) d\mathbf{x} - w_i^{(m^*+1)} \right]^2}{(m^*+1)^2 V} \quad (36.22)$$

The maximum lower bound LB* is defined as

$$\text{LB}^* = \max(\text{LB1}, \text{LB2}). \quad (36.23)$$

Both lower and upper bounds can be estimated by a set of derivative-based measures:

$$\Upsilon_i = \{v_i, w_i^{(m)}, \xi_i\}, \quad m > 0. \quad (36.24)$$

4.1.2 Upper Bounds on S_i^{tot}

Theorem 4. *There exists the following upper bound between DGSM (36.3) and the Sobol' total sensitivity index:*

$$S_i^{\text{tot}} \leq \frac{v_i}{\pi^2 V}. \quad (36.25)$$

Proof. The proof of this theorem is given in [38]. It is based on inequality

$$\int_0^1 u^2(x) dx \leq \frac{1}{\pi^2} \int_0^1 \left(\frac{\partial u}{\partial x} \right)^2 dx$$

and relationships (36.13) and (36.15).

Consider the set of values v_1, \dots, v_d , $1 \leq i \leq d$. One can expect that smaller v_i correspond to less influential variables x_i . This importance criterion is similar to the modified Morris importance measure μ^* , whose limiting values are

$$\mu_i^* = \int_{H^d} \left| \frac{\partial G(\mathbf{x})}{\partial x_i} \right| d\mathbf{x}.$$

From a practical point of view, the criteria μ_i and v_i are equivalent: they are evaluated by the same numerical algorithm and are linked by relations $v_i \leq C\mu_i$ and $\mu_i \leq \sqrt{v_i}$.

The right term in (36.25) is further called the upper bound number one (UB1).

Theorem 5. *There exists the following upper bound between DGSM (36.5) and the Sobol' total sensitivity index:*

$$S_i^{\text{tot}} \leq \frac{\varsigma_i}{V}. \quad (36.26)$$

Proof. The following inequality [10] is used:

$$0 \leq \int_0^1 u^2 dx - \left(\int_0^1 u dx \right)^2 \leq \frac{1}{2} \int_0^1 x(1-x)u'^2 dx. \quad (36.27)$$

The inequality is reduced to an equality only if u is constant. Assuming that u is given by (36.11), then $\int_0^1 u dx = 0$. From (36.27), Eq. (36.26) is obtained.

Further ς_i/D is called the upper bound number two (UB2). Note that $\frac{1}{2}x_i(1-x_i)$ for $0 \leq x_i \leq 1$ is bounded: $0 \leq \frac{1}{2}x_i(1-x_i) \leq 1/8$. Therefore, $0 \leq \varsigma_i \leq v_i/8$.

4.2 Normally Distributed Variables

4.2.1 Lower Bound on S_i^{tot}

Theorem 6. *If X_i is normally distributed with a mean μ_i and a finite variance σ_i^2 , there exists the following lower bound between DGSM (36.7) and the Sobol' total sensitivity index:*

$$\frac{\sigma_i^4}{(\mu_i^2 + \sigma_i^2)V} w_i^2 \leq S_i^{\text{tot}}. \quad (36.28)$$

Proof. Using Eq. (36.15) and Cauchy-Schwarz inequality applied on $\int_{R^d} x_i u_i(\mathbf{x}) dF(\mathbf{x})$ (with F the joint cdf), [16] give the proof of this inequality when $\mu_i = 0$ (omitting to mention this condition). The general proof, obtained by [25], is given below.

Consider a univariate function $g(X)$, with X a normally distributed variable with mean μ , finite variance σ^2 , and cdf F . With adequate conditions on g , the following equality is obtained by integrating by parts:

$$\begin{aligned}\mathbb{E}[g'(X)] &= \int_{-\infty}^{\infty} g'(x) dF(x) = \frac{1}{\sigma \sqrt{2\pi}} \int_{-\infty}^{\infty} g'(x) \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] dx \\ &= \frac{1}{\sigma \sqrt{2\pi}} \left[g(x) \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] \right]_{-\infty}^{+\infty} \\ &\quad + \frac{1}{\sigma \sqrt{2\pi}} \int_{-\infty}^{\infty} g(x) \frac{x-\mu}{\sigma^2} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right] dx \\ &= \frac{1}{\sigma^2} \int_{-\infty}^{\infty} x g(x) dF(x) - \mu \int_{-\infty}^{\infty} g(x) dF(x).\end{aligned}$$

In this equation, replacing $g(x)$ by $u_i(\mathbf{x})$ with x_i normally distributed, the w_i DGSM writes

$$w_i = \int_{R^d} \frac{\partial G(\mathbf{x})}{\partial x_i} dF(\mathbf{x}) = \int_{R^d} \frac{\partial u_i(\mathbf{x})}{\partial x_i} dF(\mathbf{x}) = \frac{1}{\sigma_i^2} \int_{R^d} x_i u_i(\mathbf{x}) dF(\mathbf{x}),$$

because $\int_{R^d} u_i(\mathbf{x}) dF(\mathbf{x}) = 0$ (due to the ANOVA decomposition condition). Moreover, the Cauchy-Schwarz inequality applied on $\int_{R^d} x_i u_i(\mathbf{x}) dF(\mathbf{x})$ gives

$$\left[\int_{R^d} x_i u_i(\mathbf{x}) dF(\mathbf{x}) \right]^2 \leq \int_{R^d} x_i^2 dF(\mathbf{x}) \int_{R^d} [u_i(\mathbf{x})]^2 dF(\mathbf{x}).$$

Combining the two latter equations leads to the expression

$$w_i^2 \leq \frac{1}{\sigma_i^4} (\mu_i^2 + \sigma_i^2) VS_i^{\text{tot}},$$

which is equivalent to Eq. (36.28).

4.2.2 Upper Bounds on S_i^{tot}

The following Theorem 7 is a generalization of Theorem 1.

Theorem 7. If X_i has a finite variance σ_i^2 and $c \leq \left| \frac{\partial G}{\partial x_i} \right| \leq C$, then

$$\frac{\sigma_i^2 c^2}{V} \leq S_i^{\text{tot}} \leq \frac{\sigma_i^2 C^2}{V}. \quad (36.29)$$

The constant factor σ_i^2 cannot be improved.

Theorem 8. If X_i is normally distributed with a finite variance σ_i^2 , there exists the following upper bound between DGSM (36.6) and the Sobol' total sensitivity index:

$$S_i^{\text{tot}} \leq \frac{\sigma_i^2}{V} v_i. \quad (36.30)$$

The constant factor σ_i^2 cannot be reduced.

Proof. The proofs of these theorems are presented in [38].

5 DGSM-Based Bounds for Groups of Variables

Let $\mathbf{x} = (x_1, \dots, x_d)$ be a point in the d -dimensional unit hypercube with Lebesgue measure $d\mathbf{x} = dx_1 \cdots dx_d$. Consider an arbitrary subset of the variables $y = (x_{i_1}, \dots, x_{i_s})$, $1 \leq i_1 \leq \dots \leq i_s \leq d$, and the set of remaining complementary variables z , so that $\mathbf{x} = (y, z)$, $d\mathbf{x} = dy dz$. Further all the integrals are written without integration limits, by assuming that each integration variable varies independently from 0 to 1.

Consider the following DGSM τ_y :

$$\tau_y = \sum_{p=1}^s \int \left(\frac{\partial G(\mathbf{x})}{\partial x_{i_p}} \right)^2 \frac{1 - 3x_{i_p} + 3x_{i_p}^2}{6} d\mathbf{x}. \quad (36.31)$$

Theorem 9. If $G(\mathbf{x})$ is linear with respect to x_{i_1}, \dots, x_{i_s} , then $V_y^{\text{tot}} = \tau_y$, or in other words $S_y^{\text{tot}} = \frac{\tau_y}{V}$.

Theorem 10. The following general inequality holds: $V_y^{\text{tot}} \leq (24/\pi^2) \tau_y$, or in other words $S_y^{\text{tot}} \leq \frac{24}{\pi^2 V} \tau_y$.

Proof. The proofs of these theorems are given in [39]. The second theorem shows that small values of τ_y imply small values of S_y^{tot} , and this allows identification of a set of unessential factors y (usually defined by a condition of the type $S_y^{\text{tot}} < \epsilon$, where ϵ is small).

5.1 Importance Criterion τ_i

Considering the one-dimensional case when the subset y consists of only one variable $y = (x_i)$, then measure $\tau_y = \tau_i$ has the form

$$\tau_i = \int \left(\frac{\partial G(\mathbf{x})}{\partial x_i} \right)^2 \frac{1 - 3x_i + 3x_i^2}{6} d\mathbf{x}. \quad (36.32)$$

It is easy to show that $v_i/24 \leq \tau_i \leq v_i/6$. From UB1 it follows that

$$S_i^{\text{tot}} \leq \frac{24}{\pi^2 V} \tau_i. \quad (36.33)$$

Thus small values of τ_i imply small values of S_i^{tot} that are characteristic for non-important variables x_i . At the same time, the following corollary is obtained from Theorem 9: if $G(\mathbf{x})$ depends linearly on x_i , then $S_i^{\text{tot}} = \tau_i/V$. Thus τ_i is closer to V_i^{tot} than v_i .

Note that the constant factor $1/\pi^2$ in (36.25) is the best possible. But in the general inequality for τ_i (36.33), the best possible constant factor is unknown.

There is a general link between importance measures τ_i , ς_i , and v_i :

$$\tau_i = -\varsigma_i + \frac{1}{6}v_i,$$

then

$$\varsigma_i = \frac{1}{6}v_i - \tau_i.$$

5.2 Normally Distributed Random Variables

Consider independent normal random variables X_1, \dots, X_d with parameters $(\mu_i, \sigma_i)_{i=1\dots d}$. Define τ_i as

$$\tau_i = \frac{1}{2} \mathbb{E} \left[\left(\frac{\partial G(\mathbf{x})}{\partial x_i} \right)^2 (x'_i - x_i)^2 \right].$$

The expectation over x'_i can be computed analytically. Then

$$\tau_i = \frac{1}{2} \mathbb{E} \left[\left(\frac{\partial G(\mathbf{x})}{\partial x_i} \right)^2 \frac{(x_i - \mu_i)^2 + \sigma_i^2}{2} \right].$$

Theorem 11. If X_1, \dots, X_d are independent normal random variables, then for an arbitrary subset y of these variables, the following inequality is obtained:

$$S_y^{\text{tot}} \leq \frac{2}{V} \tau_y.$$

Proof. The proof is given in [39].

6 DGSM-Based Upper Bounds in the General Case

As previously, consider the function $G(X_1, \dots, X_d)$, where X_1, \dots, X_d are independent random variables, defined in the Euclidian space R^d , with cdfs $F_1(x_1), \dots, F_d(x_d)$. Assume further that each X_i admits a probability density function (pdf), denoted by $f_i(x_i)$. In the following, all the integrals are written without integration limits.

The developments in this section are based on the classical L^2 -Poincaré inequality:

$$\int G(\mathbf{x})^2 dF(\mathbf{x}) \leq C(F) \int \|\nabla G(\mathbf{x})\|^2 dF(\mathbf{x}) \quad (36.34)$$

where F is the joint cdf of (X_1, \dots, X_d) . Equation (36.34) is valid for all functions G in $L^2(F)$ such that $\int G(\mathbf{x}) dF(\mathbf{x}) = 0$ and $\|\nabla f\| \in L^2(F)$. The constant $C(F)$ in Eq. (36.34) is called a Poincaré constant of F . In some cases, it exists an optimal Poincaré constant $C_{\text{opt}}(F)$ which is the best possible constant. In measure theory, the Poincaré constants are expressed as a function of so-called Cheeger constants [1] which are used for SA in [19] (see [28] for more details).

A connection between total indices and DGSM has been established by [19] for variables with continuous distributions (called Boltzmann probability measures in their paper).

Theorem 12. Let F_i and f_i be, respectively, the cdf and the pdf of X_i ; the following inequality is obtained:

$$S_i^{\text{tot}} \leq \frac{C(F_i)}{V} v_i, \quad (36.35)$$

with v_i the DGSM defined in Eq. (36.6) and

$$C(F_i) = 4 \left[\sup_{x \in \mathbb{R}} \frac{\min(F_i(x), 1 - F_i(x))}{f_i(x)} \right]^2. \quad (36.36)$$

Proof. This result comes from the direct application of the L^2 -Poincaré inequality (36.34) on $u_i(\mathbf{x})$ (see Eq. (36.11)).

In [19] and [28], the particular case of log-concave probability distribution has been developed. It includes classical distributions as, for instance, the normal, exponential, beta, gamma, and Gumbel distributions. In this case, the constant writes

$$C(F_i) = \frac{1}{f_i(\tilde{m}_i)^2} \quad (36.37)$$

with \tilde{m}_i the median of the distribution F_i . This allows to obtain analytical expressions for $C(F_i)$ in several cases [19]. In the case of a log-concave truncated distribution on $[a, b]$, the constant writes [28]

$$(F_i(b) - F_i(a))^2 / f_i \left(q_i \left(\frac{F_i(a) + F_i(b)}{2} \right) \right)^2 \quad (36.38)$$

with $q_i(\cdot)$ the quantile function of X_i . Table 36.1 gives some examples of Poincaré constants for several well-known and often used probability distributions in practice.

For studying second-order interactions, [28] have derived a similar inequality to (36.35) based on the squared crossed derivatives of the function. Assuming that second-order derivatives of G are in $L^2(F)$, it uses the so-called crossed-DGSM

$$v_{ij} = \int \left(\frac{\partial^2 G(\mathbf{x})}{\partial x_i \partial x_j} \right)^2 dF(\mathbf{x}), \quad (36.39)$$

introduced by [7]. An inequality link is made with an extension of the total Sobol' sensitivity indices to general sets of variables (called superset importance or total interaction index) proposed by [20]. In the case of a pair of variables $\{X_i, X_j\}$, the superset importance is defined as

$$V_{ij}^{\text{super}} = \sum_{I \supseteq \{i, j\}} V_I. \quad (36.40)$$

The estimation methods of this total interaction index have also been studied by [8].

Table 36.1 Poincaré constants for a few probability distributions

Distribution	Poincaré constant	Optimal constant
Uniform $\mathcal{U}[a \ b]$	$(b - a)^2 / \pi^2$	Yes
Normal $\mathcal{N}(\mu, \sigma^2)$	σ^2	Yes
Exponential $\mathcal{E}(\lambda), \lambda > 0$	$\frac{4}{\lambda^2}$	Yes
Gumbel $\mathcal{G}(\mu, \beta)$, scale $\beta > 0$	$\left(\frac{2\beta}{\log 2} \right)^2$	No
Weibull $\mathcal{W}(k, \lambda)$, shape $k \geq 1$, scale $\lambda > 0$	$\left[\frac{2\lambda(\log 2)^{(1-k)/k}}{k} \right]^2$	No

Theorem 13. For all pairs $\{i, j\}$ ($1 \leq i < j \leq d$),

$$V_{ij} \leq V_{ij}^{\text{super}} \leq C(F_i)C(F_j)v_{ij}. \quad (36.41)$$

These inequalities with the corresponding Sobol' indices write

$$S_{ij} \leq S_{ij}^{\text{super}} \leq \frac{C(F_i)C(F_j)}{V}v_{ij}. \quad (36.42)$$

Roustant et al. [28] have shown on several examples how to apply this result in order to detect pairs of inputs that do not interact together (see also [22] and [8] which use Sobol' indices).

7 Computational Costs

All DGSM can be computed using the same set of partial derivatives $\frac{\partial G(\mathbf{x})}{\partial x_i}$, $i = 1, \dots, d$. Evaluation of $\frac{\partial G(\mathbf{x})}{\partial x_i}$ can be done analytically for explicitly given easily differentiable functions or numerically:

$$\frac{\partial G(\mathbf{x}^*)}{\partial x_i} = \frac{[G(x_1^*, \dots, x_{i-1}^*, x_i^* + \delta, x_{i+1}^*, \dots, x_n^*) - G(\mathbf{x}^*)]}{\delta}. \quad (36.43)$$

This is called a finite-difference scheme (see ▶ Chap. 32, “Variational Methods”) with δ which is a small increment. There is a similarity with the elementary effect formula (2) of the Morris method which is however computed with large Δ .

In the case of straightforward numerical estimations of all partial derivatives (36.43) and computation of integrals using MC or QMC methods, the number of required function evaluations for a set of all input variables is equal to $N(d + 1)$, where N is a number of sampled points. Computing LB1 also requires values of $G(0, \mathbf{z}), G(1, \mathbf{z})$, while computing LB2 requires only values of $G(1, \mathbf{z})$. In total, numerical computation of LB* for all input variables would require $N_G^{\text{LB}*} = N(d + 1) + 2Nd = N(3d + 1)$ function evaluations. Computation of all upper bounds requires $N_G^{\text{UB}} = N(d + 1)$ function evaluations. This is the same number that the number of function evaluations required for computation of S_i^{tot} which is $N_G^S = N(d + 1)$ [31].

However, the number of sampled points N needed to achieve numerical convergence can be different for DGSM and S_i^{tot} . It is generally lower for the case of DGSM. Moreover, the numerical efficiency of the DGSM method can be significantly increased by using algorithmic differentiation in the adjoint (reverse) mode [9] (see also ▶ Chap. 32, “Variational Methods”). This approach allows estimating all derivatives at a cost independent of d , at most 4–6 times of that for evaluating the original function $G(\mathbf{x})$ [13].

8 Test Cases

In this section, three test cases are considered, in order to illustrate application of DGSM and their links with S_i^{tot} .

Example 1. Consider a linear with respect to x_i function:

$$G(x) = a(\mathbf{z})x_i + b(\mathbf{z}).$$

For this function $S_i = S_i^{\text{tot}}$, $V_i^{\text{tot}} = \frac{1}{12} \int_{H^{d-1}} a^2(\mathbf{z}) d\mathbf{z}$, $v_i = \int_{H^{d-1}} a^2(\mathbf{z}) d\mathbf{z}$, $\text{LB1} = \left(\int_{H^d} (a^2(\mathbf{z}) - 2a^2(\mathbf{z})x_i) d\mathbf{z} dx_i \right)^2 = 0$, and $\gamma(m) = \frac{(2m+1)m^2 \left(\int_{H^{d-1}} a(\mathbf{z}) d\mathbf{z} \right)^2}{4(m+2)^2(m+1)^2 V}$.

A maximum value of $\gamma(m)$ is attained at $m^* = 3.745$, while $\gamma^*(m^*) = \frac{0.0401}{V} \left(\int a(\mathbf{z}) d\mathbf{z} \right)^2$. The lower and upper bounds are $\text{LB}^* \approx 0.48S_i^{\text{tot}}$, $\text{UB1} \approx 1.22S_i^{\text{tot}}$. $\text{UB2} = \frac{1}{12V} \int_0^1 a(\mathbf{z})^2 d\mathbf{z} = S_i^{\text{tot}}$.

For this test function, $\text{UB2} < \text{UB1}$.

Example 2. Consider the so-called g-function which is often used in global SA for illustration purposes:

$$G(x) = \prod_{i=1}^d v_i,$$

where $v_i = \frac{|4x_i - 2| + a_i}{1 + a_i}$, $a_i (i = 1, \dots, d)$ are constants. It is easy to see that for this function $g_i(x_i) = (v_i - 1)$, $u_i(x) = (v_i - 1) \prod_{j=1, j \neq i}^d v_j$, and as a result $\text{LB1} = 0$. The total variance is $V = -1 + \prod_{j=1}^d \left(1 + \frac{1/3}{(1+a_j)^2} \right)$. The analytical values of S_i , S_i^{tot} and LB2 are given in Table 36.2.

By solving equation $\frac{d\gamma(m)}{dm} = 0$, $m^* = 9.64$ and $\gamma(m^*) = \frac{0.0772}{(1+a_i)^2 V}$. It is interesting to note that m^* does not depend on a_i , $i = 1, 2, \dots, d$ and d . In the

Table 36.2 The analytical expressions for S_i , S_i^{tot} and LB2 for g-function

S_i	S_i^{tot}	$\gamma(m)$
$\frac{1/3}{(1+a_i)^2 V}$	$\frac{\frac{1/3}{(1+a_i)^2} \prod_{j=1, j \neq i}^d \left(1 + \frac{1/3}{(1+a_j)^2} \right)}{V}$	$\frac{(2m+1) \left[1 - \frac{4(1-(1/2)^{m+1})}{m+2} \right]^2}{(1+a_i)^2(m+1)^2 V}$

extreme cases, if $a_i \rightarrow \infty$ for all i , $\frac{\gamma(m^*)}{S_i^{\text{tot}}} \rightarrow 0.257$, $\frac{S_i}{S_i^{\text{tot}}} \rightarrow 1$, while if $a_i \rightarrow 0$ for all i , $\frac{\gamma(m^*)}{S_i^{\text{tot}}} \rightarrow \frac{0.257}{(4/3)^{d-1}}$, $\frac{S_i}{S_i^{\text{tot}}} \rightarrow \frac{1}{(4/3)^{d-1}}$. The analytical expression for S_i^{tot} , UB1, and UB2 are given in Table 36.3.

For this test function, $\frac{S_i^{\text{tot}}}{\text{UB1}} = \frac{\pi^2}{48}$, $\frac{S_i^{\text{tot}}}{\text{UB2}} = \frac{1}{4}$; hence $\frac{\text{UB2}}{\text{UB1}} = \frac{\pi^2}{12} < 1$.

Values of S_i , S_i^{tot} , UB1, UB2, and LB2 for the case of $\mathbf{a} = [0, 1, 4.5, 9, 99, 99, 99, 99]$, $d = 8$, are given in Table 36.4 and shown in Fig. 36.1. One can see that the knowledge

S_i	0.716	0.179	0.0237	0.00720	0.0000716
S_i^{tot}	0.788	0.242	0.0343	0.0105	0.000105
UB1	3.828	1.178	0.167	0.0509	0.00051
UB2	3.149	0.969	0.137	0.0418	0.00042

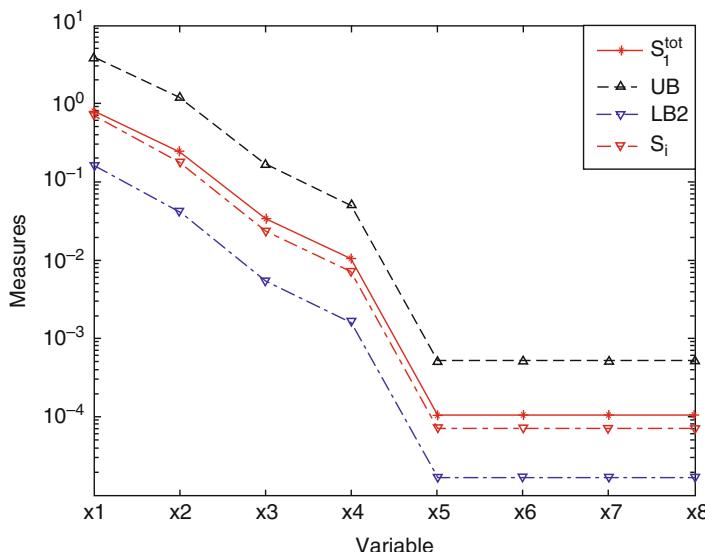

Fig. 36.1 Values of S_i , S_i^{tot} , LB2, and UB1 for all input variables. Example 2 with $\mathbf{a} = [0, 1, 4.5, 9, 99, 99, 99, 99]$, $d = 8$

of LB2 and UB1 allows to rank correctly all the variables in the order of their importance.

Example 3. Consider the reduced Morris test function with four inputs [3]:

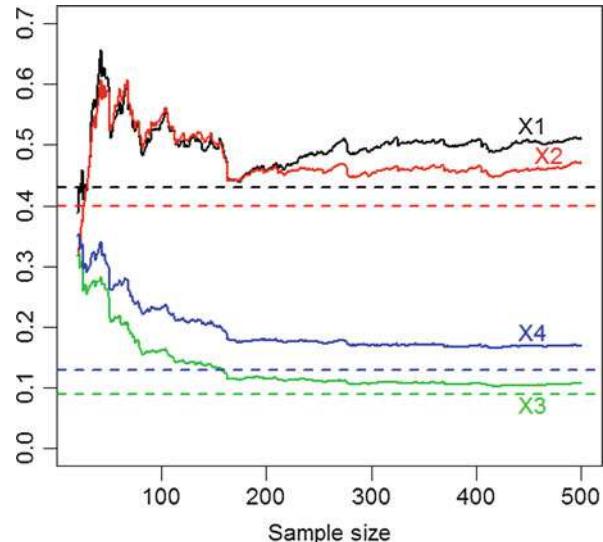

$$f(\mathbf{x}) = \sum_{i=1}^4 b_i x_i + \sum_{i \leq j}^4 b_{ij} x_i x_j + \sum_{i \leq j \leq k}^4 b_{ijk} x_i x_j x_k \quad (36.44)$$

$$\text{with } b_i = \begin{bmatrix} 0.05 \\ 0.59 \\ 10 \\ 0.21 \end{bmatrix}, \quad b_{ij} = \begin{bmatrix} 0 & 80 & 60 & 40 \\ 0 & 30 & 0.73 & 0.18 \\ 0 & 0 & 0.64 & 0.93 \\ 0 & 0 & 0 & 0.06 \end{bmatrix}, \quad b_{ij4} = \begin{bmatrix} 0 & 10 & 0.98 & 0.19 \\ 0 & 0 & 0.49 & 50 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix}.$$

The indices $b_{ijk} \forall k \neq 4$ are null.

The four input variables x_i ($i = 1, \dots, 4$) follow uniform distribution on $[0, 1]$. Sobol' indices are computed via the Monte Carlo scheme of [29] (using two initial matrices of size 10^5), while DGSM are computed with Monte Carlo sampling of size n (using derivatives computing by finite differences (36.43) with $\delta = 10^{-5}$), with n ranging from 20 to 500. Figure 36.2 shows that DGSM bounds UB_{1i} are greater than the total Sobol' indices S_{T_i} (for $i = 1, 2, 3, 4$) as expected, except for $n < 30$ which is a too small sample size. For small S_{T_i} , UB_{1i} is close to the S_{T_i} value. It confirms that DGSM bounds are first useful for screening exercises. Other

numerical tests involving nonuniform and non-normal distributions for the inputs can be found in [19] and [8].

9 Conclusions

This paper has shown that using lower and upper bounds based on DGSM is possible in most cases to get a good practical estimation of the values of S_i^{tot} at a fraction of the CPU cost for estimating S_i^{tot} . Upper and lower bounds can be estimated using MC/QMC integration methods using the same set of partial derivative values. Most of the applications show that DGSM can be used for fixing unimportant variables and subsequent model reduction because small values of DGSM imply small values of S_i^{tot} . In a general case, variable ranking can be different for DGSM and variance-based methods, but for linear function and product function, DGSM can give the same variable ranking as S_i^{tot} .

Engineering applications of DGSM can be found, for instance, in [15] and [27] for biological systems modeling, [24] for structural mechanics, [12] for an aquatic prey-predator model, [25] for a river flood model, and [41] for a hydrogeological simulator of the oil industry. One of the main prospects in practical situations is to use algorithmic differentiation in the reverse (adjoint) mode on the numerical model, allowing to estimate efficiency of all partial derivatives of this model (see ► Chap. 32, “Variational Methods”). In this case, the cost of DGSM estimations would be independent of the number of input variables. Obtaining global sensitivity information in a reasonable CPU time cost is therefore possible even for large-dimensional model (several tens and spatially distributed inputs in the recent and pioneering attempt of [25]). When the adjoint model is not available, the DGSM estimation remains a problem in high dimension, and novel ideas have to be explored [23, 24]. Coupling DGSM with non-parametric regression techniques or metamodel-based technique (see ► Chap. 38, “Metamodel-Based Sensitivity Analysis: Polynomial Chaos Expansions and Gaussian Processes”) is another research prospect as first shown by [40] and [5].

Abstract

This chapter discusses the class of moment-independent importance measures. This class comprises density-based, cumulative distribution function-based, and value of information-based sensitivity measures. The chapter illustrates the definition and properties of these importance measures as they have been proposed in the literature, reviewing a common rationale that envelops them, as well as recent results that concern the general properties of global sensitivity measures. The final part of the chapter reviews importance measures developed in the context of reliability and structural reliability theories.

1 Introduction

This chapter deals with the class of moment-independent importance measures, which comprises sensitivity measures based on discrepancies between density functions, cumulative distribution functions, and value of information. These sensitivity measures have been mainly developed in association with *factor prioritization* [44], one of the most important settings in global sensitivity analysis of model output (Section 7 in Ref. [9] reviews further sensitivity analysis settings). Factor prioritization is associated with the task of identifying key-uncertainty drivers.

The identification of key-uncertainty drivers can be performed using alternative methods. In previous chapters, sampling-based (see ► Chap. 34, “Weights and Importance in Composite Indicators: Mind the Gap”), variance-based (see ► Chap. 35, “Variance-Based Sensitivity Analysis: Theory and Estimation Algorithms”), and derivative-based methods (see ► Chap. 36, “Derivative-Based Global Sensitivity Measures”) have been illustrated. In this chapter, we explore a further class of sensitivity measures which are becoming increasingly popular among practitioners and subject of notable recent research interest, namely, moment-independent sensitivity measures. We also discuss that, as shown in recent findings, these sensitivity measures can be based on the same common rationale as variance-based and value of information-based sensitivity measures, which we also present in detail. This common rationale allows analysts to obtain a framework for analyzing several properties of sensitivity measures from a general standpoint, formulating corresponding if and only if conditions that concern important insights [12]. For instance, a null value of a probabilistic sensitivity measure is usually interpreted as an indication that the model output is independent of the model input (or group) of interest. However, this conclusion is not true in general, and recent literature has discussed the properties that reassure us that a null value of a sensitivity measure implies that the model output is statistically independent of the model input [12]. One can then examine whether variance-based, moment-independent, and value of information-based sensitivity measures possess these and other properties. The chapter concludes presenting sensitivity measures in the context of reliability studies.

The remainder of the chapter is organized as follows. First, density-based sensitivity measures are presented. The following section addresses transformation invariant global sensitivity measures. Then, value of information-based sensitivity measures is addressed. The subsequent section presents a common rationale enveloping the previously discussed sensitivity measures and discusses general properties. Another section discusses direct estimation from Monte Carlo sampling.

The last section introduces first classical reliability measures and then a recently introduced perturbation-based sensitivity measure for structural reliability.

2 Density-Based Importance Measures

This section describes the principles of the class of density-based sensitivity measures, which is timewise the first class of moment-independent sensitivity measures that have been introduced. The name moment independent communicates the intuition that these sensitivity measures take into account the change in the entire distribution (density) of the model output, instead of the variation of one of its particular moments (e.g., variance; [5, 23]). To characterize the intuition below density-based sensitivity measures, we start with an example. Consider the following input-output mapping:

$$Y = G(X_1, X_2, X_3) = X_1 X_2 + X_3 \quad (37.1)$$

and suppose that the analyst is uncertain about the model inputs. She assigns X_1 uniformly and independently distributed between -1 and 1 , and X_2 and X_3 uniformly distributed between 0 and 1 . Then, what our degree of belief about Y is displayed by the distribution of Y . If Y is a continuous random variable, then we can refer to its density, $f_Y(y)$, which is the blue curve in Fig. 37.1. Precisely, $f_Y(y)$ is the unconditional density of Y .

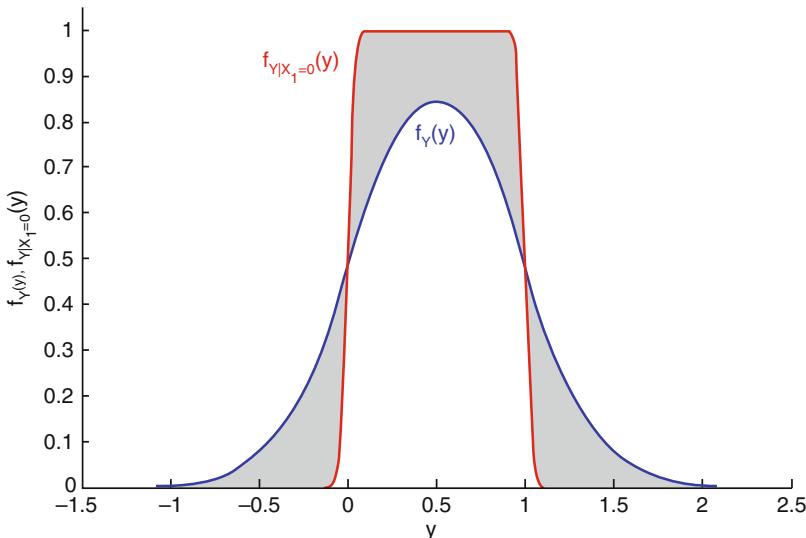

Fig. 37.1 Unconditional model output density ($f_Y(y)$, blue) and conditional model output density given that $X_1 = 0$ ($f_{Y|X_1=0}(y)$, red)

Consider now to inspect what happens if we are able to fix X_1 , say, to its mean value (which equals 0). Then, the input-output mapping becomes

$$G(0, X_2, X_3) = X_3 \quad (37.2)$$

and the conditional model output density given $X_1 = 0$ is a uniform distribution between 0 and 1. This distribution is plotted in the red curve of Fig. 37.1. Thus, receiving information that $X_1 = 0$ causes a change in the decision-maker's view about Y which is reflected by the change in the corresponding densities.

The shaded region in Fig. 37.1 displays the area enclosed between the two densities. Such area is given, in formulae, by

$$a_1(0) = \int_{\mathcal{Y}} |f_Y(y) - f_{Y|X_1=0}(y)| dy \quad (37.3)$$

where the subscript in $a_1(0)$ refers to the model input (X_1) and (0) reflects the value at which X_1 has been fixed. In our case, we register $a_1(0) = 0.4556$. In general, we shall write

$$a_i(x_i) = \int_{\mathcal{Y}} |f_Y(y) - f_{Y|X_i=x_i}(y)| dy \quad (37.4)$$

where $a_i(x_i)$ is the area enclosed between the conditional and unconditional densities, obtained by fixing the generic model input X_i at x_i .

However, because X_i is a continuous random variable, there is a finite probability that X_i assumes some other values in its support. Thus, $a_i(x_i)$ is a conditional separation for any value x_i . We can make the separation unconditional by taking the expectation over all possible values of X_i in accordance with the marginal distribution of X_i . We then write

$$\begin{aligned} \delta_i &= \frac{1}{2} \mathbb{E} \left[\int_{\mathcal{Y}} |f_Y(y) - f_{Y|X_i}(y)| dy \right] \\ &= \frac{1}{2} \int_{\mathcal{X}_i} f_{X_i}(x_i) dx_i \int_{\mathcal{Y}} |f_Y(y) - f_{Y|X_i}(y)| dy \end{aligned} \quad (37.5)$$

where the factor $\frac{1}{2}$ is inserted for normalization purposes. The sensitivity measure in Eq. (37.5) is the expected separation between the conditional and unconditional model output densities provoked by fixing X_i , with the separation measured using the L^1 -norm. The sensitivity measure in Eq. (37.5) has been introduced in Borgonovo [6] and is referred to as moment-independent importance measure [36] or Borgonovo's δ [51]. We shall refer to it as δ , for simplicity, in the remainder.

δ possesses several properties. The first is normalization, which is $0 \leq \delta_i \leq 1$. In particular, δ assumes the null value if and only if Y is independent of X_i . In fact, if Y and X_i are independent, fixing X_i leaves the distribution of Y unchanged. Conversely, note that δ_i can be rewritten as (see Plischke et al. [41]),

$$\delta_i = \frac{1}{2} \iint_{\mathcal{X}_i \times \mathcal{Y}} |f_Y(y) f_{X_i}(x_i) - f_{Y,X_i}(y, x_i)| dy dx_i \quad (37.6)$$

whence $\delta_i = 0$ implies that Y is independent of X_i . In particular, Eq. (37.6) shows that δ measures the distance between the product of the two marginals $f_Y(y)$, $f_{X_i}(x_i)$ and the joint $f_{Y,X_i}(y, x_i)$. Now, the fact that δ_i is null if and only if Y is independent of X_i is an important property, because it reassures the analyst that a null value of δ implies that the model output is independent of X_i . As shown in the literature, first-order variance-based and correlation ratios (both Pearson and Spearman) do not possess this property. For instance, for the model in Eq. (37.1) with the given model input distributions, we find that both the correlation coefficient between Y and X_1 ($\rho_1 = 0$) and the correlation ratio (first-order sensitivity index $S_1 = 0$) are null. However, fixing X_1 has an effect on the decision-maker's view about Y , as Fig. 37.1 shows.

δ is equal to unity when we resolve uncertainty in all model inputs. Formally, $\delta_{1,2,\dots,d} = 1$. In fact, suppose that we are able to fix the vector of all model inputs \mathbf{X} at $= \mathbf{x}^*$, where $\mathbf{x}^* = (x_1^*, x_2^*, \dots, x_d^*)$. The model output becomes the unique sure value $y^* = G(\mathbf{x}^*)$. The model output conditional density is, then, a Dirac- δ function centered at y^* . To illustrate, consider back our simple example in Eq. (37.1). Suppose that we know that $\mathbf{x}^* = \left(0, \frac{1}{2}, \frac{1}{2}\right)$. Then, Y is for sure equal to $G\left(0, \frac{1}{2}, \frac{1}{2}\right) = \frac{1}{2}$, and the distribution of Y is a Dirac- δ function centered at $y^* = \frac{1}{2}$. Then, it can be proven that the L^1 -distance between any density function and the Dirac- δ density is equal to 2 (see Borgonovo [6]), which leads to

$$\delta_{1,2,\dots,d} = \frac{1}{2} \mathbb{E} \left[\int_{\mathcal{Y}} |f_Y(y) - f_{Y|\mathbf{X}^*=\mathbf{x}^*}(y)| dy \right] = \frac{1}{2} \int_{\mathcal{X}_i} 2 f_{X_i}(x_i) dx_i = 1 \quad (37.7)$$

A third property concerns sequential learning. Consider going from the present state of knowledge. Suppose that we are able to fix model input X_j after we determine model input X_i . Then, we register a first change in degree of belief from $f_Y(y)$ (where we have not fixed any model input) to $f_{Y|X_i}(y)$ (Fig. 37.2). This change is quantified by δ_i .

Once we get to know X_j , we have a second shift in degree of belief from the situation in which we know X_i and the situation in which we know X_i and X_j , that is, a shift from $f_{Y|X_i}(y)$ to $f_{Y|X_i X_j}(y)$. Then, the average shift from $f_{Y|X_i}(y)$ to $f_{Y|X_i X_j}(y)$ is given by

$$\delta_{j|i} = \frac{1}{2} \mathbb{E} \left[\int_{\mathcal{Y}} |f_{Y|X_i}(y) - f_{Y|X_i, X_j}(y)| dy \right]. \quad (37.8)$$

Now, after these two shifts, we are in a state in which we know both X_i and X_j . Then, our degree of belief about is now represented by $f_{Y|X_i X_j}(y)$. This state is

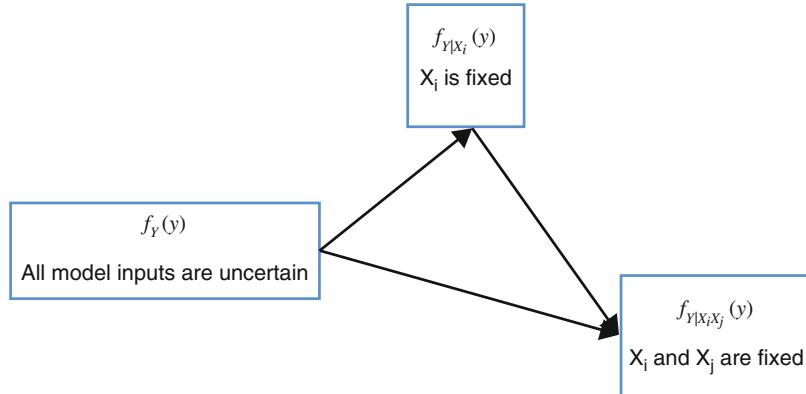

Fig. 37.2 A visual explanation of the triangular inequality for distance-based sensitivity measures

equivalently reached with a direct shift from $f_Y(y)$ to $f_{Y|X_iX_j}(y)$. This last change is quantified by

$$\delta_{i,j} = \frac{1}{2} \mathbb{E} \left[\int_{\mathcal{Y}} |f_Y(y) - f_{Y|X_i,X_j}(y)| dy \right]. \quad (37.9)$$

Then, based on the triangular inequality property of distances, it is readily seen that the three sensitivity measures δ_i , $\delta_{j|i}$, and $\delta_{i,j}$ are then related by (see Borgonovo [6])

$$\delta_{i,j} \leq \delta_i + \delta_{j|i} \quad (37.10)$$

A further property possessed by δ is transformation invariance. If $z(\cdot)$ is a monotonically increasing function, then we say that $Z(Y) = z(G(\mathbf{X}))$ is a monotonic transformation of the model output. To illustrate, suppose that $Z = \ln(\cdot)$, then a logarithmic transformation of the model in Eq. (37.1) is $Z = \ln(X_1 X_2 + X_3)$. Then, let δ_i^Z denote the sensitivity measure of X_i when the model output is transformed and δ_i^Y when the model output is not transformed. Then, as proven in [10], it is

$$\delta_i^Y = \delta_i^Z \quad (37.11)$$

In fact, for any density function, the change of variable rule says that if $Z = g(Y)$ is a monotonically increasing function, then

$$f_Y(y)dy = f_Z(z)dz \quad (37.12)$$

Hence, we have

$$\delta_i^Y = \frac{1}{2} \mathbb{E} \left[\int_{\mathcal{Y}} |f_Y(y)dy - f_{Y|X_i}(y)dy| \right] = \frac{1}{2} \mathbb{E} \left[\int_{\mathcal{Y}} |f_Z(z)dz - f_{Z|X_i}(z)dz| \right] = \delta_i^Z \quad (37.13)$$

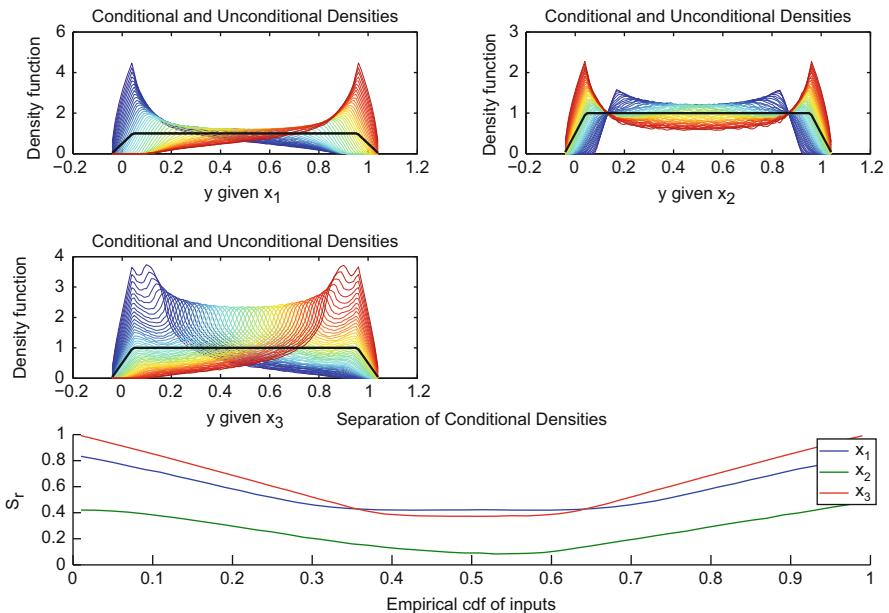

Fig. 37.3 First three graphs: unconditional model output density (black) and conditional densities given that X_1 , X_2 , and X_3 are fixed at several points in their domain, respectively. Fourth graph: the separations $a_i(x_i)$ as x_i varies between 0 and 1, for $i = 1, 2, 3$

The estimation of δ is a subject attracting attention in present research. It has been studied in a series of works [16–18, 23, 36, 41, 50, 51] that have contributed to abating computational burden. In particular, the most recent findings allow the estimation of δ at the same cost of nonparametric methods, i.e., at the cost of a single Monte Carlo loop. We illustrate by computing the moment-independent sensitivity measures for the three model inputs in the simple model of Eq. (37.1) based on the results in Plischke et al. [41]. The estimation is performed through the Matlab script deltamim.m (available upon request).

Figure 37.3 shows the results of the analysis. The first three graphs overlap the unconditional model output density $f_Y(y)$ (black) and conditional densities given that X_1 , X_2 , and X_3 are fixed at several points in their domain, respectively. These graphs visually show that all three model inputs are relevant, because they all provoke a change in model output density. They also show that X_3 and X_2 induce, in relative terms, higher fluctuations of the density when compared to X_1 .

The fourth graph displays the separations $a_i(x_i)$ as X_i varies between 0 and 1 for the three model inputs. They are symmetric and show that X_3 and X_2 are associated with separations higher in magnitude than X_1 . This information is then synthesized in the value of the δ sensitivity measures of the three model inputs, which we report in the second row of Table 37.1.

Table 37.1 shows that X_3 is the most important model input, followed by X_2 and X_1 .

Table 37.1 Numerical values of the sensitivity measures discussed in this chapter

Sensitivity measure	X_1	X_2	X_3
ρ_i Pearson correlation coefficient	0.655	0	0.655
V_i (First-order variance based)	0.412	0	0.445
δ_i (Density based)	0.29	0.13	0.312
β_i^{Ku} (Distance based)	0.29	0.13	0.312
ϵ_i (Value of information)	0.1250	0	0.1250

We conclude this section observing that the δ sensitivity measure presented above can also be seen as a representative of a general class of sensitivity measures that can be introduced by measuring some distance (or divergence) between cumulative distribution functions. Several authors make use of the Kullback-Leibler divergence to define probabilistic sensitivity measures. An early example in medical decision-making is [20]. The concept is then reconsidered in later works, such as [2, 30, 35, 39], in different fields of application. Formally, one writes

$$\theta_i = \mathbb{E} \left[\int_{\mathcal{Y}} f_{Y|X_i}(y) (\log f_{Y|X_i}(y) - \log f_Y(y)) dy \right] \quad (37.14)$$

The inner separation in Eq. (37.14) is

$$b_i(X_i) = \int_{\mathcal{Y}} f_{Y|X_i}(y) (\log f_{Y|X_i}(y) - \log f_Y(y)) dy \quad (37.15)$$

which represents the Kullback-Leibler divergence between the conditional and unconditional model output distributions. One has that $\theta_i \geq 0$, and it is equal to zero if and only if Y is independent of X_i . Also, θ_i is transformation invariant (see, among others, [12]).

Finally, while full details about estimation cannot be given due to space limitations, let us observe that the estimation of any density-based sensitivity measure involves the problem of estimating the empirical density. We refer to the works of [36, 41, 50], and [23] for a detailed discussion of the issues and for recent advances.

3 Sensitivity Measures Based on Separations Between Cumulative Distribution Functions

A second class of moment-independent sensitivity measures is represented by sensitivity measures that take into account the separation between cumulative distribution functions. In general, we write

$$\beta_i = \mathbb{E} [h(F_Y(y), F_{Y|X_i}(y))] \quad (37.16)$$

where $h(\cdot, \cdot)$ is some distance or divergence between cumulative distribution functions, $F_Y(y)$ is the unconditional model output cumulative distribution function, and

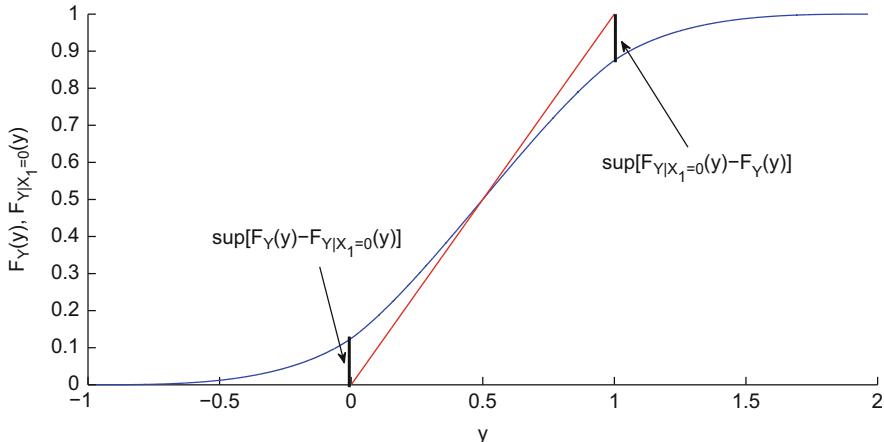

Fig. 37.4 Visual interpretation of $k_i(x_i)$ in Eq. (37.19). Kuiper's distance between cumulative distribution functions

$F_{Y|X_i}(y)$ is the cumulative distribution function conditional on fixing model input X_i . The expectation is taken in accordance with the marginal distribution of X_i .

In Baucells and Borgonovo [3], the choice of the metric is thoroughly discussed. If scale invariance is not a relevant property, one can use a metric based on a generic L_p -distance between cumulative distribution function, selecting

$$h \{F_Y(y), F_{Y|X_i}(y)\} = \left(\int (|F_Y(y) - F_{Y|X_i}(y)|)^p dy \right)^{1/p} \quad (37.17)$$

$$1 \leq p < \infty.$$

If transformation invariance is, instead, a convenient property, then one can base the sensitivity measure on the Kolmogorov-Smirnov distance and on its modifications. In Baucells and Borgonovo [3], Kuiper's distance is considered, because this metric is “equally sensitive for all values of y , and therefore puts all percentiles on an equal footing” [21, p. 140]. Kuiper's modification remedies a weakness associated with the Kolmogorov-Smirnov metric, which attributes more weight to deviations around the median rather than at distribution tails [19, 37]. A visualization of Kuiper's metric is in Fig. 37.4.

Formally, one has

$$k_i(X_i) = \sup_y \{F_Y(y) - F_{Y|X_i}(y)\} + \sup_y \{F_{Y|X_i}(y) - F_Y(y)\} \quad (37.18)$$

where $\sup_y \{F_Y(y) - F_{Y|X_i}(y)\}$ is the highest value of the difference between $F_Y(y)$ and $F_{Y|X_i}(y)$, while $\sup_y \{F_{Y|X_i}(y) - F_Y(y)\}$ is the highest value of the opposite difference.

Correspondingly, one obtains the distance-based sensitivity measure [3]:

$$\beta^{Ku} = \mathbb{E} \left[\sup_y \{F_Y(y) - F_{Y|X_i}(y)\} + \sup_y \{F_{Y|X_i}(y) - F_Y(y)\} \right] \quad (37.19)$$

As for the properties of β^{Ku} , we refer to [3] for technical details. However, we observe that β^{Ku} is nonnegative and lower than unity. It is also equal to zero if and only if Y is independent of X_i . Moreover, β^{Ku} in Eq. (37.19) is transformation invariant. It is also $\beta_{i,j}^{Ku} \leq \beta_{j|i}^{Ku} + \beta_i^{Ku}$.

Baucells and Borgonovo [3] report a thorough discussion about the selection of the metric. We limit ourselves to note that numerous modifications of the Kuiper and Kolmogorov-Smirnov metrics have been introduced. A general form is given by Mason and Shuenmeyer [37], who propose a metric of the type

$$h\{F_Y, F_{Y|X_i}\} = \sup_y \{w(F_Y(y), F_{Y|X_i}(y)) \cdot |F_Y(y) - F_{Y|X_i}(y)|\} \quad (37.20)$$

where $w[F_Y(y), F_{Y|X_i}(y)]$ is a general weighting function that allows us to assign a different relevance to different portions of the distribution. The weighting function proposed by Anderson and Darling [1] ($w(F_Y(y), F_{Y|X_i}(y)) = \sqrt{F_Y(y)[1 - F_Y(y)]}$) is one of the most well known. Anderson-Darling weight places emphasis in distribution tails. A weighting function well known in financial studies for values at risk, with focus on distribution tails, is proposed by Crnkovic and Drachman [21], who obtain a suitable modification of Kuiper's metric.

To illustrate, we conclude with the values of β^{Ku} for the model in Eq. (37.1). The sensitivity measures are computed using the subroutine betaKS2.m (available upon request). The numerical values are reported in the fourth row of Table 37.1. We observe that the values of β_i^{Ku} are equal to the values of δ_i for the three model inputs. This is not a coincidence, because, as proven in Plischke and Borgonovo [40], the two sensitivity measures β^{Ku} and δ_i are numerically identical when the conditional and unconditional distributions are unimodal.

4 Value of Information-Based Sensitivity Measures

In several applications of sensitivity analysis, the quantity estimated by a computer code is part of a broad decision-making process, in which the decision-maker is comparing a set of A alternatives. In particular, for each alternative a , the model computes a quantity Y_a of interest. In a climate change context, Y_a may represent the amount of CO₂ emissions produced under a given climate policy. In an economic context, Y_a may represent the overall loss or utility incurred when alternative a is implemented. Each Y_a is a function $G_a(\mathbf{X})$ of the n uncertain model inputs. Thus, the model produces a vector $\mathbf{y} = (y_1, y_2, \dots, y_A)$ of outputs.

The decision-maker selects the alternative that has the maximum expected utility, solving the problem

$$\max_{a=1,2,\dots,A} \{\mathbb{E}[Y_a]\} = \max_{a=1,2,\dots,A} \{\mathbb{E}[g_a(\mathbf{X})]\}. \quad (37.21)$$

Equation (37.21) implies that the decision-maker is using the model to estimate the distribution of the decision criterion under each alternative, propagates uncertainty, and then selects the alternative that produces the highest expected value. The quantity $\max_{a=1,2,\dots,A} \{\mathbb{E}[Y_a]\}$ is the value of the decision problem given the present state of information.

In this context, the effect of receiving information about X_i is twofold. On the one hand, the distributions of all Y_a 's change. We have discussed this effect in previous sections. On the other hand, the change in distributions might induce a change in the preferred alternative. In fact, after we are informed that $X_i = x_i$, the decision problem becomes to select the best alternative conditional on $X_i = x_i$. In other words, the optimal alternative is alternative a without the additional information but it might become a' when the new information has arrived. In this case, we register a change in both the preferred alternative and the value of the decision problem change. Then, the change in value of the decision problem is given by

$$e_i(X_i) = \max_{a=1,2,\dots,A} \{\mathbb{E}[Y_a|X_i]\} - \max_{a=1,2,\dots,A} \{\mathbb{E}[Y_a]\} \quad (37.22)$$

Taking the expectation with respect to X_i , we obtain the partial expected value of perfect information about X_i

$$\epsilon_i = \mathbb{E} \left[\max_{a=1,2,\dots,A} \{\mathbb{E}[Y_a|X_i]\} \right] - \max_{a=1,2,\dots,A} \{\mathbb{E}[Y_a]\} \quad (37.23)$$

The concept of value of information has been introduced by Howard [28]. The expression $\mathbb{E}[\max_{a=1,2,\dots,A} \{\mathbb{E}[Y_a|X_i]\}]$ is called in Pratt et al. [42, p. 252] *prior expected value of action posterior to perfect information*. In the remainder, we shall refer to ϵ_i as information value. As observed in Howard [28], information value is a nonnegative quantity.

In sensitivity analysis, the intuition of using information value as global importance measure is due to Felli and Hazen [25]. It has then been studied in several works [38, 46] and [48].

As for the properties of information value, we note that ϵ_i is greater than or equal to zero. Its lower bound, $\epsilon_i = 0$, is reached when Y_a is independent of X_i . Its upper bound is represented by the total information value,

$$\epsilon^T = \mathbb{E} \left[\max_{a=1,2,\dots,A} \{\mathbb{E}[Y_a|\mathbf{X}]\} \right] - \max_{a=1,2,\dots,A} \{\mathbb{E}[Y_a]\} \quad (37.24)$$

which is the value of information for resolving uncertainty in all the model inputs simultaneously.

As opposed to δ_i and β_i , a null information value does not reassure the analyst that Y is independent of X_i . In fact, it might be the case of knowing that fixing X_i never changes the preferred alternative even if Y_a is dependent on X_i . We refer to Borgonovo, Hazen, and Plischke [13] for further details. We conclude the section estimating the value of information for the model inputs of our running example. Suppose the decision-maker has two available alternatives, a and b . Alternative a leads to a sure $Y_a = \frac{1}{2}$, while alternative b leads to an uncertainty Y_b , where Y_b is in Eq. (37.1), with the usual model input distributions. The numerical values of ϵ_i are reported in Table 37.1. We observe that $\epsilon_1 = \epsilon_3 = \frac{1}{8}$, while $\epsilon_2 = 0$. This last result, as mentioned, does not mean that Y is independent of X_2 . Conversely, it indicates that fixing X_2 at any possible value does not cause the preferred alternative to change.

5 A Common Rationale: Properties of Sensitivity Measures

This section report some more recent theoretical developments. The discussion in the previous sections shows that density-based, distribution-based, and information value sensitivity measures have a common aspect. As underlined in Borgonovo, Hazen, and Plischke [13], they measure, using some form of discrepancy, the shift between the unconditional model output distribution and the conditional one, given that X_i is fixed. This common rationale is thoroughly investigated in Borgonovo, Hazen, and Plischke [13], to which we refer to full details. We succinctly report here the main findings. Let \mathbb{P}_Y be the distribution that reflects the present decision-maker degree of belief about the model output(s). Then, let $\mathbb{P}_{Y|X_i}$ be the distribution that reflects the present decision-maker degree of belief about the model output(s) when X_i is fixed. Then, consider a generic operator between distributions, say $\zeta(\cdot, \cdot)$. The operator goes from pairs of distributions $\zeta(\mathbb{P}', \mathbb{P}'')$ to \mathbb{R} . Borgonovo, Hazen, and Plischke [13] define inner operator as an operator $\zeta(\cdot, \cdot)$ that possesses the minimal property that $\zeta(\mathbb{P}, \mathbb{P}) = 0$. That is, if the two distributions coincide, then the operator returns a null value. Then, one can define the inner statistic based on inner operator $\zeta(\cdot, \cdot)$ the quantity

$$\gamma_i(X_i) = \zeta(\mathbb{P}_Y, \mathbb{P}_{Y|X_i}). \quad (37.25)$$

The inner statistic in Eq. (37.25) is a function that goes from the support of X_i into \mathbb{R} and whose numerical value depends on the value taken on by X_i . Requiring that $\gamma_i(X_i)$ is Riemann-Stieltjes integrable with respect to the marginal distribution of X_i , [13] defines the global sensitivity measure of X_i with respect to \mathbf{Y} as the quantity

$$\xi_i = \mathbb{E} [\zeta(\mathbb{P}_Y, \mathbb{P}_{Y|X_i})]. \quad (37.26)$$

Observe that the definition in Eq. (37.26) does not require independence among the model inputs. The definition also applies when a group of model inputs is considered (thus, the subscript i would denote a group of inputs). Reference [13] shows that this definition encompasses all sensitivity measures discussed in this chapter, as well as variance-based sensitivity measures. In fact, if we set

$$\gamma_i(X_i) = \mathbb{E}[(Y - \mathbb{E}[Y|X_i])^2] - \mathbb{E}[(Y - \mathbb{E}[Y])^2] \quad (37.27)$$

and average, we obtain first-order variance-based sensitivity measures. Similarly, setting $\gamma_i(X_i) = e_i(X_i)$ in Eq. (37.22) or $\gamma_i(X_i)$ equal to $a_i(x_i)$, $b_i(x_i)$, and $k_i(x_i)$ (respectively, in Eqs. (37.4), (37.15), and (37.18)) and averaging, we obtain the sensitivity measures ϵ , δ , β^{K_u} , and θ .

The choice of the inner statistic determines the properties of the corresponding global sensitivity measures. Starting from the general definition of inner operator and inner statistic, Ref. [15] proves a series if and only if conditions that link properties of the sensitivity measure to properties of the corresponding inner statistic. A property of interest in applications is transformation invariance. When the model output is sparse or ranges over several orders of magnitudes, numerical issues emerge in estimation. Analysts then resort to transformations for improving numerical accuracy and accelerating convergence. *The scaling problem most often can be overcome by performing uncertainty importance calculations based on a logarithmic scale [...] However, the log-based uncertainty importance calculations do not readily translate back to a linear scale* [29, p. 402]. The statement of Iman and Hora [29, p. 402] applies to other transformations as well. However, the problem of reverting back from the transformed to the original data is circumvented if one employs a sensitivity measure which is transformation invariant. In fact, if the sensitivity measure is transformation invariant, it assumes the same values both for the original and the transformed model output.

References [3] and [14] discuss families of transformation invariant sensitivity measures. In particular, a family of transformation invariant inner operators is obtained through the following definition [14]:

$$\zeta(\mathbb{P}, \mathbb{Q}) := \sup_{A \in \mathcal{A}} h(|\mathbb{P}(A) - \mathbb{Q}(A)|) \quad (37.28)$$

where \mathbb{P} and \mathbb{Q} are two probability measures on measurable space (Ω, \mathcal{A}) , with $h : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0}$, $h(0) = 0$ and $\sup_t \frac{h(2t)}{h(t)} < \infty$. Then, if one lets $h(t) = t$, one obtains

$$\zeta(\mathbb{P}, \mathbb{Q}) := \sup_{A \in \mathcal{A}} (|\mathbb{P}(A) - \mathbb{Q}(A)|) = d\text{var}(\mathbb{P}, \mathbb{Q}) \quad (37.29)$$

which is the variational distance. Then, by Scheffè's theorem [45], we have

$$d\text{var}(\mathbb{P}, \mathbb{Q}) = \sup_{A \in \mathcal{A}} (|\mathbb{P}(A) - \mathbb{Q}(A)|) = \frac{1}{2} \int |p(y) - q(y)| dy \quad (37.30)$$

that is, if \mathbb{P} and \mathbb{Q} have corresponding densities, then $d_{\text{var}}(\mathbb{P}, \mathbb{Q})$ is the L^1 -norm between densities.

Borgonovo, Tarantola, Plischke, and Morris [14] also show that Eq.(37.28) contains the Birnbaum-Orlicz family of metrics

$$z(\mathbb{P}, \mathbb{Q}) = \sup_{y \in \mathbb{R}} h(|F(y) - G(y)|) = d_{\text{BO}}(\mathbb{P}, \mathbb{Q}). \quad (37.31)$$

which, in turn, setting $h(t) = t$ leads to the Kolmogorov-Smirnov metric. Finally, let $t(\cdot)$ be a convex function such that $t(0) = 1$; then the family of Csiszár divergences [22]:

$$d_h(\mathbb{P}, \mathbb{Q}) = \int p(y) t\left(\frac{q(y)}{p(y)}\right) dy \quad (37.32)$$

is invariant under monotonic transformation and comprises the Kullback-Leibler divergence as a member. Selecting any member of the families in Eq.(37.28) or (37.32) as inner operators, we obtain sensitivity measures which are transformation invariant. Da Veiga [23] also discusses the properties of the Csiszar f-divergences from a sensitivity analysis viewpoint. Da Veiga [23] shows that setting $t(s) = (\sqrt{s} - 1)^2$, we obtain a global sensitivity measure based on the Hellinger distance [23], while setting $t(s) = (s - 1)^2$ or $t(s) = \frac{(s - 1)^2}{s}$ one obtains sensitivity measures based on Pearson's χ^2 or Neyman's χ^2 divergences, respectively.

6 Given Data Estimation

The estimation of probabilistic sensitivity measures has been a subject of intensive research. The reason is that, when estimating sensitivity measures from computer codes, it is important to minimize the number of model runs or to make best use of the available ones. If one aims at estimating the sensitivity measures presented in this section (i.e., variance based, density based, distribution based, and value of information based), then, one has several choices. The first is to use a so-called brute force approach. In a brute force approach, we develop an algorithm that strictly replicates the definition of the quantity to be estimated. Then, we need to estimate the inner statistic and the outer expectation. For estimating the inner statistic, we sample a value x_i randomly from the marginal distribution of X_i . Then, we fix $X_i = x_i$ in the model and propagate uncertainty from the conditional distribution of the model inputs given that $X_i = x_i$. This distribution is denoted as $F_{\mathbf{X}|X_i}(\mathbf{x}_{\sim i}; x_i)$, where $\mathbf{x}_{\sim i}$ denotes a vector containing all model inputs but X_i . Numerically, we generate a sample of size N_{int} from this conditional distribution and evaluate the model N_{int} times, to get the conditional distribution given that $X_i = x_i$. We have then the samples necessary to estimate the inner statistics (Eq.37.25) of any sensitivity measure discussed in this section, from variance-

based to value of information. This procedure needs to be repeated for as many values of X_i as possible to obtain the expectation of the inner statistic and the corresponding global sensitivity measure (Eq. 37.26). In fact, we need to compute the outer expectation. Suppose that N_{ext} is a large enough sample for the external expectation. Then, the total number of model runs needed to estimate ξ_i is equal to $N_{\text{ext}}N_{\text{int}}$. This procedure then needs to be repeated for all model inputs, leading to a total computational cost of $C^{BF} = d \cdot N_{\text{ext}} \cdot N_{\text{int}}$, where C^{BF} stands for brute force cost. Hence, the cost is linear in the number of model inputs and depends on the square of the Monte Carlo sample. Such dependence makes the estimation rapidly unfeasible. For instance, consider a model that has $d = 10$ inputs and that $N_{\text{int}} = N_{\text{ext}}$ of at least 1000 is needed to obtain accurate estimates. Then, the cost becomes equal to $C^{BF} = 10 \cdot 1000^2 = 10,000,000$.

Several designs have been identified in the literature to abate this computational cost. For instance, the design of Saltelli [43] estimates first- and total-order variance-based sensitivity measures at $N(2d + 2)$, which is a notable reduction. Nonetheless, the cost can be abated to a minimum of N model runs, i.e., all the discussed probabilistic sensitivity measures can be estimated from a single Monte Carlo loop.

Two strategies are available. The first is to fit a metamodel on the given Monte Carlo sample [32, 49]. Then, because metamodel executions are computationally inexpensive, one can resort to a brute force approach to estimate sensitivity measures, substituting the metamodel for the original model. For moment-independent methods, a combination of smoothing spline metamodeling and brute force estimation is applied in Borgonovo [11] for the estimation of the δ importance measures, and a polynomial chaos expansion is used in Caniou and Sudret [16, 17]. For value of information sensitivity measures, [48] use Gaussian process metamodeling.

A second strategy is represented by using a given data approach. This approach is receiving increasing attention and is employed in a variety of works [3, 14, 41, 46, 47]. It consists of estimating the sensitivity measures directly from the Monte Carlo sample, but without fitting a metamodel. The main intuition is to relax the point condition $X_i = x_i$, replacing it with the bin condition $X_i \in [x_i - \Delta, x_i + \Delta]$, where Δ is a positive number, $[x_i - \Delta, x_i + \Delta]$ is an interval around x_i , and, more precisely, $[x_i - \Delta, x_i + \Delta]$ is a subset of a proper partition of the support of X_i . Then, by making Δ a decreasing function of the sample size, so that $\lim_{n \rightarrow \infty} \Delta = 0$, the bin condition reduces to the point condition. This latter step is achieved by means of a partition-refining strategy. Technical details are discussed in [13].

In general terms, Borgonovo, Hazen, and Plischke [13] obtain estimators of the type

$$\hat{\xi}_i = \frac{1}{M(N)} \sum_{m=1}^{M(N)} \xi \left(\widehat{F}_Y(y), \widehat{F}_{Y|X_i \in [x_i - \Delta, x_i + \Delta]}(y) \right) \quad (37.33)$$

where $M(N)$ is the number of partitions at size N and $\xi \left(\widehat{F}_Y(y), \widehat{F}_{Y|X_i \in [x_i - \Delta, x_i + \Delta]}(y) \right)$ is an estimator of the inner statistic in which the point condition has been replaced by the bin condition.

Borgonovo, Hazen, and Plischke [13] then prove a general result showing that under the assumptions that $\xi(\cdot, \cdot)$ is a continuous function of its arguments, that the inner statistic is Riemann-Stieltjes integrable, and that $M(N)$ is a monotonically increasing function such that $\lim_{N \rightarrow \infty} \frac{N}{M(N)} = \infty$, the estimator $\hat{\xi}_i$ in Eq. (37.33) is a consistent estimator of ξ_i .

The numerical values of the sensitivity measures presented in Table 37.1 are obtained using a given data estimation approach.

We finally note that the common rationale cited in this work is also related to the recent work by Fort et al. [26].

7 Sensitivity Analysis for Reliability Studies

As a complement, this section presents other moment-independent sensitivity measures, but devoted to reliability studies. In the first part, we present traditional importance measures, while in the second part, we present sensitivity indices for structural reliability analysis.

7.1 Reliability Importance Measures

An important realm for the application of sensitivity measures is reliability analysis. In fact, the first sensitivity measure that has been introduced for determining importance is the reliability importance measure of Birnbaum [4]. Birnbaum's work is concerned with the fact that not all components contribute to system reliability in the same way and Birnbaum aims at determining the importance of the failure of a component. Then, it turns out that, under appropriate conditions, the Birnbaum importance measure of component is a local sensitivity measure equal to the partial derivative of the reliability function with respect to the failure probability of interest. Several other importance measures have followed. Among the most widely known and used are the Fussell-Vesely, criticality, risk achievement worth, and risk reduction worth (we refer to [7, 8], and [31] for a review). For the purposes of this chapter, it is important to remark that these importance measures consider aleatory uncertainty, that is, uncertainty associated with the occurrence of an event. In structural reliability studies, often epistemic uncertainty enters the picture, where by epistemic uncertainty, we mean uncertainty in a parameter (model input) of a complex structural reliability code. The next section describes a recently introduced reliability importance measure which takes this aspect into account.

7.2 Sensitivity Indices for Structural Reliability Analysis

In structural reliability analysis [33], complex numerical codes help engineers in assessing system safety. Analysts are then often interested in quantifying the

contribution to uncertainty in system response by uncertain model inputs. Lemaitre et al. [34] have recently proposed a sensitivity index based upon the modification of the probability density function (pdf) of the random inputs, when the quantity of interest is a failure probability (probability that a model output exceeds a given threshold). This method can also be used when the quantity of interest is a quantile.

Let $y = G(\mathbf{x})$ be a mapping that summarizes the system structural properties as a function of given characteristics (\mathbf{x} is the vector of model inputs, in this context). Then, $G(\mathbf{x}) < 0$ denotes system failure, while the complementary event $G(\mathbf{x}) \geq 0$ denotes that the system is operating in a safe mode. Then, assume that the model inputs $X_i, i = 1, \dots, d$, are uncertain and independently distributed with marginal densities $f_i, i = 1, \dots, d$. The system response becomes a random variable and the model writes $Y = G(\mathbf{X})$. The quantity of interest to the analyst is then the failure probability:

$$P = Pr\{G(\mathbf{X}) < 0\} = \int \mathbf{1}_{\{G(\mathbf{x}) < 0\}} f(\mathbf{x}) d\mathbf{x}, \quad (37.34)$$

where $f(\mathbf{x})$ is the pdf of \mathbf{X} . The objective of the sensitivity analysis becomes the quantification of the influence of each X_i on this probability.

The proposed approach consists in perturbing the original pdf f_i for a given input variable X_i while keeping constant the pdfs for all the other input variables $\mathbf{X}_{\sim i} = (X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_d)$. Let us call $X_{i\zeta} \sim f_{i\zeta}$ the corresponding perturbed random input. This perturbed input takes the place of the real random input X_i , in a sense of modeling error: what if the real variable were $X_{i\zeta}$ instead of X_i ? In order to answer this question, a new value for the failure probability, denoted $P_{i\zeta}$, is computed. X_i can be said influential (resp. no influential) on the failure probability if the value $P_{i\zeta}$ is different (resp. similar) from the reference value P .

Following this idea, the perturbed failure probability of the system writes

$$P_{i\zeta} = \int \mathbf{1}_{\{G(\mathbf{x}) < 0\}} \frac{f_{i\zeta}(x_i)}{f_i(x_i)} f(\mathbf{x}) d\mathbf{x}. \quad (37.35)$$

The sensitivity index of X_i is then defined as the quantity:

$$S_{i\zeta} = \left[\frac{P_{i\zeta}}{P} - 1 \right] \mathbf{1}_{\{P_{i\zeta} \geq P\}} + \left[1 - \frac{P}{P_{i\zeta}} \right] \mathbf{1}_{\{P_{i\zeta} < P\}}. \quad (37.36)$$

This sensitivity index is called density modification-based reliability sensitivity index (DMBRSI) in [34]. However, the simpler acronym PLI, for perturbation law-based sensitivity indices, was then found. It is easy to see that $S_{i\zeta} = 0$ if $P_{i\zeta} = P$, as expected if X_i is a non-influential variable or if ζ expresses a negligible perturbation. The sign of $S_{i\zeta}$ indicates how the perturbation impacts the failure probability qualitatively. An example of PLI will be given at the end of this section.

The PLI can be estimated directly from the set of simulations used to compute the system failure probability, thus limiting the number of calls to the numerical model. Under mild support constraints, a consistent estimator of $P_{i\varsigma}$ is given by

$$\hat{P}_{i\varsigma N} = \frac{1}{N} \sum_{j=1}^N \mathbf{1}_{\{G(\mathbf{x}^j) < 0\}} \frac{f_{i\varsigma}(x_i^j)}{f_i(x_i^j)}. \quad (37.37)$$

where $(\mathbf{x}^1, \dots, \mathbf{x}^N)$ is a Monte Carlo sample. This property holds in the more general case when P is originally estimated by importance sampling (e.g., see Lemaire [33]) rather than simple Monte Carlo, which is more appealing in contexts when G is time-consuming. Asymptotical properties of the indices are derived in Lemaitre et al. [34], including a central limit theorem for the plug-in estimator of $S_{i\varsigma}$.

Concerning the perturbed input density $f_{i\varsigma}$, it is defined as the closest distribution to the original f_i in the entropy sense and under some constraints of perturbation. The Kullback-Leibler divergence (Eq. 37.15) is used in [34] to quantify the distance between the reference model input density and the perturbed density. The perturbed density is then found as the solution to a constrained optimization problem, as follows:

$$\begin{aligned} \min_{f_{\text{mod}}} & \{KL(f_{\text{mod}}, f_i)\} \\ \text{s.t.} & \int g_k(x_i) f_{\text{mod}}(x_i) dx_i = \varsigma_{k,i} \quad (k = 1 \dots K) \end{aligned} \quad (37.38)$$

where $KL(f_{\text{mod}}, f_i)$ is the Kullback-Leibler divergence between the original and the perturbed model input density, g_k are assigned univariate functions, and $\varsigma_{k,i}$ are real numbers, for $i = 1, 2, \dots, d$ and $k = 1, 2, \dots, K$.

Then, there exists a unique vector $\boldsymbol{\lambda}^* \in \mathbb{R}^K$ that solves the minimization problem in Eq. (37.38) and the explicit solution is

$$f_{i\varsigma}(x_i) = f_i(x_i) \exp \left[\sum_{k=1}^K \lambda_k^* g_k(x_i) - \psi_i(\boldsymbol{\lambda}^*) \right]. \quad (37.39)$$

where

$$\psi_i(\boldsymbol{\lambda}) = \log \int f_i(x) \exp \left[\sum_{k=1}^K \lambda_k g_k(x) \right] dx. \quad (37.40)$$

Alternative types of perturbations are considered in Lemaitre et al. [34]. The first is (*mean shifting*), i.e., a perturbation in the mean:

$$\int x_i f_{\text{mod}}(x_i) dx_i = \varsigma_i. \quad (37.41)$$

A second perturbation is *variance shifting*, when the analyst is perturbing the variance of X_i :

$$\begin{cases} \int x_i f_{\text{mod}}(x_i) dx_i = \mathbb{E}[X_i], \\ \int x_i^2 f_{\text{mod}}(x_i) dx_i = \varsigma_i + \mathbb{E}[X_i]^2. \end{cases} \quad (37.42)$$

One can also incorporate in this framework a *quantile shifting*, which is especially useful if the analyst is interested in modifications in the tails of the model input distributions:

$$\int 1_{]-\infty; q_r]}(x_i) f_{\text{mod}}(x_i) dx_i = \varsigma_i \quad (37.43)$$

where q_r is the reference quantile. Equation (37.43) has the meaning that f_{mod} is a density such that its ς_i -quantile is q_r .

To illustrate the PLI indices defined in Eq. (37.36), we report the example in [34] which uses the modified version of the Ishigami function:

$$G(\mathbf{X}) = \sin(X_1) + 7 \sin(X_2)^2 + 0.1 X_3^4 \sin(X_1) + 7$$

where $X_i \sim \mathcal{U}[-\pi, \pi]$, $i = 1, \dots, 3$. Under these numerical assumptions, the system failure probability is estimated at roughly $P \simeq 0.0061$, obtained with a sample of 10^5 points. The PLI of the three model inputs undergoing a mean perturbation are displayed in Fig. 37.5, which reproduces identical numerical results as Figure 5 in [34]. ς ranges from -3 to 3 , and the sensitivity is evaluated at 60 points.

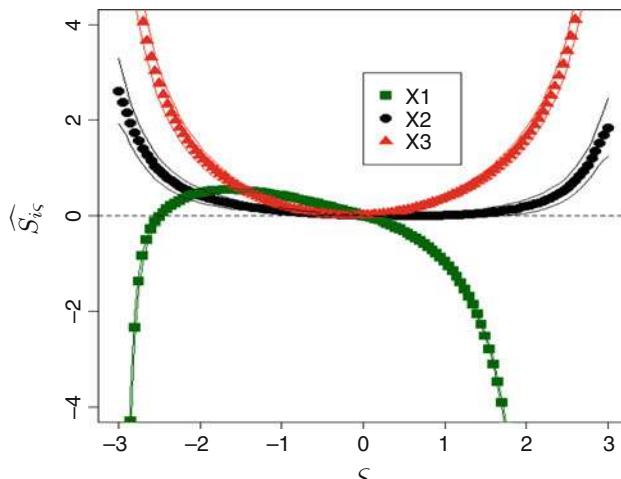

Fig. 37.5 Estimated PLI (indices \widehat{S}_i^ς) for the thresholded Ishigami function with a mean shifting

Figure 37.5 shows that a positive perturbation of the mean of X_2 or X_3 increases the failure probability for all values of ζ . Conversely, an increase in the mean or a large decrease in the mean of X_1 strongly diminishes the failure probability. Figure 37.5 also shows that the confidence intervals of the three sensitivity curves are well separated, except in the -1 to 1 zone.

8 Conclusions

We have reviewed the important class of moment-independent sensitivity measures. These sensitivity measures are subject of increasing interest among practitioners and researchers for their ability to produce reliable insights on the strength of the dependence of the model output on a given model input.

The chapter has also reviewed the fact that variance-based, moment-independent, and value of information-based sensitivity measures are particular cases of a common rationale, in which a global sensitivity measure is seen as the expected separation between the conditional and unconditional model output distribution.

The section has then reviewed estimation at minimal computational cost, namely, N model runs. We have then reported findings that concern both estimation through metamodels and, also, estimation through given data. In this second case, estimation is direct from the Monte Carlo sample and does not require the use of a metamodel.

We have completed the chapter discussing reliability importance measures. Traditional importance measures have been addressed first. We have then overviewed a perturbation-based sensitivity index for structural reliability analysis recently introduced.

We observe that moment-independent sensitivity measures, due to their more recent introduction with respect to other classes of global sensitivity measures, are a subject of increasing research interest, and, nowadays, several works are addressing the definition of new moment-independent sensitivity measures and/or studying alternative approaches to their estimation (we refer to [24, 27, 40] for recent works in progress). Also, some aspects concerning their interpretation are subject to future research. For instance, the interpretation of higher-order moment-independent sensitivity measures has not been compared to higher-order variance-based sensitivity measures. To illustrate, consider δ_{ij} in Eq. (37.9). This joint sensitivity index is clearly different from a second-order variance-based sensitivity index. In fact, δ_{ij} is the distance that we travel for getting to know both X_i and X_j . Thus, it represents the expected effect on the decision-maker's degree of belief of acquiring perfect knowledge on both model inputs. This interpretation holds for both dependent and independent model inputs. Conversely, the second variance-based sensitivity index S_{ij} represents a mathematical interaction, and, under independence, it tells us whether there is a residual term that makes the response of the input-output mapping not additive in X_i and X_j . Then, S_{ij} might be seen as closer in interpretation to $\delta_{j|i}$, which represents the additional (residual) effect on the decision-maker's degree of belief of getting to know X_j , after she has gotten to know X_i . However, $\delta_{j|i}$

addresses a different question than S_{ij} . A thorough discussion of these aspects is out of the scope of the present chapter and is part of future research.

Metamodel-Based Sensitivity Analysis: Polynomial Chaos Expansions and Gaussian Processes

38

Loïc Le Gratiet, Stefano Marelli, and Bruno Sudret

Abstract

Global sensitivity analysis is now established as a powerful approach for determining the key random input parameters that drive the uncertainty of model output predictions. Yet the classical computation of the so-called Sobol' indices is based on Monte Carlo simulation, which is not affordable when computationally expensive models are used, as it is the case in most applications in engineering and applied sciences. In this respect metamodels such as polynomial chaos expansions (PCE) and Gaussian processes (GP) have received tremendous attention in the last few years, as they allow one to replace the original, taxing model by a surrogate which is built from an experimental design of limited size. Then the surrogate can be used to compute the sensitivity indices in negligible time. In this chapter an introduction to each technique is given, with an emphasis on their strengths and limitations in the context of global sensitivity analysis. In particular, Sobol' (resp. total Sobol') indices can be computed analytically from the PCE coefficients. In contrast, confidence intervals on sensitivity indices can be derived straightforwardly from the properties of GPs. The performance of the two techniques is finally compared on three well-known analytical benchmarks (Ishigami, G-Sobol', and Morris functions) as well as on a realistic engineering application (deflection of a truss structure).

1 Introduction

In modern engineering sciences computational models are used to simulate and predict the behavior of complex systems. The governing equations of the system are usually discretized so as to be solved by dedicated algorithms. In the end a computational model (a.k.a. simulator) is built up, which can be considered as a mapping from the space of input parameters to the space of quantities of interest that are computed by the model. However, in many situations the values of the parameters describing the properties of the system, its environment, and the various initial and boundary conditions are not perfectly well known. To account for such uncertainty, they are typically described by possible variation ranges or probability distribution functions.

In this context global sensitivity analysis aims at determining which input parameters of the model influence the most the predictions, i.e., how the variability of the model response is affected by the uncertainty of the various input parameters. A popular technique is based on the decomposition of the response variance as a sum of contributions that can be associated to each single input parameter or to combinations thereof, leading to the computation of the so-called Sobol' indices.

As presented earlier in this book (see ► Chap. 35, “Variance-Based Sensitivity Analysis: Theory and Estimation Algorithms”), the use of Monte Carlo simulation

to compute Sobol' indices requires a large number of samples (typically, thousands to hundreds of thousands), which may be an impossible requirement when the underlying computational model is expensive to evaluate. To bypass this difficulty, *surrogate models* may be built. Generally speaking, a surrogate model (a.k.a. metamodel or emulator) is an approximation of the original computational model:

$$\mathbf{x} \in \mathcal{D}_X \subset \mathbb{R}^d \mapsto y = G(\mathbf{x}) \quad (38.1)$$

which is constructed based on a limited number of runs of the true model, the so-called *experimental design*:

$$\mathcal{X} = \{\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(n)}\}. \quad (38.2)$$

Once a type of surrogate model is selected, the parameters have to be fitted based on the information contained in the experimental design \mathcal{X} and associated runs of the original computational model $\mathcal{Y} = \{y_i = G(\mathbf{x}^{(i)})\}, i = 1, \dots, n\}$. Then the accuracy of the surrogate shall be estimated by some kind of validation technique. For a general introduction to surrogate modeling, the reader is referred to [60] and to the recent review by Iooss and Lemaître [33].

In this chapter, we discuss two classes of surrogate models that are commonly used for sensitivity analysis, namely, *polynomial chaos expansions* (PCE) and *Gaussian processes* (GP). The reader is referred to the books of Santner et al. [52] and Rasmussen and Williams [49] for more detail about Gaussian process regression. The use of polynomial chaos expansions in the context of sensitivity analysis has been originally presented in Sudret [61, 63] using a nonintrusive least-square method. Other nonintrusive strategies for the calculation of PCE coefficients include spectral projection through sparse grids (e.g., Crestaux et al. [20], Buzzard and Xiu [17], Buzzard [16]) and sparse polynomial expansions (e.g., Blatman and Sudret [13]). In the last 5 years, numerous application examples have been developed using PCE for sensitivity analysis, e.g., Fajraoui et al. [28], Younes et al. [70], Brown et al. [15], and Sandoval et al. [51]. Recent extensions to problems with dependent input parameters can be found in Sudret and Caniou [65] and Munoz Zuniga et al. [46].

In parallel, Gaussian process modeling has been introduced in the context of sensitivity analysis by Welch et al. [68], Oakley and O'Hagan [48], and Marrel et al. [42, 43]. Recent developments in which metamodeling errors are taken into account in the analysis have been proposed by Le Gratiet et al. [38] and Chastaing and Le Gratiet [18].

The chapter first recalls the basics of the two approaches and details how they can be used to compute sensitivity indices. The two approaches are then compared on different benchmark examples as well as on an application in structural mechanics.

2 Polynomial Chaos Expansions

2.1 Mathematical Setup

Let us consider a computational model $G : \mathbf{x} \in \mathcal{D}_X \subset \mathbb{R}^d \mapsto y = G(\mathbf{x}) \in \mathbb{R}$. Suppose that the uncertainty in the input parameters is modeled by a random vector \mathbf{X} with prescribed joint probability density function (PDF) $f_X(\mathbf{x})$. The resulting (random) quantity of interest $Y = G(\mathbf{X})$ is obtained by propagating the uncertainty in \mathbf{X} through G . Assuming that Y has a finite variance (which is a physically meaningful assumption when dealing with physical systems), it belongs to the so-called Hilbert space of second-order random variables, which allows for the following spectral representation to hold [58]:

$$Y = \sum_{j=0}^{\infty} y_j Z_j. \quad (38.3)$$

The random variable Y is therefore cast as an infinite series, in which $\{Z_j\}_{j=0}^{\infty}$ is a numerable set of random variables (which form a basis of the Hilbert space), and $\{y_j\}_{j=0}^{\infty}$ are coefficients. The latter may be interpreted as the *coordinates* of Y in this basis. In the sequel we focus on *polynomial chaos expansions*, in which the basis terms $\{Z_j\}_{j=0}^{\infty}$ are multivariate orthonormal polynomials in the input vector \mathbf{X} , i.e., $Z_j = \Psi_j(\mathbf{X})$.

2.2 Polynomial Chaos Basis

In the sequel we assume that the input variables are statistically *independent*, so that the joint PDF is the product of the d marginal distributions: $f_X(\mathbf{x}) = \prod_{i=1}^d f_{X_i}(x_i)$, where the $f_{X_i}(x_i)$ are the marginal distributions of each variable $\{X_i, i = 1, \dots, d\}$ defined on \mathcal{D}_{X_i} . For each single variable X_i and any two functions $\phi_1, \phi_2 : x \in \mathcal{D}_{X_i} \mapsto \mathbb{R}$, we define the functional inner product by the following integral (provided it exists):

$$\langle \phi_1, \phi_2 \rangle_i \stackrel{\text{def}}{=} \mathbb{E} [\phi_1(X_i) \phi_2(X_i)] = \int_{\mathcal{D}_{X_i}} \phi_1(x) \phi_2(x) f_{X_i}(x) dx. \quad (38.4)$$

Using the above notation, classical algebra allows one to build a family of *orthogonal polynomials* $\{P_k^{(i)}, k \in \mathbb{N}\}$ satisfying:

$$\left\langle P_j^{(i)}, P_k^{(i)} \right\rangle_i \stackrel{\text{def}}{=} \mathbb{E} \left[P_j^{(i)}(X_i) P_k^{(i)}(X_i) \right] = \int_{\mathcal{D}_{X_i}} P_j^{(i)}(x) P_k^{(i)}(x) f_{X_i}(x) dx = a_j^{(i)} \delta_{jk}, \quad (38.5)$$

Table 38.1 Classical families of orthogonal polynomials (taken from Sudret [62])

Type of variable	Distribution	Orthogonal polynomials	Hilbertian basis $\psi_k(x)$
Uniform $\mathcal{U}(-1, 1)$	$\mathbf{1}_{[-1,1]}(x)/2$	Legendre $P_k(x)$	$P_k(x)/\sqrt{\frac{1}{2k+1}}$
Gaussian $\mathcal{N}(0, 1)$	$\frac{1}{\sqrt{2\pi}}e^{-x^2/2}$	Hermite $H_{ek}(x)$	$H_{ek}(x)/\sqrt{k!}$
Gamma $\Gamma(a, \lambda = 1)$	$x^a e^{-x} \mathbf{1}_{\mathbb{R}^+}(x)$	Laguerre $L_k^a(x)$	$L_k^a(x)/\sqrt{\frac{\Gamma(k+a+1)}{k!}}$
Beta $\mathcal{B}(a, b)$	$\mathbf{1}_{[-1,1]}(x) \frac{(1-x)^a(1+x)^b}{B(a)B(b)}$	Jacobi $J_k^{a,b}(x)$	$J_k^{a,b}(x)/\mathfrak{J}_{a,b,k}$
			$\mathfrak{J}_{a,b,k}^2 = \frac{2^{a+b+1}}{2k+a+b+1} \frac{\Gamma(k+a+1)\Gamma(k+b+1)}{\Gamma(k+a+b+1)\Gamma(k+1)}$

See, e.g., Abramowitz and Stegun [1]. In the above equation subscript k denotes the degree of the polynomial $P_k^{(i)}$, δ_{jk} is the Kronecker symbol equal to 1 when $j = k$ and 0 otherwise and $a_j^{(i)}$ corresponds to the squared norm of $P_j^{(i)}$:

$$a_j^{(i)} \stackrel{\text{def}}{=} \| P_j^{(i)} \|_i^2 = \left\langle P_j^{(i)}, P_j^{(i)} \right\rangle_i. \quad (38.6)$$

In general orthogonal bases may be obtained by applying the Gram-Schmidt orthogonalization procedure, e.g., to the canonical family of monomials $\{1, x, x^2, \dots\}$. For standard distributions, the associated families of orthogonal polynomials are well known [69]. For instance, if $X_i \sim \mathcal{U}(-1, 1)$ has a uniform distribution over $[-1, 1]$, the resulting family is that of the so-called *Legendre polynomials*. When $X_i \sim \mathcal{N}(0, 1)$ has a standard normal distribution with zero-mean value and unit standard deviation, the resulting family is that of the *Hermite polynomials*. The families associated to standard distributions are summarized in Table 38.1 (taken from Sudret [62]).

Note that the obtained family is usually not orthonormal. By enforcing normalization, an *orthonormal family* $\left\{ \psi_j^{(i)} \right\}_{j=0}^{\infty}$ is obtained from Eqs. (38.5), (38.6) as follows (see Table 38.1):

$$\psi_j^{(i)} = P_j^{(i)} / \sqrt{a_j^{(i)}} \quad i = 1, \dots, d, \quad j \in \mathbb{N}. \quad (38.7)$$

From the sets of univariate orthonormal polynomials, one can now build *multivariate* orthonormal polynomials with a *tensor product* construction. For this purpose let us define the multi-indices $\alpha \in \mathbb{N}^d$, which are ordered lists of integers:

$$\alpha = (\alpha_1, \dots, \alpha_d), \quad \alpha_i \in \mathbb{N}. \quad (38.8)$$

One can associate a multivariate polynomial Ψ_α to any multi-index α by:

$$\Psi_\alpha(\mathbf{x}) \stackrel{\text{def}}{=} \prod_{i=1}^d \psi_{\alpha_i}^{(i)}(x_i), \quad (38.9)$$

where the univariate polynomials $\{\psi_k^{(i)}, k \in \mathbb{N}\}$ are defined above, see Eqs. (38.5), (38.7). By virtue of Eq.(38.5) and the above tensor product construction, the multivariate polynomials in the input vector X are also orthonormal, i.e.:

$$\mathbb{E}[\Psi_\alpha(X)\Psi_\beta(X)] \stackrel{\text{def}}{=} \int_{\mathcal{D}_X} \Psi_\alpha(x)\Psi_\beta(x) f_X(x) dx = \delta_{\alpha\beta} \quad \forall \alpha, \beta \in \mathbb{N}^d, \quad (38.10)$$

where $\delta_{\alpha\beta}$ is the Kronecker symbol which is equal to 1 if $\alpha = \beta$ and zero otherwise. With this notation, it can be proven that the set of all multivariate polynomials in the input random vector X forms a basis of the Hilbert space in which $Y = G(X)$ is to be represented [58]:

$$Y = \sum_{\alpha \in \mathbb{N}^d} y_\alpha \Psi_\alpha(X). \quad (38.11)$$

2.3 Nonstandard Variables and Truncation Scheme

In practical sensitivity analysis problems, the input variables may not necessarily have standardized distributions as the ones described in Table 38.1. Thus *reduced variables* U with standardized distributions are introduced first through an isoprobabilistic transform:

$$X = \mathcal{T}(U). \quad (38.12)$$

For instance, when dealing with independent uniform distributions with support $\mathcal{D}_{X_i} = [a_i, b_i]$, $i = 1, \dots, d$, the isoprobabilistic transform reads:

$$X_i = \frac{a_i + b_i}{2} + \frac{b_i - a_i}{2} U_i \quad U_i \sim \mathcal{U}([-1, 1]). \quad (38.13)$$

In the case of Gaussian independent variables $\{X_i \sim \mathcal{N}(\mu_i, \sigma_i), i = 1, \dots, d\}$, the one-to-one mapping reads:

$$X_i = \mu_i + \sigma_i U_i, \quad U_i \sim \mathcal{N}(0, 1) \quad (38.14)$$

In the general case when the input variables are non-Gaussian (e.g., Gumbel distributions, see application in the last example of Sect. 4 of this chapter), the one-to-one mapping may be obtained as follows:

$$X_i = F_{X_i}^{-1}(\Phi(U_i)) \quad U_i \sim \mathcal{N}(0, 1) \quad (38.15)$$

where F_{X_i} (resp. Φ) is the cumulative distribution function (CDF) of variable X_i (resp. the standard normal CDF).

This isoprobabilistic transform approach also allows one to address problems with *dependent* variables. For instance, if the input vector X is defined by a set of marginal distributions and a Gaussian copula, it can be transformed into a set of independent standard normal variables using the Nataf transform [22, 40].

The representation of the random response in Eq. (38.11) is exact when the infinite series is considered. However, in practice, only a finite number of terms may be computed. For this purpose a *truncation scheme* has to be selected. Since the polynomial chaos basis consists of multivariate polynomials, it is natural to consider as a truncated series all the polynomials up to a given maximum degree. Let us define the *total degree* of a multivariate polynomial Ψ_α by:

$$|\alpha| \stackrel{\text{def}}{=} \sum_{i=1}^d \alpha_i. \quad (38.16)$$

The *standard truncation scheme* consists in selecting all polynomials such that $|\alpha|$ is smaller than or equal to a given p . This leads to a set of polynomials denoted by $\mathcal{A}^{d,p} = \{\alpha \in \mathbb{N}^d : |\alpha| \leq p\}$ of cardinality:

$$\text{card } \mathcal{A}^{d,p} = \binom{d+p}{p} = \frac{(d+p)!}{d! p!}. \quad (38.17)$$

The maximal polynomial degree p may typically be equal to $3 - 5$ in practical applications. Note that the cardinality of $\mathcal{A}^{d,p}$ increases exponentially with d and p . Thus the number of terms in the series, i.e., the number of coefficients to be computed, increases dramatically when d is large, say $d > 10$. This complexity is referred to as the *curse of dimensionality*. This issue may be solved using specific algorithms to compute sparse PCE, see, e.g., Blatman and Sudret [14], and Doostan and Owhadi [23].

2.4 Computation of the Coefficients and Error Estimation

The use of polynomial chaos expansions has emerged in the late 1980s in uncertainty quantification problems under the form of *stochastic finite element methods* [29]. In this setup the constitutive equations of the physical problem are discretized both in the physical space (using standard finite element techniques) and in the random space using polynomial chaos expansion. This results in coupled systems of equations which require ad hoc solvers, thus the term “intrusive approach.”

Nonintrusive techniques such as projection or stochastic collocation have emerged in the last decade as a means to compute the coefficients of PC expansions from repeated evaluations of the existing model G considered as a black-box function. In this section we focus on a particular nonintrusive approach based on least-square analysis.

Following Berveiller et al. [7, 8], the computation of the PCE coefficients may be cast as a least-square minimization problem (originally termed “regression” problem) as follows: once a truncation scheme $\mathcal{A} \subset \mathbb{N}^d$ is chosen (for instance, $\mathcal{A} = \mathcal{A}^{d,p}$), the infinite series is recast as the sum of the truncated series and a residual:

$$Y = G(X) = \sum_{\alpha \in \mathcal{A}} y_\alpha \Psi_\alpha(X) + \varepsilon, \quad (38.18)$$

in which ε corresponds to all those PC polynomials whose index α is not in the truncation set \mathcal{A} . The least-square minimization approach consists in finding the set of coefficients $\mathbf{y} = \{y_\alpha, \alpha \in \mathcal{A}\}$ which minimizes the mean-square error:

$$\mathbb{E}[\varepsilon^2] \stackrel{\text{def}}{=} \mathbb{E} \left[\left(G(X) - \sum_{\alpha \in \mathcal{A}} y_\alpha \Psi_\alpha(X) \right)^2 \right]. \quad (38.19)$$

The set of coefficients \mathbf{y} is computed at once by solving:

$$\mathbf{y} = \arg \min_{\mathbf{y} \in \mathbb{R}^{\text{card } \mathcal{A}}} \mathbb{E} \left[\left(G(X) - \sum_{\alpha \in \mathcal{A}} y_\alpha \Psi_\alpha(X) \right)^2 \right]. \quad (38.20)$$

In practice the discretized version of the problem is obtained by replacing the expectation operator in Eq. (38.20) by the empirical mean over a sample set:

$$\hat{\mathbf{y}} = \arg \min_{\mathbf{y} \in \mathbb{R}^{\text{card } \mathcal{A}}} \frac{1}{N} \sum_{i=1}^N \left(G(\mathbf{x}^{(i)}) - \sum_{\alpha \in \mathcal{A}} y_\alpha \Psi_\alpha(\mathbf{x}^{(i)}) \right)^2. \quad (38.21)$$

In this expression, $\mathcal{X} = \{\mathbf{x}^{(i)}, i = 1, \dots, n\}$ is a sample set of points called *experimental design* (ED) that is typically obtained by Monte Carlo simulation of the input random vector X . To solve the least-square minimization problem in Eq. (38.21), the computational model G is first run for each point in the ED, and the results are stored in a vector $\mathcal{Y} = \{y^{(1)} = G(\mathbf{x}^{(1)}), \dots, y^{(n)} = G(\mathbf{x}^{(n)})\}^\top$. Then the so-called *information matrix* is calculated from the evaluation of the basis polynomials onto each point in the ED:

$$\mathbf{A} = \left\{ \mathbf{A}_{ij} \stackrel{\text{def}}{=} \Psi_j(\mathbf{x}^{(i)}), i = 1, \dots, n, j = 1, \dots, \text{card } \mathcal{A} \right\}. \quad (38.22)$$

The solution of the least-square minimization problem finally reads:

$$\hat{\mathbf{y}} = (\mathbf{y} \mathbf{A}^\top \mathbf{A})^{-1} \mathbf{A}^\top \mathcal{Y}. \quad (38.23)$$

The points used in the experimental design may be obtained from crude Monte Carlo simulation. However other types of designs are of common use, especially Latin hypercube sampling (LHS), see McKay et al. [45], or quasi-random sequences such as the Sobol' or Halton sequence [47]. The size of the experimental design is of crucial importance: it must be larger than the number of unknowns $\text{card } \mathcal{A}$ for the problem to be well posed. In practice we use the thumb rule $n \approx 2\text{--}3 \text{ card } \mathcal{A}$ [10].

The simple least-square approach summarized above does not allow one to cope with the curse of dimensionality. Indeed the standard truncation scheme requires approximately $3 \cdot \binom{d+p}{p}$ runs of the original model $G(\mathbf{x})$, which is in the order of 10^4 when, e.g., $d \geq 15$, $p \geq 5$. However, in practice most of the problems lead eventually to *sparse expansions*, i.e., PCE in which most of the coefficients are zero or negligible. In order to find directly the significant polynomials and associated coefficients, sparse PCEs have been introduced recently by Blatman and Sudret [11, 12], and Bieri and Schwab [9]. The recent developments make use of specific selection algorithms which, by solving a penalized least-square problem, lead by construction to sparse expansions. Of interest in this chapter is the use of the *least-angle regression* algorithm (LAR, Efron et al. [27]), which was introduced in the field of uncertainty quantification by Blatman and Sudret [14]. Details can be found in Sudret [64]. Note that other techniques based on compressive sensing have also been developed recently, see, e.g., Doostan and Owhadi [23], Sargsyan et al. [53], and Jakeman et al. [34].

2.5 Error Estimation

The truncation of the polynomial chaos expansion introduces an approximation error which may be computed a posteriori. Based on the data contained in the experimental design, the *empirical error* may be computed from Eq. (38.21) once least-square minimization problem has been solved:

$$\varepsilon_{\text{emp}} = \frac{1}{N} \sum_{i=1}^N \left(G(\mathbf{x}^{(i)}) - \sum_{\alpha \in \mathcal{A}} \hat{y}_\alpha \Psi_\alpha(\mathbf{x}^{(i)}) \right)^2. \quad (38.24)$$

However, this estimator usually underestimates severely the mean-square error in Eq. (38.19). In particular, if the size N of the experimental design is close to the number of unknown coefficients $\text{card } \mathcal{A}$, the empirical error tends to zero, whereas the true mean square error does not.

A more robust error estimator can be derived based on the *cross-validation* technique. The experimental design is split into a training set and a validation set: the coefficients of the expansion are computed using the training set (Eq. (38.21)), whereas the error is estimated using the validation set. The *leave-one-out* cross-validation is a particular case in which all points but one are used to compute the coefficients. Setting aside $\mathbf{x}^{(i)} \in \mathcal{X}$, a PCE denoted by $G^{\text{PC}\backslash i}(X)$ is built up using

the experimental design $\mathcal{X} \setminus \mathbf{x}^{(i)} \stackrel{\text{def}}{=} \{\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(i-1)}, \mathbf{x}^{(i+1)}, \dots, \mathbf{x}^{(n)}\}$. Then the error is computed at point $\mathbf{x}^{(i)}$:

$$\Delta_i \stackrel{\text{def}}{=} G(\mathbf{x}^{(i)}) - G^{\text{PC}\setminus i}(\mathbf{x}^{(i)}). \quad (38.25)$$

The LOO error is defined by:

$$\varepsilon_{\text{LOO}} = \frac{1}{n} \sum_{i=1}^n \Delta_i^2 = \frac{1}{n} \sum_{i=1}^n \left(G(\mathbf{x}^{(i)}) - G^{\text{PC}\setminus i}(\mathbf{x}^{(i)}) \right)^2. \quad (38.26)$$

After some algebra this reduces to:

$$\varepsilon_{\text{LOO}} = \frac{1}{n} \sum_{i=1}^n \left(\frac{G(\mathbf{x}^{(i)}) - G^{\text{PC}}(\mathbf{x}^{(i)})}{1 - h_i} \right)^2, \quad (38.27)$$

where h_i is the i -th diagonal term of the projection matrix $\mathbf{A}(\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T$ (matrix \mathbf{A} is defined in Eq. (38.22)) and $G^{\text{PC}}(\cdot)$ is now the PC expansion built up from the *full* experimental design \mathcal{X} .

As a conclusion, when using a least-square minimization technique to compute the coefficients of a PC expansion, an *a posteriori* estimator of the mean-square error is readily available. This allows one to compare PCEs obtained from different truncation schemes and select the best one according to the leave-one-out error estimate.

2.6 Post-processing for Sensitivity Analysis

2.6.1 Statistical Moments

The truncated PC expansion $\hat{Y} = G^{\text{PC}}(\mathbf{X}) = \sum_{\alpha \in \mathcal{A}} \hat{y}_\alpha \Psi_\alpha(\mathbf{X})$ contains all the information about the statistical properties of the random output $Y = G(\mathbf{X})$. Due to the orthogonality of the PC basis, mean and standard deviation of \hat{Y} may be computed directly from the coefficients \hat{y} . Indeed, since $\Psi_0 \equiv 1$, we get $\mathbb{E}[\Psi_\alpha(\mathbf{X})] = 0 \quad \forall \alpha \neq 0$. Thus the mean value of \hat{Y} is the first term of the series:

$$\mathbb{E}[\hat{Y}] = \mathbb{E} \left[\sum_{\alpha \in \mathcal{A}} \hat{y}_\alpha \Psi_\alpha(\mathbf{X}) \right] = \hat{y}_0. \quad (38.28)$$

Similarly, due to Eq. (38.10) the variance of \hat{Y} may be cast as:

$$\sigma_{\hat{Y}}^2 \stackrel{\text{def}}{=} \text{Var}[\hat{Y}] = \mathbb{E} \left[(\hat{Y} - \hat{y}_0)^2 \right] = \sum_{\substack{\alpha \in \mathcal{A} \\ \alpha \neq 0}} \hat{y}_\alpha^2. \quad (38.29)$$

In other words the mean and variance of the random response may be obtained by a mere combination of the PCE coefficients once the latter have been computed.

2.6.2 Sobol' Decomposition and Indices

As previously discussed in ► Chap. 35, “Variance-Based Sensitivity Analysis: Theory and Estimation Algorithms” global sensitivity analysis is based on Sobol' decomposition of the computational model G (a.k.a *generalized ANOVA decomposition*), which reads [55]:

$$G(\mathbf{x}) = G_0 + \sum_{i=1}^d G_i(x_i) + \sum_{1 \leq i < j \leq d} G_{ij}(x_i, x_j) + \cdots + G_{12\dots d}(\mathbf{x}), \quad (38.30)$$

that is, as a sum of a constant G_0 , univariate functions $\{G_i(x_i), 1 \leq i \leq d\}$, bivariate functions $\{G_{ij}(x_i, x_j), 1 \leq i < j \leq d\}$, etc. A recursive construction is obtained by the following recurrence relationship:

$$\begin{aligned} G_0 &= \mathbb{E}[G(\mathbf{X})] \\ G_i(x_i) &= \mathbb{E}[G(\mathbf{X})|X_i = x_i] - G_0 \\ G_{ij}(x_i, x_j) &= \mathbb{E}[G(\mathbf{X})|X_i, X_j = x_i, x_j] - G_i(x_i) - G_j(x_j) - G_0. \end{aligned} \quad (38.31)$$

Using the *set notation* for indices:

$$A \stackrel{\text{def}}{=} \{i_1, \dots, i_s\} \subset \{1, \dots, d\}, \quad (38.32)$$

the Sobol' decomposition in Eq. (38.30) reads:

$$G(\mathbf{x}) = G_0 + \sum_{\substack{A \subset \{1, \dots, d\} \\ A \neq \emptyset}} G_A(\mathbf{x}_A), \quad (38.33)$$

where \mathbf{x}_A is a subvector of \mathbf{x} which only contains the components that belong to the index set A . It can be proven that the summands are orthogonal with each other:

$$\mathbb{E}[G_A(\mathbf{x}_A) G_B(\mathbf{x}_B)] = 0 \quad \forall A, B \subset \{1, \dots, d\}, \quad A \neq B. \quad (38.34)$$

Using this orthogonality property, one can decompose the variance of the model output:

$$V \stackrel{\text{def}}{=} \text{Var}[Y] = \text{Var} \left[\sum_{\substack{A \subset \{1, \dots, d\} \\ A \neq \emptyset}} G_A(\mathbf{x}_A) \right] = \sum_{\substack{A \subset \{1, \dots, d\} \\ A \neq \emptyset}} \text{Var}[G_A(\mathbf{x}_A)] \quad (38.35)$$

as the sum of so-called *partial variances* defined by:

$$V_A \stackrel{\text{def}}{=} \text{Var}[G_A(X_A)] = \mathbb{E}[G_A^2(X_A)]. \quad (38.36)$$

The Sobol' index attached to each subset of variables $A \stackrel{\text{def}}{=} \{i_1, \dots, i_s\} \subset \{1, \dots, d\}$ is finally defined by:

$$S_A = \frac{V_A}{V} = \frac{\text{Var}[G_A(X_A)]}{\text{Var}[Y]}. \quad (38.37)$$

First-order Sobol' indices quantify the portion of the total variance V that can be apportioned to the sole input variable X_i :

$$S_i = \frac{V_i}{V} = \frac{\text{Var}[G_i(X_i)]}{\text{Var}[Y]}. \quad (38.38)$$

Second-order indices quantify the joint effect of variables (X_i, X_j) that cannot be explained by each single variable separately:

$$S_{ij} = \frac{V_{ij}}{V} = \frac{\text{Var}[G_{ij}(X_i, X_j)]}{\text{Var}[Y]}. \quad (38.39)$$

Finally, *total* Sobol' indices S_i^{tot} quantify the total impact of a given parameter X_i including all of its interactions with other variables. They may be computed by the sum of the Sobol' indices of any order that contain X_i :

$$S_i^{\text{tot}} = \sum_{A \ni i} S_A. \quad (38.40)$$

Among other methods, Monte Carlo estimators of the various indices are available in the literature and thoroughly discussed in (see ▶ Chap. 35, “[Variance-Based Sensitivity Analysis: Theory and Estimation Algorithms](#)”). Their computation usually requires 10^{3-4} runs of the model G for each index, which leads to a global computational cost that is not affordable when G is expensive to evaluate.

2.6.3 Sobol' Indices and PC Expansions

As can be seen by comparing Eqs. (38.18) and (38.33), both polynomial chaos expansions and Sobol' decomposition are sums of orthogonal functions. Taking advantage of this property, it is possible to derive *analytic expressions* for Sobol' indices based on a PC expansion, as originally shown in Sudret [61, 63]. For this purpose let us consider the set of multivariate polynomials Ψ_α which depend *only* on a subset of variables $A = \{i_1, \dots, i_s\} \subset \{1, \dots, d\}$:

$$\mathcal{A}_A = \{\alpha \in \mathcal{A} : \alpha_k \neq 0 \text{ if and only if } k \in A\}. \quad (38.41)$$

The union of all these sets is by construction equal to \mathcal{A} . Thus we can reorder the terms of the truncated PC expansion so as to exhibit the Sobol' decomposition:

$$G^{\text{PC}}(\mathbf{x}) = y_0 + \sum_{\substack{A \subset \{1, \dots, d\} \\ A \neq \emptyset}} G_A^{\text{PC}}(\mathbf{x}_A) \quad \text{where} \quad G_A^{\text{PC}}(\mathbf{x}_A) \stackrel{\text{def}}{=} \sum_{\alpha \in \mathcal{A}_A} y_\alpha \Psi_\alpha(\mathbf{x}). \quad (38.42)$$

Consequently, due to the orthogonality of the PC basis, the partial variance V_A reduces to:

$$V_A = \text{Var}\left[G_A^{\text{PC}}(\mathbf{x}_A)\right] = \sum_{\alpha \in \mathcal{A}_A} y_\alpha^2. \quad (38.43)$$

In other words, from a given PC expansion, the Sobol' indices *at any order* may be obtained by a mere combination of the squares of the coefficients. More specifically, the PC-based estimator of the first-order Sobol' indices read:

$$\hat{S}_i = \frac{\sum_{\alpha \in \mathcal{A}_i} \hat{y}_\alpha^2}{\sum_{\alpha \in \mathcal{A}, \alpha \neq 0} \hat{y}_\alpha^2} \quad \text{where} \quad \mathcal{A}_i = \{\alpha \in \mathcal{A} : \alpha_i > 0, \alpha_j \neq i = 0\}. \quad (38.44)$$

and the total PC-based Sobol' indices read:

$$\hat{S}_i^{\text{tot}} = \frac{\sum_{\alpha \in \mathcal{A}_i^{\text{tot}}} \hat{y}_\alpha^2}{\sum_{\alpha \in \mathcal{A}, \alpha \neq 0} \hat{y}_\alpha^2} \quad \mathcal{A}_i^{\text{tot}} = \{\alpha \in \mathcal{A} : \alpha_i > 0\}. \quad (38.45)$$

2.7 Summary

Polynomial chaos expansions allow one to cast the random response $G(X)$ as a truncated series expansion. By selecting an orthonormal basis w.r.t. the input parameter distributions, the corresponding coefficients can be given a straightforward interpretation: the first coefficient y_0 is the mean value of the model output, whereas the variance is the sum of the squares of the remaining coefficients. Similarly, the Sobol' indices are obtained by summing up the squares of suitable coefficients. Note that in low dimension ($d < 10$), the coefficients can be computed by solving a mere ordinary least-square problem. In higher dimensions advanced techniques leading to sparse expansions must be used to keep the total computational cost (measured in terms of the size N of the experimental design) affordable. Yet the post-processing to get the Sobol' indices from the PCE coefficients is independent of the technique used.

3 Gaussian Process-Based Sensitivity Analysis

3.1 A Short Introduction to Gaussian Processes

Let us consider a probability space $(\Omega_Z, \mathcal{F}_Z, \mathbb{P}_Z)$, a measurable space $(\mathcal{S}, \mathcal{B}(\mathcal{S}))$ and an arbitrary set T . A stochastic process $Z(\mathbf{x})$, $\mathbf{x} \in T$, is Gaussian if and only if, for any finite subset $C \subset T$, the collection of random variables $Z(C)$ has a Gaussian joint distribution. In our framework, T and S represent the input and the output spaces. Therefore, we have $T = \mathbb{R}^d$ and $S = \mathbb{R}$.

A Gaussian process is entirely specified by its mean $m(\mathbf{x}) = \mathbb{E}_Z[Z(\mathbf{x})]$ and covariance function $k(\mathbf{x}, \mathbf{x}') = \text{cov}_Z(Z(\mathbf{x}), Z(\mathbf{x}'))$ where \mathbb{E}_Z and cov_Z denote the expectation and the covariance with respect to $(\Omega_Z, \mathcal{F}_Z, \mathbb{P}_Z)$. The covariance function $k(\mathbf{x}, \mathbf{x}')$ is a positive definite kernel. It is often considered stationary, i.e., $k(\mathbf{x}, \mathbf{x}')$ is a function of $\mathbf{x} - \mathbf{x}'$. The covariance kernel is the most important term of a Gaussian process regression. Indeed, it controls the smoothness and the scale of the approximation. A popular choice for $k(\mathbf{x}, \mathbf{x}')$ is the stationary isotropic squared exponential kernel defined as :

$$k(\mathbf{x}, \mathbf{x}') = \sigma^2 \exp\left(-\frac{1}{2\theta^2} \|\mathbf{x} - \mathbf{x}'\|^2\right).$$

It is parametrized by the parameter θ – also called characteristic length scale or correlation length – and the variance parameter σ^2 . We give in Fig. 38.1 examples of realizations of Gaussian processes with stationary isotropic squared exponential kernels.

We observe that $m(\mathbf{x})$ is the trend around which the realizations vary, σ^2 controls the range of their variation, and θ controls their oscillation frequencies. We highlight that Gaussian processes with squared exponential covariance kernels are infinitely differentiable almost surely. As mentioned in [59], this choice of kernel can be unrealistic due to its strong regularity.

3.2 Gaussian Process Regression Models

The principle of Gaussian process regression is to consider that the prior knowledge about the computational model $G(\mathbf{x})$, $\mathbf{x} \in \mathbb{R}^d$, can be *modeled* by a Gaussian process $Z(\mathbf{x})$ with a mean denoted by $m(\mathbf{x})$ and a covariance kernel denoted by $k(\mathbf{x}, \mathbf{x}')$. Roughly speaking, we consider that the true response is a realization of $Z(\mathbf{x})$. Usually, the mean and the covariance are parametrized as follows:

$$m(\mathbf{x}) = \mathbf{f}^\top(\mathbf{x})\boldsymbol{\beta}, \quad (38.46)$$

and

$$k(\mathbf{x}, \mathbf{x}') = \sigma^2 r(\mathbf{x}, \mathbf{x}'; \boldsymbol{\theta}), \quad (38.47)$$

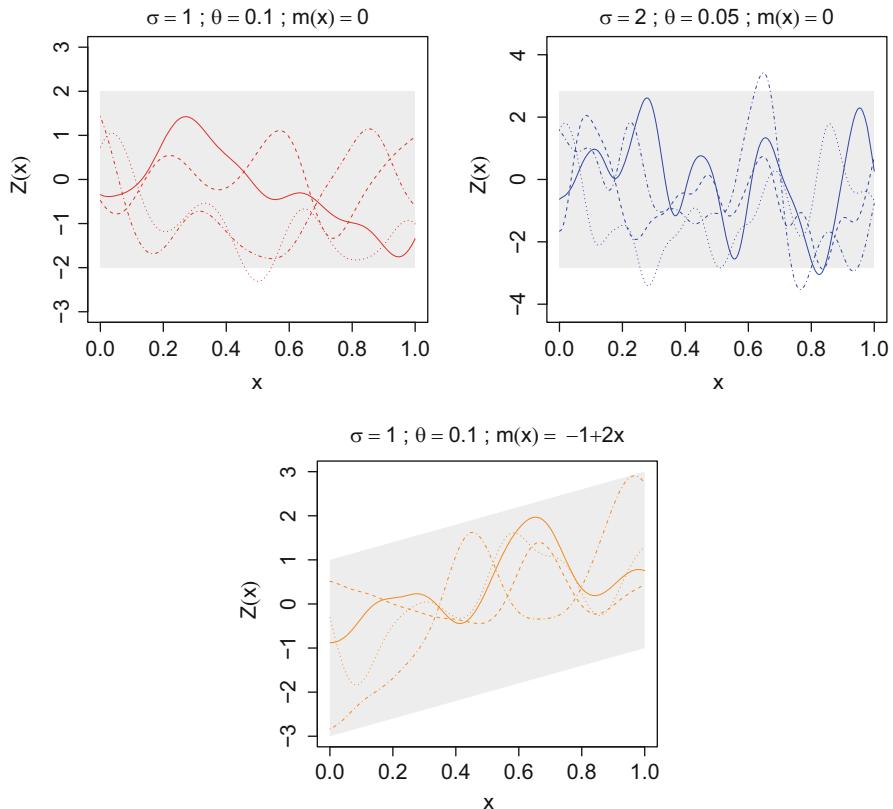

Fig. 38.1 Examples of Gaussian process realizations with squared exponential kernels and different means. The *shaded areas* represent the point-wise 95% confidence intervals

where $\mathbf{f}^T(\mathbf{x})$ is a vector of p prescribed functions, and $\boldsymbol{\beta}$, σ^2 , and $\boldsymbol{\theta}$ have to be estimated. The mean function $m(\mathbf{x})$ describes the trend and the covariance kernel $k(\mathbf{x}, \mathbf{x}')$ describes the regularity and characteristic length scale of the model.

3.2.1 Predictive Distribution

Consider an experimental design $\mathcal{X} = \{\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(n)}\}$, $\mathbf{x}^{(i)} \in \mathbb{R}^d$ and the corresponding model responses $\mathcal{Y} = G(\mathcal{X})$. The predictive distribution of $G(\mathbf{x})$ is given by:

$$[Z(\mathbf{x}) | Z(\mathcal{X}) = \mathcal{Y}, \sigma^2, \boldsymbol{\theta}] \sim \text{GP}(m_n(\mathbf{x}), k_n(\mathbf{x}, \mathbf{x}')), \quad (38.48)$$

where GP stands for “Gaussian Process,”

$$m_n(\mathbf{x}) = \mathbf{f}^T(\mathbf{x})\bar{\boldsymbol{\beta}} + \mathbf{r}^T(\mathbf{x})\mathbf{R}^{-1}(\mathcal{Y} - \mathbf{F}\bar{\boldsymbol{\beta}}), \quad (38.49)$$

$$k_n(\mathbf{x}, \mathbf{x}') = \sigma^2 \left(1 - (\mathbf{f}^\top(\mathbf{x}) \mathbf{r}^\top(\mathbf{x})) \begin{pmatrix} 0 & \mathbf{F}^\top \\ \mathbf{F} & \mathbf{R} \end{pmatrix} \begin{pmatrix} \mathbf{f}(\mathbf{x}') \\ \mathbf{r}(\mathbf{x}') \end{pmatrix} \right). \quad (38.50)$$

In these expressions $\mathbf{R} = [r(\mathbf{x}^i, \mathbf{x}^j; \boldsymbol{\theta})]_{i,j=1,\dots,n}$, $\mathbf{r}(\mathbf{x}) = [r(\mathbf{x}, \mathbf{x}^{(i)}; \boldsymbol{\theta})]_{i=1,\dots,n}$, $\mathbf{F} = [\mathbf{f}^\top(\mathbf{x}^{(i)})]_{i=1,\dots,n}$ and

$$\bar{\boldsymbol{\beta}} = (\mathbf{F}^\top \mathbf{R}^{-1} \mathbf{F})^{-1} \mathbf{F}^\top \mathbf{R}^{-1} \mathcal{Y}. \quad (38.51)$$

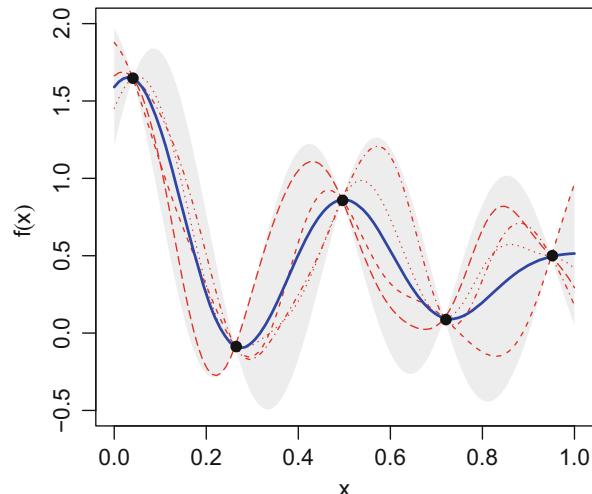

The term $\bar{\boldsymbol{\beta}}$ denotes the posterior distribution mode of $\boldsymbol{\beta}$ obtained from the improper non-informative prior distribution $\pi(\boldsymbol{\beta}) \propto 1$ [50].

Remark. The predictive distribution is given by the Gaussian process $Z(\mathbf{x})$ conditioned by the known observations \mathcal{Y} . The Gaussian process regression metamodel is given by the conditional expectation $m_n(x)$ and its mean-square error is given by the conditional variance $k_n(\mathbf{x}, \mathbf{x})$. An illustration of $m_n(x)$ and $k_n(\mathbf{x}, \mathbf{x})$ is given in Fig. 38.2.

The reader can note that the predictive distribution (38.48) integrates the posterior distribution of $\boldsymbol{\beta}$. However, the hyper-parameters σ^2 and $\boldsymbol{\theta}$ are not known in practice and shall be estimated with the maximum likelihood method [32, 52] or a cross-validation strategy [3]. Then, their estimates are plugged in the predictive distribution. The restricted maximum likelihood estimate of σ^2 is given by:

$$\hat{\sigma}^2 = \frac{(\mathcal{Y} - \mathbf{F}\bar{\boldsymbol{\beta}})^\top \mathbf{R}^{-1} (\mathcal{Y} - \mathbf{F}\bar{\boldsymbol{\beta}})}{n - p}. \quad (38.52)$$

Fig. 38.2 Examples of predictive distribution. The *solid line* represents the mean of the predictive distribution, the *nonsolid lines* represent some of its realizations, and the *shaded area* represents the 95% confidence intervals based on the variance of the predictive distribution

Unfortunately, such a closed form expression does not exist for θ and it has to be numerically estimated.

Remark. Gaussian process regression can easily be extended to the case of noisy observations. Let us suppose that \mathcal{Y} is tainted by a white Gaussian noise ε :

$$\mathcal{Y}_{\text{obs}} = \mathcal{Y} + \sigma_\varepsilon(\mathbf{X})\varepsilon.$$

The term $\sigma_\varepsilon(\mathbf{X})$ represents the standard deviation of the observation noise. The mean and the covariance of the predictive distribution $[Z(\mathbf{x})_{\text{obs}} | Z(\mathbf{X}) = \mathcal{Y}_{\text{obs}}, \sigma^2, \theta]$ is then obtained by replacing in Equations (38.49), (38.50), and (38.51) the correlation matrix \mathbf{R} by $\sigma^2 \mathbf{R} + \Delta_\varepsilon$ where Δ_ε is a diagonal matrix given by :

$$\Delta_\varepsilon = \begin{pmatrix} \sigma_\varepsilon(\mathbf{x}^{(1)}) & & & \\ & \sigma_\varepsilon(\mathbf{x}^{(2)}) & & \\ & & \ddots & \\ & & & \sigma_\varepsilon(\mathbf{x}^{(n)}) \end{pmatrix}.$$

We emphasize that the closed form expression for the restricted maximum likelihood estimate of σ^2 does not exist anymore. Therefore, this parameter has to be numerically estimated.

3.2.2 Sequential Design

To improve the global accuracy of the GP model, it is usual to augment the initial design set \mathbf{X} with new points. An important feature of Gaussian process regression is that it provides an estimate of the model mean-square error through the term $k_n(\mathbf{x}, \mathbf{x}')$ (38.50) which can be used to select these new points. The most common but not efficient sequential criterion consists in adding the point $\mathbf{x}^{(n+1)}$ where the mean-square error is the largest:

$$\mathbf{x}^{(n+1)} = \arg \max_{\mathbf{x}} k_n(\mathbf{x}, \mathbf{x}). \quad (38.53)$$

More efficient criteria can be found in Bates et al. [4], van Beers and Kleijnen [6], and Le Gratiet and Cannamela [37].

3.2.3 Model Selection

To build up a GP model, the user has to make several choices. Indeed, the vector of functions $\mathbf{f}(\mathbf{x})$ and the class of the correlation kernel $r(\mathbf{x}, \mathbf{x}'; \theta)$ need to be set (see Rasmussen and Williams [49] for different examples of correlation kernels). These choices and the relevance of the model are tested a posteriori with a validation procedure. If the number n of observations is large, an external validation may be performed on a test set. Otherwise, a cross-validation procedure may be used. An interesting property of GP models is that a closed form expression exists for the

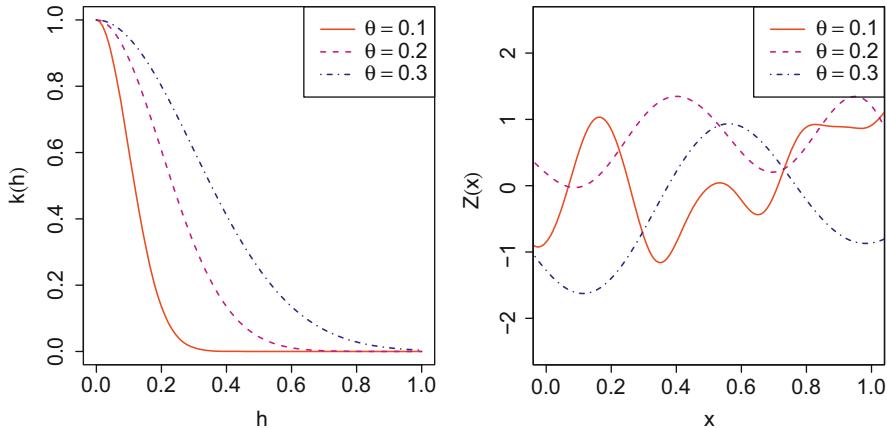

Fig. 38.3 The squared exponential kernel in function of $h = |x - x'|$ with different correlation lengths θ and examples of resulting Gaussian process realizations

cross-validation predictive distribution, see for instance Dubrule [25]. It allows for deriving efficient methods of parameter estimation [3] or sequential design [37].

Some usual stationary covariance kernel are listed below.

The squared exponential covariance function. The form of this kernel is given by:

$$k(\mathbf{x}, \mathbf{x}') = \sigma^2 \exp\left(-\frac{1}{2\theta^2} \|\mathbf{x} - \mathbf{x}'\|^2\right).$$

This covariance function corresponds to Gaussian processes which are infinitely differentiable in mean square and almost surely. We illustrate in Fig. 38.3 the one-dimensional squared exponential kernel with different correlation lengths and examples of resulting Gaussian process realizations.

The ν -Matérn covariance function. This covariance kernel is defined as follow (see [59]):

$$k_\nu(h) = \frac{2^{1-\nu}}{\Gamma(\nu)} \left(\frac{\sqrt{2}||h||}{\theta} \right)^\nu K_\nu \left(\frac{\sqrt{2}\nu||h||}{\theta} \right),$$

where ν is the regularity parameter, K_ν is a modified Bessel function, and Γ is the Euler Gamma function. A Gaussian process with a ν -Matérn covariance kernel is ν -Hölder continuous in mean square and ν' -Hölder continuous almost

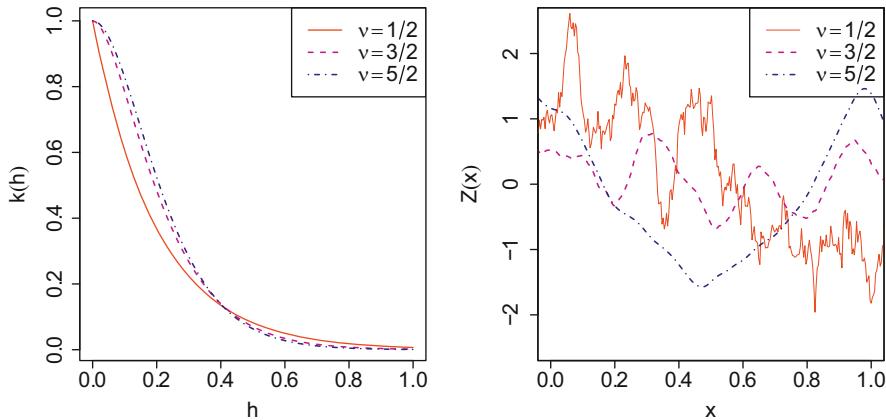

Fig. 38.4 The ν -Matérn kernel in function of $h = x - x'$ with different regularity parameters ν and examples of resulting Gaussian process realizations

surely with $\nu' < \nu$. Three popular choices of ν -Matérn covariance kernels are the ones for $\nu = 1/2$, $\nu = 3/2$, and $\nu = 5/2$:

$$k_{\nu=1/2}(h) = \exp\left(-\frac{\|h\|}{\theta}\right),$$

$$k_{\nu=3/2}(h) = \left(1 + \frac{\sqrt{3}\|h\|}{\theta}\right) \exp\left(-\frac{\sqrt{3}\|h\|}{\theta}\right),$$

and

$$k_{\nu=5/2}(h) = \left(1 + \frac{\sqrt{5}\|h\|}{\theta} + \frac{5\|h\|^2}{3\theta^2}\right) \exp\left(-\frac{\sqrt{5}\|h\|}{\theta}\right).$$

We illustrate in Fig. 38.4 the one-dimensional ν -Matérn kernel for different values of ν .

The γ -exponential covariance function. This kernel is defined as follow:

$$k_\gamma(h) = \exp\left(-\left(\frac{\|h\|}{\theta}\right)^\gamma\right).$$

For $\gamma < 2$ the corresponding Gaussian process are not differentiable in mean square, whereas for $\gamma = 2$ it is infinitely differentiable (it corresponds to the squared exponential kernel). We illustrate in Fig. 38.5 the one-dimensional γ -exponential kernel for different values of γ .

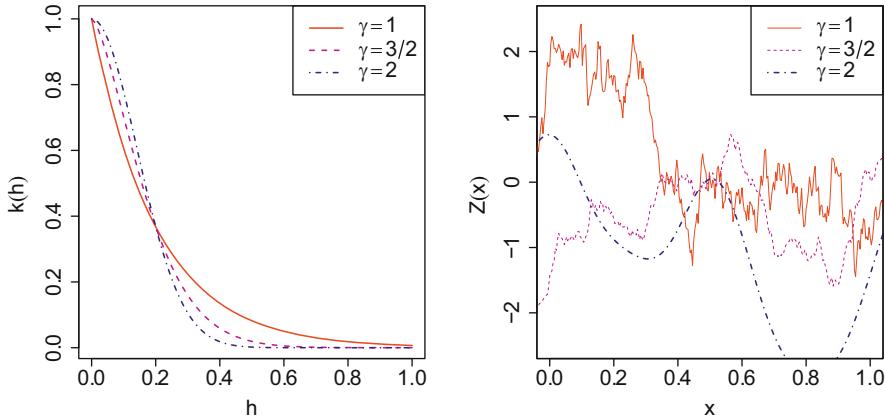

Fig. 38.5 The γ -exponential kernel in function of $h = \mathbf{x} - \mathbf{x}'$ with different regularity parameters γ and examples of resulting Gaussian process realizations

3.2.4 Sensitivity Analysis

To perform a sensitivity analysis from a GP model, two approaches are possible. The first one consists in substituting the true model $G(\mathbf{x})$ with the mean of the conditional Gaussian process $m_n(\mathbf{x})$ in (38.49). Then, a sensitivity analysis can be performed on the mean $m_n(\mathbf{x})$. This approach is used in Durrande et al. [26] which develops a class of covariance kernels dedicated to sensitivity analysis. However, it may provide biased sensitivity index estimates. Furthermore it does not allow one to quantify the error on the sensitivity indices due to the metamodel approximation. The second one consists in substituting $G(\mathbf{x})$ by a Gaussian process $Z_n(\mathbf{x})$ having the predictive distribution $[Z(\mathbf{x})|Z(\mathcal{X}) = \mathcal{Y}, \sigma^2, \theta]$ shown in (38.48) (see Oakley and O'Hagan [48], Marrel et al. [43], Le Gratiet et al. [38], Chastaing and Le Gratiet [18]). This approach makes it possible to quantify the uncertainty due to the metamodel approximation and allows for building unbiased index estimates.

Other interesting works on GP-based sensitivity analysis are the ones of Gramacy et al. [31], Gramacy and Taddy [30] to take into account non-stationarities, Storlie et al. [60] where a comparison between various metamodels with GP is performed, and Svenson et al. [67] to deal with massive data corrupted by a noise.

3.3 Main Effects Visualization

From now on, the input parameter $\mathbf{x} \in \mathbb{R}^d$ is considered as a random input vector $\mathbf{X} = (X_1, \dots, X_d)$ with independent components. Before focusing on variance-based sensitivity indices, the inference about the main effects is studied in this section. Main effects are a powerful tool to visualize the impact of each input variable on the model output (see, e.g., Oakley and O'Hagan [48]). The main effect of the group of input variables \mathbf{X}_A , $A \subset \{1, \dots, d\}$ is defined by $\mathbb{E}[G(\mathbf{X})|\mathbf{X}_A]$.

Since the original model G may be time-consuming to evaluate, it is substituted for by its approximation, i.e., $G(\mathbf{X}) \approx \mathbb{E}[Z_n(\mathbf{X})|\mathbf{X}_A]$, where $Z_n(\mathbf{x}) \sim [Z(\mathbf{x})|Z(\mathcal{X}) = \mathcal{Y}, \sigma^2, \theta]$. Since $\mathbb{E}[Z_n(\mathbf{X})|\mathbf{X}_A]$ is a linear transformation of the Gaussian process $Z_n(\mathbf{x})$, it is also a Gaussian process. The expectations, variances, and covariances with respect to the posterior distribution of $[Z(\mathbf{x})|Z(\mathcal{X}) = \mathcal{Y}, \sigma^2, \theta]$ are denoted by $\mathbb{E}_Z[\cdot]$, $\text{Var}_Z(\cdot)$ and $\text{Cov}_Z(\cdot, \cdot)$. Then, we have:

$$\mathbb{E}[Z_n(\mathbf{X})|\mathbf{X}_A] \sim \text{GP}(\mathbb{E}[m_n(\mathbf{X})|\mathbf{X}_A], \mathbb{E}[\mathbb{E}[k_n(\mathbf{X}, \mathbf{X}')|\mathbf{X}_A]|\mathbf{X}'_A]). \quad (38.54)$$

The term $\mathbb{E}[m_n(\mathbf{X})]$ represents the approximation of $\mathbb{E}[G(\mathbf{X})|\mathbf{X}_A]$, and $\mathbb{E}[\mathbb{E}[k_n(\mathbf{X}, \mathbf{X}')|\mathbf{X}_A]|\mathbf{X}'_A]$ is the mean-square error due to the metamodel approximation. Therefore, with this method, one can quantify the error on the main effects due to the metamodel approximation. For more detail about this approach, the reader is referred to Oakley and O'Hagan [48] and Marrel et al. [43].

3.4 Variance of the Main Effects

Although the main effect enables one to visualize the impact of a group of variables on the model output, it does not quantify it. To perform such an analysis, consider the variance of the main effect:

$$V_A = \text{Var}(\mathbb{E}[Z_n(\mathbf{X})|\mathbf{X}_A]), \quad (38.55)$$

or its normalized version which corresponds to the Sobol' index:

$$S_A = \frac{V_A}{V} = \frac{\text{Var}(\mathbb{E}[Z_n(\mathbf{X})|\mathbf{X}_A])}{\text{Var}(Z_n(\mathbf{X}))}. \quad (38.56)$$

Sobol' indices are the most popular measures to carry out a sensitivity analysis since their value can easily be interpreted as the part of the total variance due to a group of variables. However, in contrary to the partial variance V_A , it does not provide information about the order of magnitude of the contribution to the model output variance of variable group \mathbf{X}_A .

3.4.1 Analytic Formulae

The above indices are studied in Oakley and O'Hagan [48] where the estimation of V_A and V is performed separately. Indeed, computing the Sobol' index S_A requires considering the joint distribution of V_A and V , which makes it impossible to derive analytic formulae. According to Oakley and O'Hagan [48], closed form expressions in terms of integrals can be obtained for the two quantities $\mathbb{E}_Z[V_A]$ and $\text{Var}_Z(V_A)$. The quantity $\mathbb{E}_Z[V_A]$ is the sensitivity measure and $\text{Var}_Z(V_A)$ represents the error due to the metamodel approximation. Nevertheless, V_A is not a linear transform of $Z_n(\mathbf{X})$ and its full distribution cannot be established. We note that Marrel et al. [44] suggest a strategy to efficiently simulate V_A .

3.4.2 Variance Estimates with Monte Carlo Integration

To evaluate the Sobol' index S_A , it is possible to use the pick-freeze approaches presented previously in this chapter (see ► Chap. 35, “Variance-Based Sensitivity Analysis: Theory and Estimation Algorithms”) and in Sobol' [55], Sobol' et al. [57], and Janon et al. [35]. By considering the formula given in Sobol' [55], S_A can be approximated by:

$$S_{A,N} = \frac{\frac{1}{N} \sum_{i=1}^N Z_n(\mathbf{X}^{(i)}) Z_n(\mathbf{X}_A^{(i)}) - \left(\frac{1}{2N} \sum_{i=1}^N Z_n(\mathbf{X}^{(i)}) + Z_n(\mathbf{X}_A^{(i)}) \right)^2}{\frac{1}{N} \sum_{i=1}^N Z_n(\mathbf{X}^{(i)})^2 - \left(\frac{1}{2N} \sum_{i=1}^N Z_n(\mathbf{X}^{(i)}) + Z_n(\mathbf{X}_A^{(i)}) \right)^2}, \quad (38.57)$$

where $(\mathbf{X}^{(i)}, \mathbf{X}_A^{(i)})_{i=1,\dots,N}$ is a N -sample from the random variable $(\mathbf{X}, \mathbf{X}^A)$.

In particular, this approach avoids to compute the integrals presented in Oakley and O'Hagan [48] and thus simplify the estimation of V_A and V . Furthermore, it takes into account their joint distribution.

Remark. This result can easily be extended to the total Sobol' index $S_i^{\text{tot}} = \sum_{A \supset i} S_A$. The reader is referred to Sobol' et al. [57] and ► Chap. 35, “Variance-Based Sensitivity Analysis: Theory and Estimation Algorithms” for examples of pick-freeze estimates of S_A^{tot} .

3.5 Numerical Estimates of Sobol' Indices by Gaussian Process Sampling

The sensitivity index $S_{A,N}$ (38.57) is obtained after substituting the Gaussian process $Z_n(\mathbf{x})$ for the original computational model $G(\mathbf{x})$. Therefore, it is a random variable defined on the same probability space as $Z_n(\mathbf{x})$. The aim of this section is to present a simple methodology to get a sample $S_{A,N}$ of S_A . From this sample, an estimate of S_A (38.56) and a quantification of its uncertainty can be deduced.

Sampling from the Gaussian Predictive Distribution

To obtain a realization of $S_{A,N}$, one has to obtain a sample of $Z_n(\mathbf{x})$ on $(\mathbf{X}^{(i)}, \mathbf{X}_A^{(i)})_{i=1,\dots,N}$ and then use Eq. (38.57). To deal with large N , an efficient strategy is to sample $Z_n(\mathbf{x})$ using the Kriging conditioning method, see, for example, Chilès and Delfiner [19]. Consider first the unconditioned, zero-mean Gaussian process:

$$\tilde{Z}(\mathbf{x}) = \text{GP}(0, k(\mathbf{x}, \mathbf{x}')). \quad (38.58)$$

Then, the Gaussian process:

$$\tilde{Z}_n(\mathbf{x}) = m_n(\mathbf{x}) - \tilde{m}_n(\mathbf{x}) + \tilde{Z}(\mathbf{x}), \quad (38.59)$$

where $\tilde{m}_n(\mathbf{x}) = \mathbf{f}^\top(\mathbf{x})\tilde{\boldsymbol{\beta}} + \mathbf{r}^\top(\mathbf{x})\mathbf{R}^{-1}\left(\tilde{Z}(\mathcal{X}) - \mathbf{F}\tilde{\boldsymbol{\beta}}\right)$ and $\tilde{\boldsymbol{\beta}} = (\mathbf{F}^\top\mathbf{R}^{-1}\mathbf{F})^{-1}\mathbf{F}^\top\mathbf{R}^{-1}$. $\tilde{Z}(\mathcal{X})$ has the same distribution as $Z_n(\mathbf{x})$. Therefore, one can compute realizations of $Z_n(\mathbf{x})$ from realizations of $\tilde{Z}(\mathbf{x})$. Since $\tilde{Z}(\mathbf{x})$ is not conditioned, the problem is numerically easier. Among the available Gaussian process sampling methods, several can be mentioned: Cholesky decomposition [49], Fourier spectral decomposition [59], Karhunen-Loeve spectral decomposition [49], and the propagative version of the Gibbs sampler [36].

Remark. Let suppose that a new point $\mathbf{x}^{(n+1)}$ is added to the experimental design \mathcal{X} . A classical result of conditional probability implies that the new predictive distribution $[Z(\mathbf{x})|Z(\mathcal{X}) = \mathcal{Y}, Z(\mathbf{x}^{(n+1)}) = G(\mathbf{x}^{(n+1)}), \sigma^2, \boldsymbol{\theta}]$ is identical to $[Z_n(\mathbf{x})|Z_n(\mathbf{x}^{(n+1)}) = G(\mathbf{x}^{(n+1)}), \sigma^2, \boldsymbol{\theta}]$. Therefore, $Z_n(\mathbf{x})$ can be viewed as an unconditioned Gaussian process and, using the Kriging conditioning method, realizations of $[Z(\mathbf{x})|Z(\mathcal{X}) = \mathcal{Y}, Z(\mathbf{x}^{(n+1)}) = G(\mathbf{x}^{(n+1)}), \sigma^2, \boldsymbol{\theta}]$ can be derived from realizations of $Z_n(\mathbf{x})$ using the following equation:

$$Z_{n+1}(\mathbf{x}) = \frac{k_n(\mathbf{x}^{(n+1)}, \mathbf{X})}{k_n(\mathbf{x}^{(n+1)}, \mathbf{x}^{(n+1)})} (G(\mathbf{x}^{(n+1)}) - Z_n(\mathbf{x}^{(n+1)})) + Z_n(\mathbf{x}). \quad (38.60)$$

Therefore, it is easy to calculate a new sample of $S_{A,N}$ after adding a new point $\mathbf{x}^{(n+1)}$ to the experimental design set \mathcal{X} . This result is used in the function “sobolGP” of the R CRAN package “sensitivity” to perform sequential design for sensitivity analysis using a stepwise uncertainty reduction (SUR) strategy [5,38,39].

3.5.1 Metamodel and Monte Carlo Sampling Errors

Let us denote by $\{S_{A,i}^N, i = 1, \dots, m\}$ a sample set of $S_{A,N}$ (38.57) of size $m > 0$. From this sample set, the following unbiased estimate of S_A can be deduced:

$$\hat{S}_A = \frac{1}{m} \sum_{i=1}^m S_{A,i}^N. \quad (38.61)$$

with variance:

$$\hat{\sigma}_{\hat{S}_A}^2 = \frac{1}{m-1} \sum_{i=1}^m (S_{A,i}^N - \hat{S}_A)^2. \quad (38.62)$$

The term $\hat{\sigma}_{\hat{S}_A}^2$ represents the uncertainty on the estimate of S_A (38.56) due to the metamodel approximation. Therefore, with the presented strategy, one can obtain both an unbiased estimate of the sensitivity index S_A and a quantification of its uncertainty. The same procedure can be used to estimate the total Sobol’ indices.

Finally it may be of interest to evaluate the error due to the pick-freeze approximation and to compare it to the error due to the metamodel. To do so, one can use the central limit theorem [18,35] or a bootstrap procedure [38]. In particular,

a methodology to evaluate the uncertainty on the sensitivity index due to both the Gaussian process and to the pick-freeze approximations is presented in Le Gratiet et al. [38]. It makes it possible to determine the value of N such that the pick-freeze approximation error is negligible compared to that of the metamodel.

3.6 Summary

Gaussian process regression makes it possible to perform sensitivity analysis on complex computational models using a limited number of model evaluations. An important feature of this method is that one can propagate the Gaussian process approximation error to the sensitivity index estimates. This allows the construction of sequential design strategies optimized for sensitivity analysis. It also provides a powerful tool to visualize the main effect of a group of variables and the uncertainty of its estimate. Another advantage of this approach is that Gaussian process regression has been thoroughly investigated in the literature and can be used in various problems. For example, the method can be adapted for non-stationary numerical models by using a treed Gaussian process as in Gramacy and Taddy [30]. Furthermore, it can also be used for multifidelity computer codes, i.e., codes which can be run at multiple level of accuracy (see Le Gratiet et al. [38]).

4 Applications

In this section, metamodel-based sensitivity analysis is illustrated on several academic and engineering examples.

4.1 Ishigami Function

The Ishigami function is given by:

$$G(x_1, x_2, x_3) = \sin(x_1) + 7 \sin(x_2)^2 + 0.1x_3^4 \sin(x_1). \quad (38.63)$$

The input distributions of X_1 , X_2 , and X_3 are uniform over the interval $[-\pi, \pi]^3$. This is a classical academic benchmark for sensitivity analysis, with first-order Sobol' indices:

$$S_1 = 0.3138 \quad S_2 = 0.4424 \quad S_3 = 0. \quad (38.64)$$

To compare polynomial chaos expansions and Gaussian process modeling on this example, experimental designs of different sizes n are considered. For each size n , 100 Latin hypercube sampling (LHS) sets are computed so as to replicate the procedure and assess statistical uncertainty.

For the polynomial chaos approach, the coefficients are calculated based on a degree-adaptive LARS strategy (for details, see Blatman and Sudret [14]), resulting in a sparse basis set. The maximum polynomial degree is adaptively selected in the interval $3 \leq p \leq 15$ based on LOO cross-validation error estimates (see Eq. (38.27)).

For the Gaussian process approach, a tensorized Matérn-5/2 covariance kernel is chosen (see Rasmussen and Williams [49]) with trend functions given by:

$$\mathbf{f}^T(\mathbf{x}) = \{1 \ x_2 \ x_2^2 \ x_1^3 \ x_2^3 \ x_1^4 \ x_2^4\}. \quad (38.65)$$

To select $\mathbf{f}^T(\mathbf{x})$, we use a classical stepwise regression (i.e., the model errors are considered independent and identically distributed according to a normal distribution) with the Bayesian information criterion and a bidirectional selection. This allows to merely obtain a relevant linear trend for the Gaussian process regression.

The hyper-parameters $\boldsymbol{\theta}$ are estimated with a leave-one-out cross-validation procedure, while the parameters $\boldsymbol{\beta}$ and σ^2 are estimated with a restricted maximum likelihood method.

First we illustrate in Fig. 38.6 the accuracy of the models with respect to the sample size n . The Nash-Sutcliffe model efficiency coefficient (also called predictivity coefficient) is defined as follows:

$$Q^2 = 1 - \frac{\sum_{i=1}^{n_{\text{test}}} (G(\mathbf{x}^{(i)}) - \hat{G}(\mathbf{x}^{(i)}))^2}{\sum_{i=1}^{n_{\text{test}}} (G(\mathbf{x}^{(i)}) - \bar{G})^2}, \quad \bar{G} = \frac{1}{n_{\text{test}}} \sum_{i=1}^{n_{\text{test}}} G(\mathbf{x}^{(i)}), \quad (38.66)$$

where $\hat{G}(\mathbf{x}^{(i)})$ is the prediction given by the polynomial chaos or the Gaussian process regression model on the i^{th} point of a test sample of size $n_{\text{test}} = 10,000$. This test sample set is randomly generated from a uniform distribution. The closer Q^2 is to 1, the more accurate the metamodel is.

We emphasize that checking the metamodel accuracy (see Fig. 38.6) is very important since a metamodel-based sensitivity analysis provides sensitivity indices for the metamodel and not for the true model $G(\mathbf{x})$. Therefore, the estimated indices are relevant only if the considered surrogate model is accurate.

Figure 38.7 shows the Sobol' index estimates with respect to the sample size n . For the Gaussian process regression approach, the convergence is reached for $n = 100$. It corresponds to a Q^2 coefficient greater than 90%. Convergence of the PCE approach is somewhat faster, with comparable accuracy achieved with $n = 60$ and almost perfect accuracy for $n = 100$. Therefore, the convergence of the estimators of the Sobol' indices in Eqs. (38.36), (38.37), (38.38) and (38.39) is expected to be comparable to that of Q^2 . Note that the PCE approach also provides second-order and total Sobol' indices for free, as shown in Sudret [64].

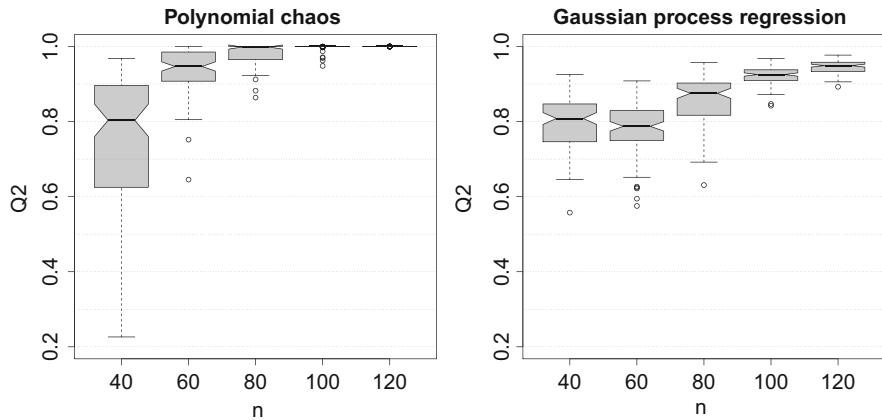

Fig. 38.6 Q^2 coefficient as a function of the sample size n for the Ishigami function. For each n , the box-plots represent the variations of Q^2 obtained over 100 LHS replications

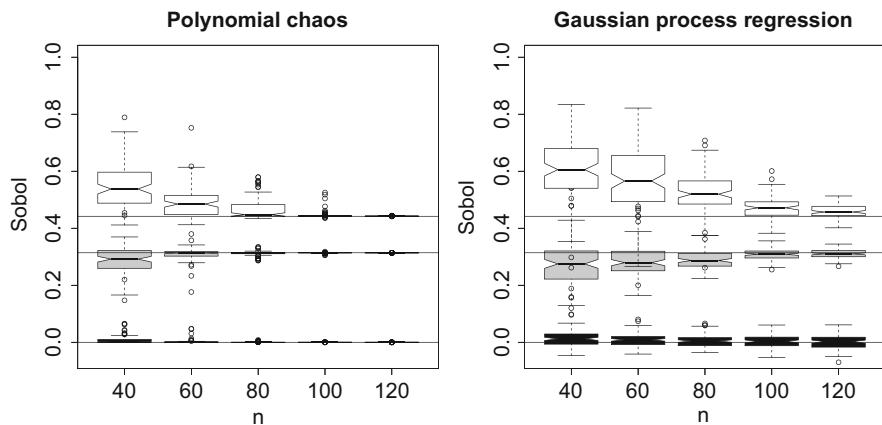

Fig. 38.7 First-order Sobol' index estimates as a function of the sample size n for the Ishigami function. The horizontal solid lines represent the exact values of S_1 , S_2 , and S_3 . For each n , the box-plot represents the variations obtained from 100 LHS replications. The validation set comprises $n_{\text{test}} = 10,000$ samples

4.2 G-Sobol' Function

The G-Sobol' function is given by :

$$G(\mathbf{x}) = \prod_{i=1}^d \frac{|4x_i - 2| + a_i}{1 + a_i}, \quad a_i \geq 0. \quad (38.67)$$

To benchmark the described metamodel-based sensitivity analysis methods in higher dimension, we select $d = 15$. The exact first-order Sobol' indices S_i are given by the following equations:

$$\begin{aligned} V_i &= \frac{1}{3(1+a_i)^2}, \quad i = 1, \dots, d, \\ V &= \prod_{i=1}^d (1+V_i) - 1, \\ S_i &= V_i/V. \end{aligned} \tag{38.68}$$

In this example, vector $\alpha = \{a_1, a_2, \dots, a_d\}$ is equal to:

$$\alpha = \{1, 2, 5, 10, 20, 50, 100, 500, 1000, 1000, 1000, 1000, 1000, 1000, 1000\}. \tag{38.69}$$

As in the previous section, different sample sizes n are considered and 100 LHS replications are computed for each n . Sparse polynomial chaos expansions are obtained with the same strategy as for the Ishigami function: adaptive polynomial degree selection with $3 \leq p \leq 15$ and LARS-based calculation of the coefficients. For the Gaussian process regression model, a tensorized Matérn-5/2 covariance kernel is considered with a constant trend function $f(x) = 1$. The hyper-parameter θ is estimated with a leave-one-out cross-validation procedure, and the parameters β and σ^2 are estimated with the maximum likelihood method.

The accuracy of the metamodels with respect to n is presented in Fig. 38.8. It is computed from a test sample set of size $n_{\text{test}} = 10,000$. The convergence of the estimates of the first four first-order Sobol' indices is represented in Fig. 38.9.

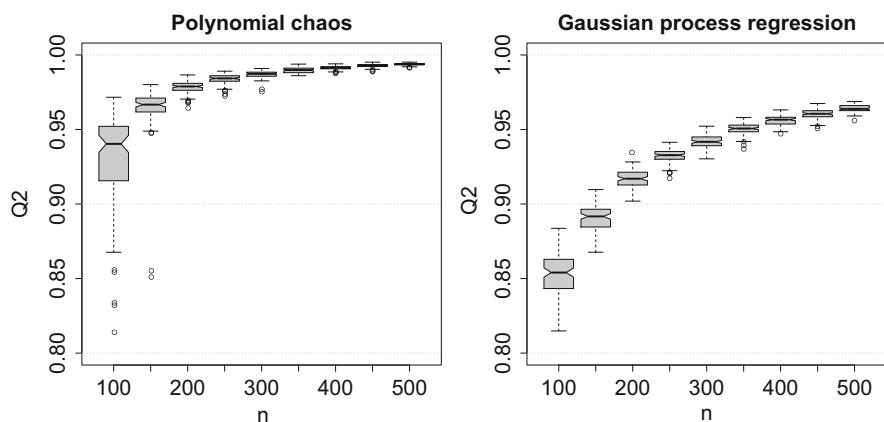

Fig. 38.8 Q^2 coefficient as a function of the sample size n for G-Sobol' academic example. For each n , the box-plot represents the variations of Q^2 obtained from 100 LHS

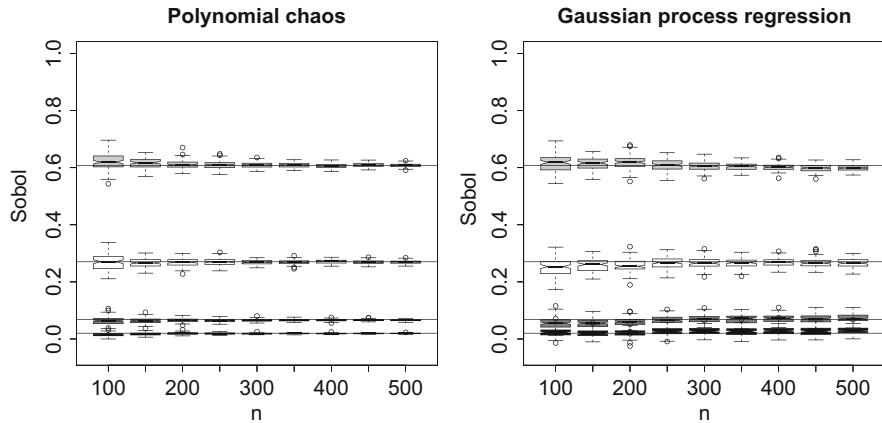

Fig. 38.9 Sobol' index estimates with respect to the sample size n for G-Sobol' function. The horizontal solid lines represent the true values of S_1 , S_2 , S_3 , and S_4 . For each n , the box-plot represents the variations obtained from 100 LHS

Table 38.2 Sobol' index estimates for the G-Sobol' function. The median and the root mean-square error (RMSE) of the estimates are given for $n = 100$ and $n = 500$

S_{15}	0.000	0.000	0.000	8.6×10^{-4}	9.7×10^{-6}	7.2×10^{-4}	3.1×10^{-4}	0.013	0.013

Both metamodel-based estimations yield excellent results already with $n = 100$ samples in the experimental design. This is expected due to the good accuracy of both metamodels for all the n considered (see Fig. 38.8).

Finally, Table 38.2 provides the Sobol' index estimates median and root mean-square error for $n = 100$ and $n = 500$. As presented in Fig. 38.9, the estimates of the largest Sobol' indices are very accurate. Note that the remaining first-order

indices are insignificant. One can observe that the RMS error over the 100 LHS replications is slightly smaller when using PCE for both $n = 100$ and $n = 500$ ED points. Note that the second-order and total Sobol' indices are also available for free when using PCE.

4.3 Morris Function

The Morris function is given by:

$$G(\mathbf{x}) = \sum_{i=1}^{20} \beta_i w_i + \sum_{i < j}^{20} \beta_{ij} w_i w_j + \sum_{i < j < l}^{20} \beta_{ijl} w_i w_j w_l + 5w_1 w_2 w_3 w_4 \quad (38.70)$$

where $X_i \sim \mathcal{U}(0, 1)$, $i = 1, \dots, 20$, and $w_i = 2(x_i - 1/2)$ for all i except for $i = 3, 5, 7$ where $w_i = 2(1.1x_i/(x_i + 0.1) - 1/2)$. The coefficients are defined as $\beta_i = 20$, $i = 1, \dots, 10$; $\beta_{ij} = -15$, $i, j = 1, \dots, 6$; and $\beta_{ijl} = -10$, $i, j, l = 1, \dots, 5$. The remaining coefficients are set equal to $\beta_i = (-1)^i$ and $\beta_{ij} = (-1)^{i+j}$ and all the rest are zero. The reference values of the first-order Sobol' indices of the Morris function are calculated by a large Monte Carlo-based sensitivity analysis ($n = 10^6$).

As in the previous section, different sample sizes n are considered and 100 LHS replications are computed for each n . Sparse polynomial chaos expansions are obtained by adaptive polynomial degree selection $5 \leq p \leq 13$ and LARS-based calculation of the coefficients.

Furthermore, a tensorized Matérn-5/2 covariance kernel is used for the Gaussian process regression and the following trend has been selected with a stepwise regression procedure (as in Fig. 38.1):

$$\begin{aligned} \mathbf{f}^\top(\mathbf{x}) = \{ & 1 \ x_1 \ x_2 \ x_3 \ x_4 \ x_5 \ x_6 \ x_7 \ x_8 \ x_9 \ x_{10} \ x_{13} \ x_{14} \ x_{19} \ x_{1x2} \ x_{2x4} \ x_{1x4} \\ & x_{1x6} \ x_{2x6} \ x_{3x4} \ x_{4x6} \ x_{2x3} \ x_{1x5} \ x_{2x5} \ x_{3x6} \ x_{4x5} \ x_{1x3} \ x_{5x6} \ x_{3x5} \\ & x_{9x13} \ x_{7x8} \}. \end{aligned} \quad (38.71)$$

The accuracy of the metamodels with respect to n is presented in Fig. 38.10. It is computed from a test sample of size $n_{\text{test}} = 10,000$. As expected due to the complexity and dimensionality of the Morris function, both metamodels show a slower overall convergence rate with the number of samples with respect to the previous examples. Polynomial chaos expansions show in this case remarkably more scattering in their performance for smaller experimental designs with respect to Gaussian process regression. This is likely due to the comparatively large amount of prior information in the form of trend functions provided to the Gaussian process, not used for PCE.

The convergence of the estimates of three selected first-order Sobol' indices (the largest S_9 and two intermediate ones S_3 and S_8) is represented in Fig. 38.11. Both methods perform very well with as few as 250 samples. PCE, however,

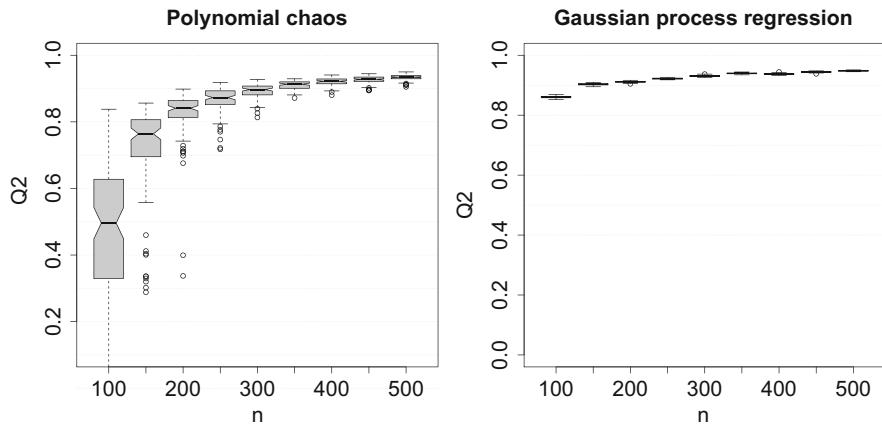

Fig. 38.10 Q^2 coefficient as a function of the sample size n for the Morris function example. For each n , the box-plot represents the variations of Q^2 obtained from 100 LHS

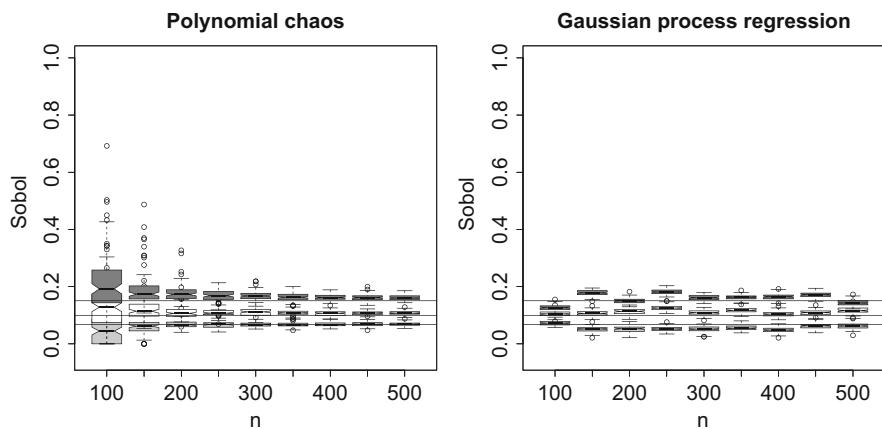

Fig. 38.11 First-order Sobol' index estimates as a function of the sample size n for the Morris function. The horizontal solid lines represent the exact values of S_3 , S_8 , and S_9 . For each n , the box-plot represents the variations obtained from 100 LHS replications

shows a more standard convergence behavior both in mean value in dispersion. Gaussian process regression retrieves the Sobol' estimates very accurately even with extremely small experimental designs, but no clear convergence pattern can be seen for larger datasets. This is due to the fact that the error on the Sobol' indices is essentially caused by the Monte Carlo errors. Therefore, increasing the accuracy of the Kriging model does not improve the accuracy of the index estimates.

Finally, Table 38.3 provides the a detailed breakdown of the Sobol' index estimates, including median and root mean-square error (RMSE), for $n = 100$ and $n = 500$.

Table 38.3 First-order Sobol' indices estimation for the Morris function. The median and the root mean-square error (RMSE) of the estimates are given for $n = 100$ and $n = 500$

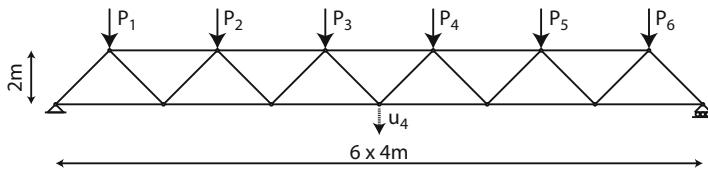

Fig. 38.12 Model of a truss structure with 23 members. The quantity of interest is the maximum displacement at mid-span u_4

4.4 Maximum Deflection of a Truss Structure

Sensitivity analysis is also of great interest for engineering models whose input parameters may have different distributions. As an example consider the elastic truss structure depicted in Fig. 38.12 (see, e.g., Blatman and Sudret [11]). This truss is made of two types of bars, namely, horizontal bars with cross-section A_1 and Young's modulus (stiffness) E_1 on the one hand and oblique bars with cross-section A_2 and Young's modulus (stiffness) E_2 on the other hand. The truss is loaded with

Table 38.4 Probabilistic input model of the truss structure

Variable	Distribution	Mean	Standard deviation
E_1, E_2 (Pa)	Lognormal	2.1×10^{11}	2.1×10^{10}
A_1 (m^2)	Lognormal	2.0×10^{-3}	2.0×10^{-4}
A_2 (m^2)	Lognormal	1.0×10^{-3}	1.0×10^{-4}
P_1-P_6 (N)	Gumbel	5.0×10^4	7.5×10^3

six vertical loads applied on the top chord. Of interest is the maximum vertical displacement (called deflection) at mid-span. This quantity is computed using a finite element model comprising elastic bar elements.

The various parameters describing the behavior of this truss structure are modeled by independent random variables that account for the uncertainty in both the physical properties of the structure and the applied loads. Their distributions are gathered in Table 38.4.

These input variables are collected in the random vector:

$$\mathbf{X} = \{E_1, E_2, A_1, A_2, P_1, \dots, P_6\}. \quad (38.72)$$

Using this notation, the maximal deflection of interest is cast as:

$$u_4 = G^{\text{FE}}(\mathbf{X}). \quad (38.73)$$

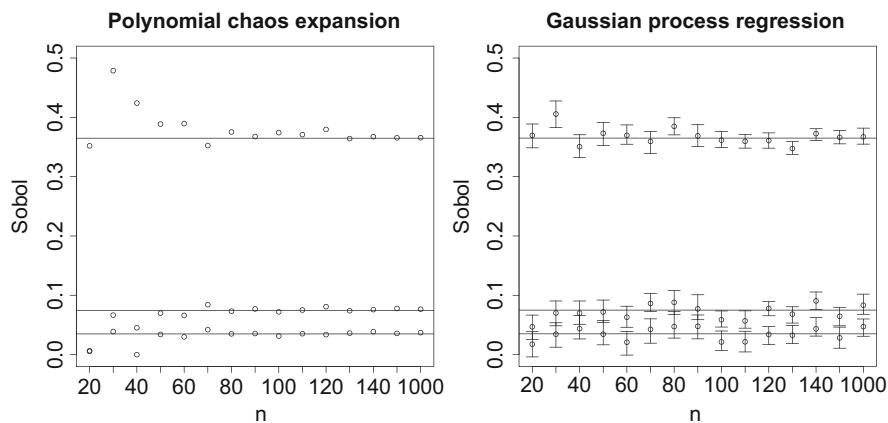

Different sparse polynomial chaos expansions are calculated assuming a maximal degree $3 < p < 10$ using LARS and the best expansion (in terms of smallest LOO error) is retained. For the Gaussian process regression model, a tensorized Matérn-5/2 covariance kernel is considered with a constant trend function $\mathbf{f}(\mathbf{x}) = 1$. The hyper-parameter θ is estimated with a leave-one-out cross-validation procedure, and the parameters β and σ^2 are estimated with the maximum likelihood method.

The first-order Sobol' indices obtained from PCE and GP metamodels are reported in Table 38.5 in the case when the experimental design is of size 100. In decreasing importance order, the important variables are the properties of the chords (horizontal bars), and then the loads close to mid-span, namely, P_3 and P_4 . The Sobol' indices of the latter are identical due to the symmetry of the model. Then come the loads P_2 and P_5 . The other variables (the loads P_1 and P_6 and the properties of the oblique bars) appear unimportant.

The estimates of the three largest first-order Sobol' indices which correspond to variables E_1 , P_3 , and P_5 obtained for various sizes n of the LHS experimental design are plotted in Fig. 38.13 as a function of n . The reference solution is obtained by Monte Carlo sampling with a sample set of size 6,000,000. Both PCE- and GP-based Sobol' indices converge to stable estimates as soon as $n \geq 60$. Furthermore, for the GP-based Sobol' index estimates, the 95% confidence intervals considering both the metamodel and the Monte Carlo errors are provided.

Table 38.5 Truss structure – First-order Sobol' indices

Variable	Reference	PCE	Gaussian Process
A_1	0.365	0.366	0.384
E_1	0.365	0.369	0.362
P_3	0.075	0.078	0.075
P_4	0.074	0.076	0.069
P_5	0.035	0.036	0.029
P_2	0.035	0.036	0.028

**Fig. 38.13** Truss structure – First-order Sobol' index estimates as a function of the sample size n for the truss model. The horizontal solid lines represent reference values of input variables E_1 , P_3 , and P_5 from a Monte Carlo estimate on 6,000,000 samples. For the Gaussian process regression, the segments represent the 95% confidence intervals taking both into account the metamodel and the Monte Carlo errors

5 Conclusions

Sobol' indices are recognized as good descriptors of the sensitivity of the output of a computational model to its various input parameters. Classical estimation methods based on Monte Carlo simulation are computationally expensive though. The required costs, in the order of $10^3 - 10^4$ model evaluations, are often not compatible with the advanced simulation models encountered in engineering applications.

For this reason, surrogate models may be first built up from a limited number of runs of the computational model (the so-called experimental design), and the sensitivity analysis is then carried out by substituting the surrogate model for the original one.

Polynomial chaos expansions and Gaussian processes are two popular methods that can be used for this purpose. The advantage of the PCE approach is that the Sobol' indices at any order may be computed *analytically* once the expansion is available. In this contribution, least-square minimization techniques are presented to compute the PCE coefficients, yet any intrusive or nonintrusive method could be used as an alternative.

In contrast Gaussian process surrogate models are used together with Monte Carlo simulation for estimating the Sobol' indices. The advantage of this approach is that the metamodel error can be included in the estimators. Note that bootstrap techniques can be used similarly to calculate and include metamodeling error also for PCE-based sensitivity analysis, as demonstrated by Dubreuil et al. [24].

As shown in the various comparisons, PCE and GP give similar accuracy (measured in terms of the Q^2 validation coefficient) for a given size of the experimental design in a broad range of applications. The replication of the analyses with different random designs of the same size show a smaller scatter using GP for extremely small designs, whereas PCE becomes more stable for medium-size designs. Selecting the best technique is in the end problem-dependent, and it is worth comparing the two approaches using the same experimental design, as it can be done in recent sensitivity analysis toolboxes such as OpenTURNS [2] and UQLab [41].

Finally it is worth mentioning that the so-called derivative-based global sensitivity measures (DGSM) originally introduced by Sobol' and Kucherenko [56] can also be computed using surrogate models. In particular, polynomial chaos expansions may be used to compute the DGSM analytically, as shown in Sudret and Mai [66]. Furthermore, Gaussian process regression can also be used as presented in De Lozzo and Marrel [21]. The recent combination of polynomial chaos expansions and Gaussian processes into *PC-Kriging* [54] also appears promising for estimating sensitivity indices from extremely small experimental designs.

Abstract

This section presents several sensitivity analysis methods to deal with spatial and/or temporal models. Focusing on the variance-based approach, solutions are proposed to perform global sensitivity analysis with functional inputs and outputs. Some of these solutions are illustrated on two industrial case studies: an environmental model for flood risk assessment and an atmospheric dispersion model for radionuclide release. These test cases are fully described at the beginning of the paper. Then a section is dedicated to spatiotemporal inputs and proposes several sensitivity analysis methods. The use of metamodels is also addressed. Pros and cons of the various methods are then discussed. In a subsequent section, solutions to deal with spatiotemporal outputs are proposed: aggregated, site, and block indices are described. The use of functional metamodels for sensitivity analysis purpose is also discussed.

1 Introduction

Most of the methods of sensitivity analysis (SA) tools presented in the previous papers are initially defined for scalar variables, while industrial and environmental applications often deal with more complex input or output parameters. Indeed, these parameters can be spatial, temporal, spatiotemporal, or functional in a more general way. Classical SA methods must be adapted to address the problems posed by this kind of data as input of numerical models but also as output. Among the factors hindering the use of SA methods in the domain of spatiotemporal data are the explosion of dimensionality problems and the lack of maturity of certain models. We will examine in particular several other limits: (i) spatial model input data generally exhibit some autocorrelation, yet conventional sensitivity analysis methods only consider independent scalar variables; (ii) notions of scale, support, and resolution, which play a prominent role in spatial modeling, are ignored in the formal frameworks of conventional sensitivity analysis methods; and (iii) the problem of the interpretation of SA in the case of functional output. Hence, there appears to be a great need to adapt sensitivity analysis methods to the specific context of spatially distributed modeling. Some ideas have already been provided in the literature to address this issue. First, in existing research related to sensitivity analysis, one may find some publications that deal with correlated input variables, but these studies rarely examine the particular case of spatial dependence. In addition, spatial statistics, and more specifically geostatistics, offer theoretical frameworks to describe the uncertainty weighting on spatially distributed data and to grasp the notions of spatial scale, support, or resolution. Geostatistics also provide tools to simulate these spatial uncertainties. However, this theoretical corpus has never been linked to that of sensitivity analysis of numerical models.

This paper aims at proposing solutions to perform SA with functional inputs and outputs, focusing on the variance-based global sensitivity analysis (VB-GSA). First of all, some industrial and environmental applications which involve spatial and/or temporal uncertain inputs and outputs are presented. Then, solutions recently proposed to deal with functional inputs and outputs are detailed, and in parallel, some of them are applied on the industrial test cases in order to illustrate their implementation and efficiency.

2 Environmental and Industrial Applications

2.1 NOE Environmental Model for Flood Risk Assessment

Flood risk research makes intensive use of numerical modeling to forecast flooding events, assess the impacts of potential flooding events in terms of human well-being and economic and social development, and design efficient flood management policies. These models simulate hydrological, hydraulic, and economic processes over a given study area. They are usually spatially distributed and often make use of geographic information systems (GIS) tools.

The NOE model is a spatially distributed code which is used to assess the economic impact of flood risk [11]. It calculates the so-called EAD risk indicator (expected annual damage [€/year]), which is defined as the expected economic losses due to flooding events over one year on a given study area. The EAD indicator is spatially distributed and mapped over the floodplain. Its estimation requires to compute flood damages and flood return intervals for a range of flood scenarios of various magnitudes (e.g., a 10-year flood, a 30-year flood, etc.). The return intervals of these scenarios are computed from a series of annual maximum flows at a gauging station. The estimation of economic damages caused by a given flood scenario (Fig. 39.1) is based on the combination of various input data: (i) a *hazard map* which gives maximum water depths, water velocity, and flood duration over the study area for this flood scenario; (ii) a *land use map* which identifies and locates the various assets at stake over the study area (e.g., buildings, agricultural land, shops, factories, etc.); and (iii) a set of so-called damage functions that describe the vulnerability of flood-exposed assets.

As a study area, we selected the Lower Orb River fluvial plain, located in the south of France (Hérault). This 63 sq. km area has a Mediterranean subhumid regime and suffers from frequent flooding events that may result in large economic losses. For example, the flood of Dec. 1995–Jan. 1996, with a peak discharge of 1,700 m³/s, affected approximately 15,000 people and caused a total amount of damage of 53 M€ [42].

The NOE model has both spatially distributed inputs and a spatial output. It also has two important characteristics that need to be stressed out. First, the model end user (e.g., a water manager) is interested in the whole output map of the EAD risk indicator, but he/she is also interested in knowing the aggregated value of the EAD risk indicator over one district, one city, or the entire floodplain. We

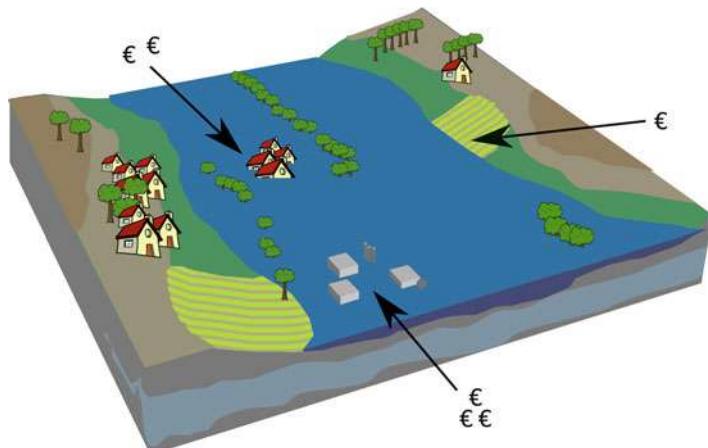

Fig. 39.1 NOE model: estimation of economic losses for a given flood scenario

thus say that the NOE model is *spatially additive*, which means that the output of interest over a given spatial support $v \subset \mathbb{R}^2$ is the sum $Y_v = \int_{z \in v} Y(z) dz$. Many other environmental models are also spatially additive (e.g., models that describe the rainfall over a study area), but some are not (e.g., a model that predicts the maximum pollutant concentration $\max \{Y(z)|z \in v\}$ over a study area). Second, the NOE model is also a *point-based* model, meaning that the value of model output at a given location $z \in \mathbb{R}^2$ only depends on the set of scalar inputs and on the values $W_i(z)$ of spatially distributed inputs *at that same location only* [21]. Such point-based models are encountered in various fields of environmental and earth sciences, whenever spatial interactions in the physical processes under study can be neglected in a first approximation.

2.2 Ceres-Mithra Model for Radionuclide Atmospheric Dispersion

In case of radioactive material release in the environment as a consequence of nuclear power plant accident or accidental releases due to other events, the first concern relates to the dispersion of these radioactive substances in the air. Atmospheric dispersion process is very efficient to characterize the transport of the released substances to long distance and define the geographical areas that are likely to be contaminated. The prediction of radionuclide dispersion in the atmosphere is an important element for the emergency response procedures and risk assessment. Numerical modeling is an essential tool for an accurate prediction of the plume contamination spread and an assessment of environmental risks associated with the site. The CEA has developed the Ceres-Mithra (C-M) application to model the radionuclide atmospheric dispersion and evaluate the consequences

on human health of radioisotope releases in the environment. This application is used either for crisis management or to perform assessment calculations for regulatory safety documents relative to nuclear facilities. Following an accidental release of radionuclides in the atmosphere, C-M evaluates instantaneous and time-integrated activity concentrations (resp. Bq.m^{-3} and Bq.s.m^{-3}) for different points and moments. To do this, several phenomena are simulated: transport, diffusion, impaction, and sedimentation. Atmospheric transport modeling is carried out with the Gaussian puff model [32]. This model assumes that a sequence of individual puffs of pollutant is released from the source. Different standard deviation equations can be used; Doury's formulas [10] which are function of travel time are the default option used in this study. Instantaneous and time-integrated volume activity concentrations are predicted.

However, C-M code depends on many uncertain input parameters related to the various phenomena involved: radionuclide parameters (e.g., deposition velocity), release parameters (height of release, source term activity), and meteorological parameters (wind speed and direction, atmospheric stability, and rain). Given the uncertain parameters, C-M code provides spatial maps of radionuclide volume and surface concentration for various moments defined by the scenario. These data can be instantaneous or integrated over time. C-M outputs can be viewed as functional outputs (spatiotemporal).

In this paper, we consider the scenario studied by Marrel et al. [30]. It is made up of a *cesium 137* (noted ^{137}Cs) simultaneous release occurring in two CEA installations, with distinct locations and heights of release, during one hour with a constant ^{137}Cs activity. The radionuclide atmospheric dispersion is studied during two hours from the beginning of the accidental releases, with time steps of 20 min. This dispersion process is particularly a function of the radionuclide deposition velocity and of the released radionuclide quantity. With respect to the weather conditions, there is no rain, and the temperature, the hydrometry, and the atmospheric stability are constant. Moreover, we assumed that the wind is blowing from the West, with an origin direction lying in $[249^\circ; 333^\circ]$; this situation represents a dry weather class which is the most likely one. Moreover, it is important to take into account the time variation of the wind speed and direction because of its role in the radioactive puff spread. Figure 39.2 represents the flowchart of this scenario. The objective is to assess how the uncertainties on the inputs can affect the C-M forecasts and more precisely to quantify the influence of each input variable (in their whole range of variations) on model responses. The challenge here is to extend the sensitivity analysis tools to an output which varies in space and time.

3 Methods for Spatiotemporal Inputs

Most SA techniques were initially designed for models with independent and scalar random inputs only: this is a first obstacle that limits its extension to spatial models. Indeed, in a spatial model, some model inputs are not scalar values but 2D raster

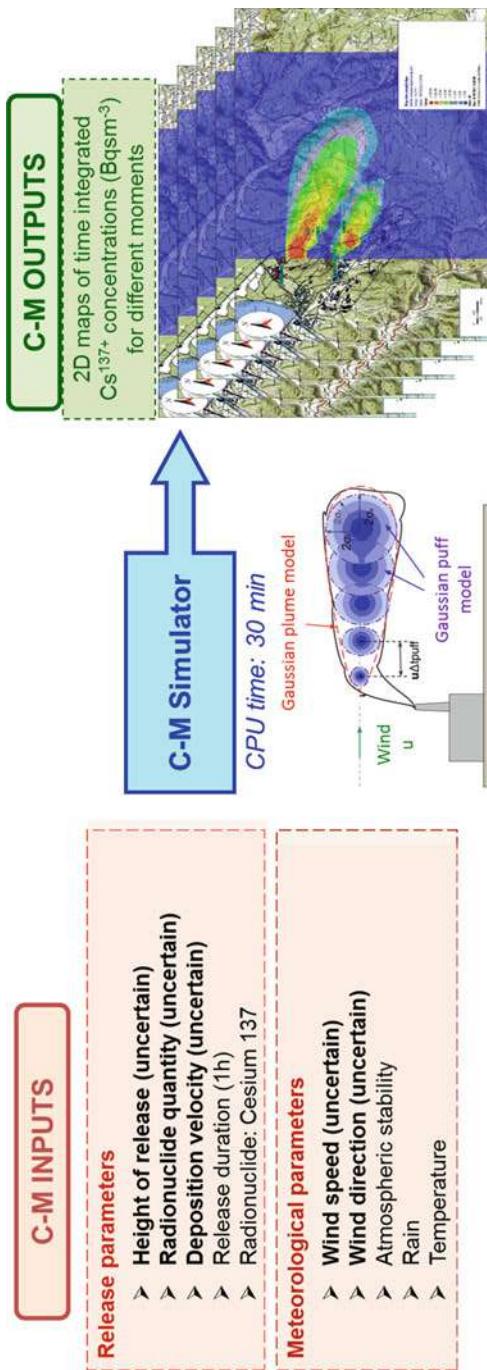

Fig. 39.2 Flowchart of the C-M model, with the uncertain inputs in bold and the spatial outputs of the simulator

or vector data and may exhibit some sort of spatial autocorrelation; the original framework of VB-GSA does not fit any longer in this case. In this paper, we explore this issue and investigate how variance-based sensitivity indices can be calculated in numerical models with spatially distributed inputs. Only models with scalar outputs are considered here (spatially distributed outputs will be studied in the second part of the paper). We consider the model f with d scalar inputs $\mathbf{X} = (X_1, \dots, X_d)$ and a functional input $\{W_z\}_{z \in \mathbb{D}_z}$ indexed by the continuous variable z defined on the domain \mathbb{D}_z , where \mathbb{D}_z can be a time interval or a spatial domain, for example. The model is defined by:

$$\begin{aligned} f : \mathbb{R}^d \times \mathbb{F} &\rightarrow \mathbb{R} \\ (\mathbf{X}, W_z) &\mapsto Y = f(\mathbf{X}, W_z) \end{aligned} \quad (39.1)$$

where \mathbb{F} is functional space composed of functions mapping from \mathbb{D}_z to \mathbb{R} . The inputs \mathbf{X} are modeled by random variables which are characterized by their probability density function $\mu_{\mathbf{X}}$, and $\{W_z\}_{z \in \mathbb{D}_z}$ is a stochastic process. $\{W_z\}_{z \in \mathbb{D}_z}$ can also be denoted $\{W(z) : z \in \mathbb{D}_z\}$. In the case of a spatiotemporal input, z can be time or spatial coordinates. One realization of $\{W_z\}_{z \in \mathbb{D}_z}$ is a function mapping from \mathbb{D}_z to \mathbb{R} , where \mathbb{D}_z can be a time interval or a spatial domain, for example.

In its initial form summarized in Paper 5 (see ►Chap. 35, “Variance-Based Sensitivity Analysis: Theory and Estimation Algorithms”), VB-GSA is designed to deal with scalar inputs X_i only, which are modeled as independent random variables. However, the definition of variance-based sensitivity indices can be extended without modification to vector or functional inputs, as long as the independence assumption between inputs is verified. Hence, the issue of computing variance-based sensitivity indices for spatiotemporal inputs is not a problem of *defining* such indices.

A first issue related to spatiotemporal inputs is *simulating random samples* for such inputs. This topic is extensively covered in the spatial statistics literature. Several approaches are available to model and simulate uncertainty on spatiotemporal data: stationary random fields, Markov random fields, random point processes, spectral decomposition, to name a few. This subject will not be further elaborated in this chapter. A second issue related to spatiotemporal inputs is purely technical: how to handle these inputs in the available open-source libraries dedicated to sensitivity analysis? How to store them? How to pass them to standardized routines that compute sensitivity indices? A third issue related to spatiotemporal inputs is how to handle these inputs in metamodeling.

A number of authors have recently introduced methods to tackle these issues. Iooss and Ribatet [24], Lilburne and Tarantola [27], and Iooss [23] make a partial state of the art of these approaches. In this section, we offer to make an updated state of the art of these methods, compare these methods on some analytical test cases, discuss their pros and cons, and give practice-oriented criteria to choose the appropriate method for a given problem.

3.1 Variance-Based Sensitivity Indices for Spatiotemporal Inputs (Without Metamodeling)

3.1.1 Macro-parameter

A first approach is to consider the spatiotemporal input $\{W(z) : z \in \mathbb{D}_z\}$, or more precisely its numerical representation, as a vector of m scalar inputs $\mathbf{W} = (W_1 \dots W_m)$. Following [24], we will use the term *macro-parameter* to refer to this method. Most often, the temporal or spatial domain \mathbb{D}_z is discretized as a regular grid with m elements:

$$\mathbb{D}_z \xrightarrow{\text{discretization}} (z^{(1)}, \dots, z^{(m)}) \in \mathbb{D}_z^m.$$

In this case, scalar inputs $\mathbf{W} = (W_1, \dots, W_m)$ are simply the values $(W(z^1), \dots, W(z^m))$ at the grid points. Spatiotemporal inputs may also be stored in a more complex format, for example, as a vector layer in a geographic information system, comprising numerous spatial objects with various alpha-numerical attributes. In such case, scalar inputs $\mathbf{W} = (W_1, \dots, W_m)$ are the values of the attributes of each spatial object in the layer, and m is a multiple of the number of objects. In both cases, the model (39.1) is replaced by its discretized version:

$$\begin{aligned} f^* : \mathbb{R}^d \times \mathbb{R}^m &\rightarrow \mathbb{R} \\ (\mathbf{X}, \mathbf{W}) &\mapsto Y = f^*(\mathbf{X}, \mathbf{W}) \end{aligned} \tag{39.2}$$

The scalar inputs W_i are modeled by random variables and characterized by their joint probability density function $\mu_{\mathbf{W}}$. In some cases, it may be possible to consider that the W_i are independent random variables: spatiotemporal correlation of uncertainty in $\{W(z) : z \in \mathbb{D}_z\}$ is then neglected. In other cases, random variables (W_1, \dots, W_m) are not independent, and their joint probability $\mu_{\mathbf{W}}$ must be fully characterized. The first- and total-order variance-based sensitivity indices of spatiotemporal input $\{W(z) : z \in \mathbb{D}_z\}$ are then computed as the variance-based sensitivity indices of the group of scalar inputs (W_1, \dots, W_m) .

The macro-parameter approach was used by [22] to carry out a sensitivity analysis of the GeoPEARL pesticide leaching model. In this work, each spatially distributed soil property (soil horizon thickness, clay or organic matter content, etc.) was represented on a spatial grid by a set of 258 scalar parameters W_i that were assumed to be statistically independent. Hence, spatial autocorrelation of uncertainty was neglected. For each soil property, sensitivity indices were estimated for the whole group (W_1, \dots, W_m) by a pseudo Monte Carlo procedure.

The main drawback of the macro-parameter approach is its computational burden. The number of scalar inputs that must be sampled to estimate sensitivity indices is equal to $d + m$ where d is the number of model inputs X_1, \dots, X_d and m is the dimension of spatiotemporal input $\{W(z) : z \in \mathbb{D}_z\}$ (e.g., the number of cells in a grid or number of spatial objects in a GIS vector layer). As soon as the

dimension m gets too large ($m \gg 100$), the large samples required to estimate sensitivity indices may be difficult to handle.

3.1.2 Dimension Reduction

The dimension reduction approach is similar to the macro-parameter method, except that it results in a partial loss of the information contained in the initial spatiotemporal input $\{W(z) : z \in \mathbb{D}_z\}$. The idea is to find a way to approximate $\{W(z) : z \in \mathbb{D}_z\}$ by a deterministic function ϕ of a small number of scalar inputs W_1, \dots, W_m , with m small—typically $m \leq 100$, much less than the dimension of the initial spatiotemporal data:

$$\forall z \in \mathbb{D}_z, \quad W(z) \approx \phi(W_1, \dots, W_m, z) \quad (39.3)$$

Scalar inputs $\mathbf{W} = (W_1, \dots, W_m)$ are modeled by random variables and characterized by their probability density function $\mu_{\mathbf{W}}$. Model (39.1) is then replaced by its discretized version (39.2). Variance-based sensitivity indices are computed either for each scalar parameter W_j if they are assumed independent or for the whole input group (W_1, \dots, W_m) .

Here are some examples of works based on this approach. Volkova et al. [46] carried out sensitivity analysis of a model of groundwater transport for radionuclide migration on a radwaste disposal site. To represent spatially distributed soil properties such as the hydraulic conductivity or infiltration, they divided up the spatial domain \mathbb{D}_z into four zones v_1 to v_4 ($m = 4$); each soil property was then described by a single scalar random variable W_i on each zone v_i , which was assumed to represent the average value of the soil property over the zone. All these random variables were assumed independent, and first- and total-order sensitivity indices were estimated for each of them. Romary [34] also uses a *dimension reduction* approach to perform the sensitivity analysis of an oil reservoir model in which one of the model inputs is a spatially distributed permeability field $\{W(z) : z \in \mathbb{D}_z\}$. This input field is first expanded on an orthogonal basis (Karhunen-Loëve expansion); the main coefficients W_i of this expansion are then considered as new, uncorrelated inputs, and sensitivity indices are estimated for each of them. A last example of the *dimension reduction* approach is given by [15], who performed the variance-based sensitivity analysis of the SWAT computer model (Soil and Water Assessment Tool). In the original SWAT model, the study area \mathbb{D}_z was divided into 11 topographical sub-basins and further into 156 hydrological response units, and 15 soil properties were given for each of these units. For sensitivity analysis, the spatial variability of soil properties was reduced, and each spatially distributed input variable was considered homogeneous over supports of larger size (either sub-basins or region composed of many hydrological response units grouped by soil types, land use types, or growing crops). This dimension reduction resulted in a downsizing of the total number of input variables, from more than 1000 in the initial model to only $m = 82$ in the reduced setting.

3.1.3 Switch or Trigger Input

The *switch input* or *trigger input* approach was first suggested by [7]. It is not specifically dedicated to spatiotemporal inputs and can also be used for scalar inputs. As we will explain it later, it is different in its principle compared to the macro-parameter and dimension reduction methods, and the practitioner should be careful in the interpretation of the resulting sensitivity indices. However, because this approach was used in the literature to deal with spatially distributed inputs, we find it useful to mention it here.

The core idea of the method is to modify model (39.1) by introducing a boolean random variable ξ such that $\mathbb{P}(\xi = 0) = \mathbb{P}(\xi = 1) = 1/2$:

$$\begin{aligned} f^* : \mathbb{R}^d \times \{0, 1\} &\rightarrow \mathbb{R} \\ (\mathbf{X}, \xi) &\mapsto Y = f^*(\mathbf{X}, \xi). \end{aligned} \quad (39.4)$$

ξ is named the *trigger* input. It is a switch between two situations: when $\xi = 0$, model output Y is evaluated using a fixed nominal value W_z^0 of input W_z , and when $\xi = 1$, model output Y is evaluated using a random realization of input W_z . Using this stratagem, the variance-based sensitivity indices S_ξ and S_ξ^{tot} of trigger input ξ are taken as a measure of the influence of spatiotemporal input W_z on the variance of model output Y .

Crosetto and Tarantola [7] applied this method on a GIS-based hydrologic model that simulate flood discharges from forecast rainfall on a given area. Five spatially distributed inputs $W_i(z)$ were considered: rainfall intensity maps, vector layer on flood-exposed assets, porosity maps, interception map, and soil moisture map. These inputs include 2D and 3D data, quantitative raster data, categorical raster data, and vector data. A stochastic process was defined for each of them to generate random error maps to be added to the initial maps. For one of the inputs (the rainfall intensity map), the stochastic process accounted for spatial autocorrelation in $W_i(z)$: random realizations of an error Gaussian random field were generated using Cholesky decomposition technique. For the other inputs, stochastic processes did not account for the spatial autocorrelation of uncertainty. Five trigger variables ξ_1 to ξ_5 were included in the sensitivity analysis, and first- and total-order sensitivity indices S_ξ and S_ξ^{tot} were estimated for each of them using the E-FAST procedure.

One must note that the sensitivity indices obtained using the trigger input approach do not have the same meaning than the sensitivity indices obtained with macro-parameter or dimension reduction methods. This point is discussed in further section (pros and cons of available methods).

3.1.4 Map Labeling

Lilburne and Tarantola [27] suggest to represent the uncertainty of spatiotemporal input W_z using a restricted set of n_L randomly generated realizations (n_L possibly large). Each realization is *labeled* by a single integer ranging from 1 to n_L and stored in some permanent memory space. The random realization associated with label l is denoted by $W_z^{(l)}$. These n_L realizations are considered as equiprobable.

Model (39.1) is then modified by introducing a random label L which follows a discrete uniform pdf in $\llbracket 1; n_L \rrbracket$:

$$\begin{aligned} f^* : \mathbb{R}^d \times \llbracket 1; n \rrbracket &\rightarrow \mathbb{R} \\ (\mathbf{X}, L) &\mapsto Y = f(\mathbf{X}, W_z^{(L)}). \end{aligned} \quad (39.5)$$

Hence, spatiotemporal input W_z is replaced by a reference to the random label L : for each model run, the sampled value $l^{(i)}$ of the label indicates that random realization $W_z^{(l^{(i)})}$ of the spatiotemporal input must be considered to evaluate model f for this run. First- and total-order sensitivity indices S_L and S_L^{tot} of random label L are then computed: these indices are taken as a measure of the influence of W_z on the variance of model output Y .

Lilburne and Tarantola [27] applied the *map labeling* approach to a spatial model for simulating nitrate transport from paddock to groundwater (AquiferSim). Four spatially distributed inputs were considered (soil map, land use map, river recharge map, and aquifer transmissivity map), and a small set of up to $n_L = 4$ random realizations was generated for each of them. The *map labeling* approach was also used by [35] to perform sensitivity analysis of a model for oil reservoir production forecasting. Two spatially distributed inputs were considered (basin geometry and heat flow map), and a small set of $n_L = 8$ (basin geometry) or $n_L = 4$ (heat flow) random realizations was generated for each of them.

3.2 Variance-Based Sensitivity Analysis with Metamodels

When the computer model is too CPU time-consuming to allow a sufficient number of model calculations, it can be approximated by a metamodel, estimated on a few simulations of the model (learning sample), as described in Paper 8 (see ▶ Chap. 38, “Metamodel-Based Sensitivity Analysis: Polynomial Chaos Expansions and Gaussian Processes”). Then, the sensitivity indices are directly estimated on the metamodel. In the case of functional inputs, the application of such approach raises the problem of taking into account a functional input in a metamodel. In what follows, several strategies are proposed to address this problem.

3.2.1 Metamodel with Dimension Reduction

At first, a reduction method such as projection on a functional basis can be used. The functions of the decomposition can be *known* (polynomial, Fourier, or wavelet basis) or estimated (e.g., functional proper component analysis). The main coefficients of the decomposition are selected (reduction model step), and a metamodel is estimated taking as inputs these coefficients. Then, using the obtained metamodel, VB-GSA methods defined for group of variables such as Sobol indices [25] can be applied to compute the global influence of this group of coefficients and, consequently, estimate the influence of the functional input.

3.2.2 Joint Metamodeling

As proposed by [24], another method could be to use a joint metamodel approach. This technique was initially introduced to approximate stochastic computer codes; [48] proposed to model the mean and dispersion of computer code outputs by two interlinked generalized linear models. This approach, called joint modeling, was previously studied in the context of experimental data modeling [31, 43]. Iooss and Ribatet [24], Gijbels et al. [17], and Marrel et al. [29] proposed to use more complex metamodels such as nonparametric models (generalized additive models, extended generalized linear models, and Gaussian processes, respectively) and to extend this method to functional input, considering this input as an uncontrollable parameter (i.e., governed by a seed variable). In this framework, the functional input is represented by a seed variable denoted X_ε lying in the set of all natural numbers \mathbb{N} , the other scalar inputs remain $\mathbf{X} = (X_1, \dots, X_d)$, and the model is defined by:

$$\begin{aligned} f : \mathbb{R}^d \times \mathbb{N} &\rightarrow \mathbb{R} \\ (\mathbf{X}, X_\varepsilon) &\mapsto Y = f(\mathbf{X}, X_\varepsilon) . \end{aligned} \quad (39.6)$$

Joint metamodels yield two metamodels, one for the mean and another for the dispersion component:

$$Y_m(\mathbf{X}) = \mathbb{E}(Y|\mathbf{X}) \quad (39.7)$$

$$Y_d(\mathbf{X}) = \text{Var}(Y|\mathbf{X}) = \mathbb{E}[(Y - Y_m(\mathbf{X}))^2|\mathbf{X}] . \quad (39.8)$$

Referring to the total variance formula, the variance of the output variable Y can be rewritten and deduced from the two metamodels:

$$\begin{aligned} \text{Var}(Y) &= \text{Var}[\mathbb{E}(Y|\mathbf{X})] + \mathbb{E}[\text{Var}(Y|\mathbf{X})] \\ &= \text{Var}[Y_m(\mathbf{X})] + \mathbb{E}[Y_d(\mathbf{X})] . \end{aligned} \quad (39.9)$$

Furthermore, the variance of Y is the sum of the contributions of all the input variables $\mathbf{X} = (X_1, \dots, X_d)$ and X_ε :

$$\text{Var}(Y) = V_\varepsilon(Y) + \sum_{i=1}^d \sum_{|J|=i} [V_J(Y) + V_{J\varepsilon}(Y)] \quad (39.10)$$

where $V_\varepsilon(Y) = \text{Var}[\mathbb{E}(Y|X_\varepsilon)]$, $V_i(Y) = \text{Var}[\mathbb{E}(Y|X_i)]$, $V_{i\varepsilon}(Y) = \text{Var}[\mathbb{E}(Y|X_i X_\varepsilon)] - V_i(Y) - V_\varepsilon(Y)$, $V_{ij}(Y) = \text{Var}[\mathbb{E}(Y|X_i X_j)] - V_i(Y) - V_j(Y)$, ... Variance of the mean component $Y_m(\mathbf{X})$ denoted hereafter Y_m can be also decomposed:

$$\text{Var}(Y_m) = \sum_{i=1}^d \sum_{|J|=i} V_J(Y_m) . \quad (39.11)$$

Note that

$$\begin{aligned} V_i(Y_m) &= \text{Var}[\mathbb{E}(Y_m|X_i)] \\ &= \text{Var}\{\mathbb{E}[\mathbb{E}(Y|\mathbf{X})|X_i]\} \\ &= \text{Var}[\mathbb{E}(Y|X_i)] = V_i(Y). \end{aligned} \quad (39.12)$$

Moreover, Sobol indices for variable Y according to input variables $\mathbf{X} = (X_i)_{i=1..d}$ can be derived from their usual definition given in Paper 5 (see ► Chap. 35, “Variance-Based Sensitivity Analysis: Theory and Estimation Algorithms”):

$$S_J = \frac{V_J(Y_m)}{\text{Var}(Y)}. \quad (39.13)$$

These Sobol indices can be computed using the same classical Monte Carlo techniques: these algorithms are applied to the metamodel defined by the mean component Y_m of the joint model.

Thus, all terms contained in $\text{Var}[Y_m(\mathbf{X})]$ of Eq. (39.9) have been considered. Then, $\mathbb{E}[Y_d(\mathbf{X})]$ can be estimated by a simple numerical integration of $Y_d(\mathbf{X})$ following the distribution of \mathbf{X} . $Y_d(\mathbf{X})$ is evaluated with a metamodel, for example, the dispersion component of the joint model. Therefore, the total sensitivity index of X_ε is given by:

$$S_\varepsilon^{\text{tot}} = \frac{V_\varepsilon(Y) + \sum_{i=1}^d \sum_{|J|=i} V_{J\varepsilon}(Y)}{\text{Var}(Y)} = \frac{\mathbb{E}[Y_d(\mathbf{X})]}{\text{Var}(Y)}. \quad (39.14)$$

As $Y_d(\mathbf{X})$ is a positive random variable, positivity of $S_\varepsilon^{\text{tot}}$ is guaranteed. In practice, [29] propose to estimate $\text{Var}(Y)$ from the data or from simulations of the fitted joint model, using Eq. (39.9). If $\text{Var}(Y)$ is computed from the data, the authors recommend to estimate $\mathbb{E}[Y_d(\mathbf{X})]$ with $\text{Var}(Y) - \text{Var}[Y_m(\mathbf{X})]$ to satisfy Eq. (39.9).

If the seed variable X_ε manages one (or several) stochastic process (which is here the functional input), $S_\varepsilon^{\text{tot}}$ is interpreted as the total sensitivity index of this stochastic process. Consequently, $S_\varepsilon^{\text{tot}}$ could reveal if the functional input is nonsignificant. This approach can also be used for scalar inputs: X_ε can manage one of a group of scalar inputs.

The limitation of this approach is that only the total part of uncertainty related to W_ε is estimated; its individual effect is not distinguished from its interaction with the other parameters. However, these potential interactions could be pointed out, considering all the primary and total effects of all the other parameters. This sensitivity analysis could constitute, for example, a preliminary step before a VB-GSA taking into account more explicitly the functional input.

3.2.3 Distance-Based Metamodel

In order to take into account more explicitly the functional input in a metamodel, the uncertainty related to $\{W_t\}_{t \in T}$ can be represented by a distance function measuring the *dissimilarity* between any two realizations of this stochastic process. This approach is based on the concept of distance between parameter fields [3, 40, 44].

Several types of distances can be defined, but the important point is that the distance should be chosen such that it can be computed rapidly and help predicting if two parameter fields will lead to similar or different model outputs Y . For example, [45] propose to use the Hausdorff distance to quantify the differences in the geometry of complex 3D models (having different fault systems, horizon geometries, etc.). In their application of oil recovery from a production well, [40] define the square distance between two parameter fields as the integrated square difference between the responses computed for the two parameter fields with a fast streamline solver. The distance between every pair of parameter fields is computed and used as a base for mapping all the parameter fields in an abstract metric space. Going a step further, [4] use the same framework to formulate the inverse problem. In a similar way, several authors recently proposed to handle functional inputs in a Gaussian process metamodel using covariance functions adapted to the study of functional variables [12, 18], such as a covariance function depending on functional distances as those previously mentioned. Still in the framework of Gaussian process metamodel, [33] proposes, for time-varying inputs and outputs, a correlation function based on a weighted distance between input functions, suggesting a belief that at any time, the output is most sensitive to *recent* values of the input function.

Whatever the kind of distance chosen to take into account the functional inputs in the distance-based metamodel, the latter, once built, is then directly used to compute the VB-GSA indices with classical intensive Monte Carlo methods.

3.3 Pros and Cons of Available Methods

We discuss here the pros and cons of the various methods displayed in the previous section. All these methods intend to compute variance-based sensitivity indices that could measure the influence of an uncertain spatiotemporal input $\{W(z) : z \in \mathbb{D}_z\}$ on the variance of model output Y . However, they do not produce exactly the same information.

3.3.1 Methods Do Not Produce the Same Information

First, the information brought by the *macro-parameter* and *dimension reduction* methods is slightly different depending on whether sensitivity indices S_W , S_W^{tot} are computed for the whole group of inputs $\mathbf{W} = (W_1, \dots, W_m)$ or if separate sensitivity indices S_{W_j} , $S_{W_j}^{\text{tot}}$ are computed for each parameter W_j , $j \in \{1, \dots, m\}$.

Indeed, the set of first-order indices $(S_{W_j})_{j \in \llbracket 1; m \rrbracket}$ does not bring the same information as the first-order sensitivity index S_W of the whole spatiotemporal input W_z , because S_W accounts for the role of the interactions between $(W_j)_{j \in \llbracket 1; m \rrbracket}$, while first-order indices S_{W_j} do not. In the same way, the set of total-order indices

$(S_{W_j}^{\text{tot}})_{j \in \llbracket 1; m \rrbracket}$ does not bring the same information as the total-order sensitivity index S_W^{tot} , because interactions between scalar parameters W_j are counted multiple times in the set of indices $(S_{W_j}^{\text{tot}})_{j \in \llbracket 1; m \rrbracket}$, while it is counted just once in S_W^{tot} . Hence,

the set of sensitivity indices $(S_{W_j}, S_{W_j}^{\text{tot}})_{j \in [1; m]}$ does not yield a good measure of the main and total contributions of W_z to the variance of model output Y . One must also note that separate sensitivity indices S_{W_j} , $S_{W_j}^{\text{tot}}$ can be computed for each parameter W_j , $j \in \{1, \dots, m\}$ if and only if those parameters W_j are assumed to be independent. Otherwise, only group sensitivity indices should be computed, because usual variance-based sensitivity indices are not defined for dependent variables. Besides, the *dimension reduction with grouping* method only yields an approximation of sensitivity indices of W_z , as the total information initially contained in W_z is reduced to a small set of scalar parameters.

It should also be noted that in the *joint metamodeling* method, only total-order sensitivity index S_W^{tot} can be estimated, but first-order index S_W remains unknown.

Results of a numerical study [36] also clearly suggest that the *trigger* method does not produce the same information as other methods. Sensitivity index of the *trigger* parameter ξ proved to be always smaller than the measure S_W brought by the *macro-parameter* or *map labeling* methods. One possible explanation is that, in the *trigger* method, uncertainty in W_z is taken into account only when the sampled value of the trigger input is equal to $\xi = 1$, that is, one out of every two model runs in average ($\mathbb{P}(\xi = 0) = \mathbb{P}(\xi = 1) = 1/2$). Hence, the effect of uncertain model input W_z on the variance of model output Y is systematically underestimated. This result leads us to believe that the *trigger* method is not appropriate to deal with spatially distributed inputs in variance-based global sensitivity analysis.

3.3.2 Computational Cost

The methods displayed in the previous section also differ in their computational cost. The cost of a method depends on (i) the number of model simulations it requires and (ii) the number of random realizations of spatiotemporal input W_z needed. We compare these costs with the hypothesis that the same sampling procedure is used for all methods in which sensitivity indices are estimated from a pseudo Monte Carlo sample, with a base sample size N and a total sample size $N \cdot (d + 2)$ where d is the number of model inputs or groups of model inputs. Computational costs associated with each method are given in Table 39.1. It appears that the least CPU-intensive approaches are the *map labeling* and the *joint metamodeling* methods.

3.3.3 Spatiotemporal Data Handling

In many environmental case studies, spatiotemporal model inputs are stored in user-specific formats, for example, .tiff images or shapefiles to be read by geographic information systems. Handling such files may raise some technical issues when performing sensitivity analysis. Some methods displayed in the previous section allow to easily handle spatiotemporal inputs, no matter how they are stored on the computer. In the *map labeling*, *trigger*, and *joint metamodeling* methods, the random realizations of W_z can be generated using any stochastic process \mathcal{P} , based on any algorithm and any software. On the contrary, in the *macro-parameter* or *dimension reduction* methods, the spatiotemporal inputs must be represented by a vector of

Table 39.1 Methods for VB-GSA indices with spatiotemporal inputs. Column (a): number of map realizations needed. Column (b): coupling with a metamodel is possible. Column (c): possibility to cope with several spatial inputs. Column (d): Possibility to model spatiotemporal autocorrelation in $\{W(z) : z \in \mathbb{D}_z\}$. Column (e): sensitivity indices associated with W_z

Method	(a)	(b)	(c)	(d)	(e)	Comments
Macro-parameter	N	No	Yes	No	Indices of the group of inputs $(W_j)_{j \in \{1, \dots, m\}}$	Possibly intractable for large data
Dimension reduction	N	No	Yes	No	Indices of the group of inputs $(W_j)_{j \in \{1, \dots, m\}}$	Simplification of the input data
Trigger	$\sim N/2$	No	Yes	Yes	Indices of the trigger input ξ	A measure of sensitivity is obtained, which is not equal to variance-based sensitivity indices of $W(z)$.
Map labeling	$n_L < N$	No	Yes	Yes	Indices of the label input L	Spatially distributed input $W(z)$ is under-sampled compared to other inputs
Joint GAM metamodel	$\ll N$	Yes	No	Yes	Total-order index S_Z^{tot} only	Use of a metamodel

numbers or a matrix to be used in sensitivity analysis. It is then more difficult with this method to deal with spatiotemporal data stored in user-specific file formats.

Before illustrating some of the previously presented methods on the NOE case study, we can mention the recent work of [14] who have proposed a VB-GSA method in the specific case where the computer code is a functional linear model and the functional inputs are known stochastic processes. Nevertheless, as these two requirements are rarely met in practice, we will not detail this method here.

3.4 Application on NOE Test Case

Saint-Geours et al. [38] applied a VB-GSA to the NOE model. Here we briefly summarize their main results, considering a single scalar output Y , which is the total expected annual damage [€] over the entire Orb Delta.

3.4.1 Modeling Uncertainty on Spatial Inputs

The hazard map $(W_{z,1})$ is a GIS raster map (regular grid) that gives water depths across the study area. Uncertainty in $W_{z,1}$ derives from the combination of various input uncertainties in the inundation mapping process; however, for the sake of

simplicity, we considered the error on the high-resolution digital terrain model (DTM) as the single uncertainty source in the hazard map $W_{z,1}$. The DTM—a raster surface of 5 m cell size—was initially built by stereophotogrammetry. Both measurement errors and interpolation errors affect the quality of this input data [47]. These errors are spatially auto-correlated and are modeled by a zero-mean Gaussian random field with an exponential variogram model $\gamma(\cdot)$, whose characteristics were determined from a set of 500 control field points (sill = 17 cm, range = 500 m, nugget = 0.02).

The land use map ($W_{z,2}$) is a GIS vector map, which exhibits at least two types of uncertainty: (i) semantic errors (misclassification of polygonal features representing assets) and (ii) geometric errors [2]. Semantic errors are described by a confusion matrix that gives a confusion probability $p(a, b)$ for each pair of possible land use types (a, b) [13]. Geometric errors are accounted for by randomizing the surface area of each polygonal feature, using a corrective random coefficient $\alpha \sim U[0.75; 0.85]$ —which corresponds to a digitalizing error of 0.3 mm at the map scale [20].

From this description of uncertainty, two stochastic processes \mathcal{P}_1 and \mathcal{P}_2 were designed to generate any number of random realizations of $W_{z,1}$ and $W_{z,2}$.

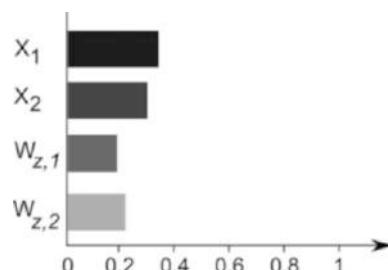

3.4.2 Propagating Uncertainty: The Map Labeling Method

To estimate variance-based sensitivity indices associated with spatial inputs $W_{z,1}$ and $W_{z,2}$, we use the *map labeling* method of [27]. The uncertainty of W_z is represented using a set of n_L randomly generated realizations (n_L possibly large). Each realization is then *labeled* by a single integer. Sample sizes $n_{L,1} = 1000$ and $n_{L,2} = 100$ were used for the two spatial inputs of the NOE model (hazard map $W_{z,1}$ and land use map $W_{z,2}$).

3.4.3 Results

Figure 39.3 displays the total-order sensitivity indices S_i^{tot} computed for each uncertain model input with respect to the aggregated model output $Y_v = \int_{z \in v} Y(z) dz$ over the entire Orb floodplain. The nonspatially distributed inputs (flood return intervals X_1 and damage functions X_2) prove to be the most important sources of uncertainty when aggregating the EAD risk indicator over the total floodplain. On the contrary, the contribution of the two spatially distributed inputs, that is, the hazard map $W_{z,1}$ and the land use map $W_{z,2}$, is small.

Fig. 39.3 Total-order sensitivity indices S_i^{tot} of model inputs X_1 (flood return intervals), X_2 (depth-damage functions), $W_{z,1}$ (hazard map), and $W_{z,2}$ (land use map) with respect to the aggregated output (EAD flood damage indicator) over the entire Orb floodplain

4 Methods for Spatiotemporal Outputs

We consider the model f with d real scalar inputs $\mathbf{X} = (X_1, \dots, X_d)$ and a functional output $Y \in \mathbb{F}$. The functional space \mathbb{F} is a subset of functions mapping from \mathbb{D}_z to \mathbb{R} , where \mathbb{D}_z can be a time interval or a spatial domain, for example. The model is defined by:

$$\begin{aligned} f : \mathbb{R}^d &\rightarrow \mathbb{F} \\ \mathbf{X} &\mapsto Y(z) = f(\mathbf{X}; z) \end{aligned} \quad (39.15)$$

for any $z \in \mathbb{D}_z$. The inputs \mathbf{X} are modeled by random variables and characterized by their probability density function $\mu_{\mathbf{X}}$.

We also consider a discretization of \mathbb{D}_z with p elements:

$$\mathbb{D}_z \xrightarrow{\text{discretization}} \mathcal{Z} = (z^{(1)}, \dots, z^{(p)}) \in \mathbb{D}_z^p.$$

In this case, the model (39.15) is replaced by its discretized version:

$$\begin{aligned} \mathbf{f} : \mathbb{R}^d &\rightarrow \mathbb{R}^p \\ \mathbf{X} &\mapsto \mathbf{Y} = \mathbf{f}(\mathbf{X}) = (f(\mathbf{X}; z^{(1)}), \dots, f(\mathbf{X}; z^{(p)}))^T. \end{aligned} \quad (39.16)$$

where the output \mathbf{Y} belongs to \mathbb{R}^p .

4.1 Sensitivity Index Maps

For any sensitivity measure S , a common approach to deal with multidimensional output consists in running a separate sensitivity analysis for each component of the vectorial output in Eq. (39.16). This leads to d vectors of sensitivity indices $(\mathbf{S}_i)_{1 \leq i \leq d}$, with $\mathbf{S}_i = (S_i^{(1)}, \dots, S_i^{(p)})$ where $S_i^{(j)}$ is the sensitivity index associated to the input X_i with respect to the j th output component. When \mathbf{Y} is a spatial field, as in the Ceres-Mithra and the NOE test cases, for example, \mathbf{S}_i can be plotted over the grid \mathcal{Z} and provide a sensitivity index map for any input parameter (see, e.g., Marrel et al. [30] and Ceres-Mithra results on page 1351 or NOE results on page 1349). Such spatial measures can be called “site sensitivity indices” and make sense.

This approach has some severe limits. Firstly, computing sensitivity index maps is computationally expensive : $d \times p$ sensitivity indices have to be estimated, instead of only d sensitivity indices for a scalar output. This is especially true when \mathcal{Z} is a fine spatial grid with hundreds, even thousands, of nodes. Secondly, the interpretation of sensitivity index maps is not straightforward: conclusions have to be drawn based on the comparison of vectorial sensitivity indices, not scalar ones; it is usually impossible to find a unique ranking of model inputs from these sensitivity index maps (see Ceres-Mithra results on page 1351 and NOE results on page 1349).

4.2 Block Sensitivity Indices

Another common approach to deal with a multidimensional output \mathbf{Y} is to simply extract a scalar quantity of interest from \mathbf{Y} and to compute sensitivity indices with respect to it. When a model has a spatiotemporal output $Y(z)$, modelers are most often interested in the aggregated value of model output over a given spatiotemporal subset $v \subset \mathbb{D}_z$ of the spatial domain or time interval. Hence, a common quantity of interest is the average value $Y_v = \int_{z \in v} Y(z) dz$, or $Y_v = \frac{1}{q} \sum_{j=1}^q f(\mathbf{X}; z^{(j)})$ using a discretization of v . We call *block sensitivity indices*, denoted by $S_{\{i\}}^{\text{tot}}(v)$, the total-order indices computed with respect to the scalar output Y_v .

These *block sensitivity indices* $S_{\{i\}}^{\text{tot}}(v)$ can be computed over subsets $v \subset \mathbb{D}_z$ of varying sizes and locations. They can bring valuable insights on the model behavior at different spatiotemporal scales (see NOE results on page 1349). However, they do not give a full functional restitution of sensitivity analysis and do not provide complete information on local model behavior in the functional domain \mathbb{D}_z .

4.3 Aggregated Sensitivity Indices

A full functional sensitivity analysis for spatiotemporal outputs, which would provide both local and global information on model behavior in the spatiotemporal domain \mathbb{D}_z , remains a challenge. In the following paragraphs, we will attempt to give some solutions to address the shortcomings of both the sensitivity index maps and the block sensitivity indices.

Firstly, a few authors suggested to use dimension reduction to deal with spatiotemporal outputs in sensitivity analysis. They expanded multidimensional output \mathbf{Y} on some appropriate basis and then separately computed sensitivity measures with respect to the more informative components of this expansion. Particularly, [5] used an empirical orthogonal decomposition of the multidimensional output (Legendre polynomial, principal component analysis, or partial least square) and computed usual variance-based sensitivity indices with respect to the coefficients of this expansion, keeping only the main components. However, this method limits the analysis to the principal characteristics rather than the whole behavior of the model output. Furthermore, the interpretation of sensitivity indices computed with respect to the coefficient of a functional decomposition is tricky.

More recently, [16] defined *aggregated Sobol indices* for any input parameter X_i , $i \in \{1, \dots, d\}$, based on the decomposition of the multidimensional output variance. To achieve this, they consider the multidimensional model $\mathbf{Y} = \mathbf{f}(\mathbf{Y}) \in \mathbb{R}^p$ satisfying $\mathbb{E}[\|\mathbf{f}(\mathbf{X})\|^2] < \infty$ and apply the Hoeffding decomposition to the function $\mathbf{f}, \mathbb{R}^d \mapsto \mathbb{R}^p$:

$$\mathbf{f}(\mathbf{X}) = \mathbf{f}_0 + \mathbf{f}_i(X_i) + \mathbf{f}_{\sim i}(\mathbf{X}_{\sim i}) + \mathbf{f}_{i,\sim i}(X_i, \mathbf{X}_{\sim i})$$

where $\mathbf{f}_0 = \mathbb{E}[\mathbf{Y}]$, $\mathbf{f}_i = \mathbb{E}[\mathbf{Y}|X_i] - \mathbf{f}_0$, $\mathbf{f}_{\sim i} = \mathbb{E}[\mathbf{Y}|\mathbf{X}_{\sim i}] - \mathbf{f}_0$ and $\mathbf{f}_{i,\sim i} = \mathbf{Y} - \mathbf{f}_{\sim i} - \mathbf{f}_i - \mathbf{f}_0$, with $\mathbf{X}_{\sim i} = (X_j)_{\substack{1 \leq j \leq d \\ j \neq i}}$. Then, they compute the covariance matrix of both sides of

this equality and apply the trace operator in order to turn the matrix format into a scalar one:

$$\text{trace}(\Sigma) = \text{trace}(C_i) + \text{trace}(C_{\sim i}) + \text{trace}(C_{i,\sim i})$$

where $\Sigma = \mathbb{V}[\mathbf{f}(X)]$, $C_i = \mathbb{V}[\mathbf{f}_i(X)]$, and so on. Contrarily to the determinant operator, the trace one allows an additive decomposition of the output to the Hoeffding expansion. Finally, dividing both sides by $\text{trace}(\Sigma)$ leads notably to the first-order index:

$$S_i = \frac{\text{trace}(C_i)}{\text{trace}(\Sigma)} = \frac{\sum_{l=1}^p \mathbb{V}[Y_l] S_i^{(l)}}{\sum_{l=1}^p \mathbb{V}[Y_l]} \quad (39.17)$$

where $\mathbb{V}[Y_l]$ is the variance associated to the l th scalar output and $S_i^{(l)}$ is the first-order Sobol index associated to the l th output for the i th input parameter.

Gamboa et al. [16] estimate this index using the pick-and-freeze estimator

$$S_{i,N} = \frac{\sum_{l=1}^p \left(\frac{1}{N} \sum_{j=1}^N Y_l^{(j)} Y_l^{[i],(j)} - \left(\frac{1}{N} \sum_{j=1}^N \frac{Y_l^{(j)} + Y_l^{[i],(j)}}{2} \right)^2 \right)}{\sum_{l=1}^p \left(\frac{1}{N} \sum_{j=1}^N \frac{(Y_l^{(j)})^2 + (Y_l^{[i],(j)})^2}{2} - \left(\frac{1}{N} \sum_{j=1}^N \frac{Y_l^{(j)} + Y_l^{[i],(j)}}{2} \right)^2 \right)} \quad (39.18)$$

where $(X^{(j)}, Y^{(j)})_{1 \leq j \leq N}$ is a sample of N independent realizations of (\mathbf{X}, \mathbf{Y}) and where $\mathbf{Y}^{[i]} = \mathbf{f}(X_i, \mathbf{X}'_{\sim i})$ with $\mathbf{X}'_{\sim i}$ being an independent copy of $\mathbf{X}_{\sim i}$. Total indices can be computed in the same way thanks to the relation $S_i^{\text{tot}} = S_i + S_{i,\sim i} = 1 - S_{\sim i}$ and formulas (39.17)–(39.18).

These aggregated Sobol indices are equal to the sensitivity measures defined by Lamboni et al. [26], when all the terms of the output Proper Orthonormal Decomposition Chatterjee [6] used in their work are kept in the global sensitivity index computation. More precisely, these authors consider the following expansion of the model output:

$$\mathbf{Y} = \boldsymbol{\mu} + \mathcal{V}\mathbf{H}$$

where $\boldsymbol{\mu} = \mathbb{E}[\mathbf{Y}]$, \mathcal{V} is the matrix whose columns $\mathbf{v}_1, \dots, \mathbf{v}_p$ are the eigenvectors of Σ , also called components, and $\mathbf{H} = \mathcal{V}^T (\mathbf{Y} - \boldsymbol{\mu})$ is a random vector. Note that for any $k, l \in \{1, \dots, p\}$, $\mathbb{E}[H_k] = 0$, $\mathbb{E}[H_k H_l] = \lambda_k \delta_{kl}$ and $\mathbb{V}[H_k] = \lambda_k$, λ_k being the k th eigenvalue of Σ associated to the eigenvector \mathbf{v}_k , also called principal component.

Then, for any $w \subset \{1, \dots, d\} \setminus \emptyset$, the corresponding sensitivity index for the k th principal component \mathbf{v}_k is defined by

$$S_{w,k} = \frac{\mathbb{V}_{w,k}}{\lambda_k}$$

where $\mathbb{V}_{w,k} = \mathbb{V}[\mathbb{E}[H_k | \mathbf{X}_w]] - \sum_{u,u \subset w} \mathbb{V}_{u,k}$ and $\mathbb{V}_{\emptyset,k} = 0$, with $\mathbf{X}_w = (X_i)_{i \in w}$. Particularly, for any $i \in \{1, \dots, d\}$, the first-order and total variance-based sensitivity indices \mathbf{v}_k are

$$S_{i,k} = \frac{\mathbb{V}[\mathbb{E}[H_k | X_i]]}{\lambda_k} \text{ and } S_{i,k}^{\text{tot}} = \sum_{\substack{w \subset \{1, \dots, d\} \\ w \ni i}} S_{w,k}.$$

Using these component-based sensitivity indices, Lamboni et al. [26] suggested to define corresponding first-order and total-aggregated sensitivity indices:

$$S_i = \frac{\sum_{k=1}^p \lambda_k S_{i,k}}{\text{trace}(\Sigma)} = \frac{\sum_{k=1}^p \lambda_k S_{i,k}}{\sum_{k=1}^p \lambda_k} \text{ and } S_i^{\text{tot}} = \sum_{\substack{w \subset \{1, \dots, d\} \\ w \ni i}} S_i. \quad (39.19)$$

This first-order Sobol index S_i has an expression similar to the one of [16] presented in Eq. (39.17). Moreover, it can easily be proven that these terms are equal. For the estimation step, we consider an N -sample $(\mathbf{X}^{(i)}, \mathbf{Y}^{(i)})_{1 \leq i \leq N}$ associated to a particular Sobol index computation method and replace the covariance matrix Σ by the empirical one

$$\hat{\Sigma} = \frac{1}{N} \sum_{i=1}^N (\mathbf{Y}^{(i)} - \bar{\mathbf{Y}})(\mathbf{Y}^{(i)} - \bar{\mathbf{Y}})^T \quad (39.20)$$

where $\bar{\mathbf{Y}} = \frac{1}{N} \sum_{i=1}^N \mathbf{Y}^{(i)}$. Similarly, we note $\hat{\lambda}_k$ and $\hat{\mathbf{v}}_k$, the k th eigenvalue and eigenvector of $\hat{\Sigma}$, respectively, and we consider the score matrix $\hat{H} = (\hat{H}_{ik})_{\substack{1 \leq i \leq N \\ 1 \leq k \leq p}}$

where $\hat{H}_{ik} = \langle \mathbf{Y}^{(i)} - \bar{\mathbf{Y}}, \hat{\mathbf{v}}_k \rangle_2$, $\langle \cdot, \cdot \rangle_2$ being the scalar product on \mathbb{R}^p . Finally, for any $k \in \{1, \dots, p\}$ and any $i \in \{1, \dots, d\}$, $S_{i,k}$ is estimated by $\hat{S}_{i,k}$ computed from the chosen Sobol index computation method and the N -sample $(\mathbf{X}^{(j)}, H_{jk})_{1 \leq j \leq N}$. Moreover, we have

$$\hat{S}_i = \frac{\sum_{k=1}^p \hat{\lambda}_k \hat{S}_{i,k}}{\text{trace}(\hat{\Sigma})}. \quad (39.21)$$

To conclude, the variance-based global sensitivity analysis method suggested by Gamboa et al. [16] gives aggregated sensitivity indices which summarize the influence of each model input X_i on the variance of multidimensional output \mathbf{Y} . The approach of Lamboni et al. [26] also leads to the computation of similar aggregated sensitivity indices: when all the terms are kept in the expansion of model output \mathbf{Y} , both aggregated sensitivity indices of Gamboa et al. [16] and Lamboni et al. [26] are

equal. These aggregated sensitivity indices are global measures that summarize the local model behavior over spatiotemporal domain \mathbb{D}_z . A unique ranking of model inputs can be derived from these aggregated sensitivity indices.

Remark 1. Previous sensitivity index maps and block sensitivity indices and their estimation often require thousands of model evaluations. Recently, Da Veiga [8] introduced the use of dependence measures in global sensitivity analysis, and De Lozzo and Marrel [9] developed it to the specific case of screening. One of these new indices is based on the Hilbert-Schmidt independence criterion (HSIC), which is defined, for any pair of measurable random variables (X, Y) , as the Hilbert-Schmidt norm of the cross-covariance operator between some function transformations of X and Y in reproducing kernel Hilbert spaces [19]. Da Veiga [8] noted that SA with HSIC-based sensitivity measure requires fewer model evaluations compared to variance-based ones. Moreover, kernels dedicated to functional data allow to deal easily with spatiotemporal inputs and outputs. These recent tools have to be confirmed by industrial applications but already represent an alternative for sensitivity analysis with spatial output.

4.4 Use of Metamodels

All the methods discussed above (sensitivity index maps, block sensitivity indices, aggregated sensitivity indices) are based on intensive Monte Carlo methods and require lots of simulations to be estimated. Some spatiotemporal models can be too time-consuming to be directly used to conduct such variance-based methods. To avoid the problem of huge calculation time, it can be useful to replace the complex computer code by a metamodel as introduced in the first section. The problem of building a metamodel for a functional output has recently been addressed by Shi et al. [41] and Bayarri et al. [1] who proposed an approach based upon functional decomposition, such as wavelets. Recently, Marrel et al. [28] proposed a complete methodology to perform sensitivity analysis of two-dimensional output: their approach consists in building a functional metamodel and computing variance-based sensitivity indices at each location of the spatial output map. The maps of Sobol indices thus obtained yield the identification of global and local influence of each input variable and the detection of areas with interactions. The functional metamodel is based on a decomposition on a basis of orthogonal functions followed by a metamodeling of the coefficients related to the main decomposition components. This method can be applied with any kind of orthogonal functions such as wavelets, Fourier functions, principal component analysis, polynomial chaos, etc. For example, in Marrel et al. [28], the authors use a wavelet decomposition and Gaussian process metamodels. As this decomposition seems to require a large number of metamodels to be built, Marrel et al. [30] then propose to apply this method but using a Proper Orthogonal Decomposition Chatterjee [6] instead of the wavelet decomposition in order to reduce the number of metamodels.

4.5 Application on NOE Test Case

Saint-Geours et al. [38] performed a variance-based global sensitivity analysis on the NOE model, considering as a spatial output the map $Y(z)$ of the EAD risk indicator. They first computed sensitivity index maps and then block sensitivity indices over spatial subsets $v \subset \mathbb{D}_z$. They investigated how the value of block sensitivity indices may vary depending on the spatial support chosen for averaging model output. We briefly summarize their findings below.

4.5.1 Sensitivity Index Maps

As explained on page 1344, sensitivity index maps can be computed by estimating $\mathbf{S}_i = (S_i^{(1)}, \dots, S_i^{(p)})$ where $S_i^{(j)}$ is the sensitivity index associated to the input X_i with respect to the value of output map at a specific location $z^{(j)} \in \mathbb{D}_z$. \mathbf{S}_i is then plotted over the grid \mathcal{Z} and provides a sensitivity index map for any input parameter X_i . Figure 39.4 displays the maps \mathbf{S}_i for all uncertain inputs of the NOE model. Spatial distribution of sensitivity indices proves to be heterogeneous. For example, by comparing these sensitivity maps with a map of the study area, we can find that the hazard map $W_{z,1}$ and the land use map $W_{z,2}$ display smaller sensitivity indices on the urban areas than on the areas covered with agricultural land. The interpretation of this finding will not be discussed here, but it brought a better understanding of the NOE model behavior.

4.5.2 Block Sensitivity Indices and Change of Support Effect

On the NOE model, three individual spatial supports v_1 , v_2 , and v_3 of increasing surface area were considered. These three supports were selected at random, and their study is only meant to be illustrative: v_1 is a single house located on the western bank of the Orb Delta ($|v_1| = 1$ ha), second support v_2 is the administrative district of Sauvian ($|v_2| = 13$ sq. km), and v_3 is the entire floodplain ($|v_3| = 63$ sq. km). Figure 39.5 displays the block sensitivity indices $S_{\{i\}}^{\text{tot}}(v)$ (as explained on page 1345) computed for each uncertain model input with respect to the aggregated model output $Y_v = \int_{z \in v} Y(z) dz$ over spatial supports v_1 (house), v_2 (district), and v_3 (floodplain). It clearly suggests that the ranking of uncertainty sources depends on the surface area of the spatial support v (*change of support effect*). The variance of the aggregated model output on v_1 (smallest support) appears to be mainly explained by the uncertainty on the two spatially distributed inputs, that is, the hazard map $W_{z,1}$ and the land use map $W_{z,2}$ (sensitivity indices, 0.65 and 0.8, respectively). On the contrary, the nonspatially distributed inputs (flood return intervals X_1 and damage functions X_2) prove to be the most important sources of uncertainty when aggregating the EAD risk indicator over the total floodplain v_3 (largest support).

This *change of support* effect can be explained theoretically. Let us consider from now on a model $Y = f(\mathbf{X}, W_z)$ with a *single* spatial input $W_z = \{W(z) : z \in \mathbb{D}_z\}$ which is assumed to be a second-order stationary random field (SRF) with an isotropic covariance function $C(\cdot)$. Let us also assume that model f is point based, that is, there exists a mapping $f_{loc.} : \mathbb{R}^d \times \mathbb{R} \rightarrow \mathbb{R}$ such that $\forall z \in \mathbb{D}_z$,

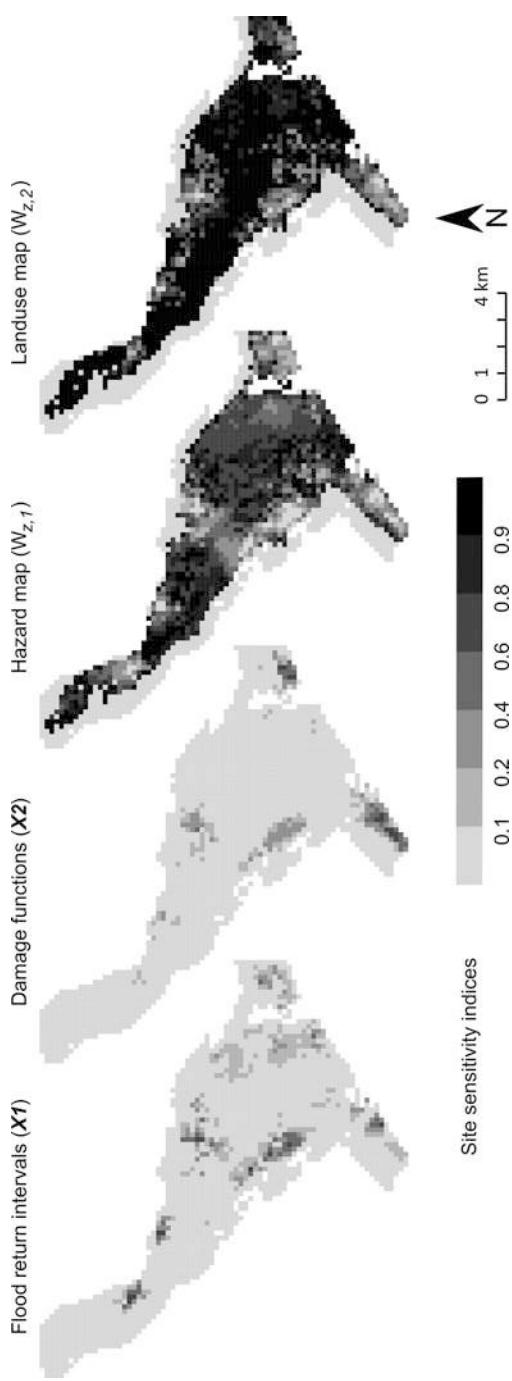

Fig. 39.4 Maps S_{ti} of site sensitivity indices for each model input

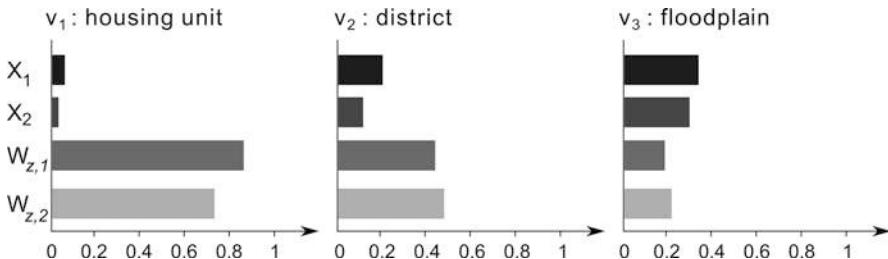

Fig. 39.5 Block sensitivity indices $S_{i,i}^{tot}(v)$ on spatial supports v_1 to v_3

$Y(z) = f_{loc}(\mathbf{X}, W(z))$. Under the stationary hypothesis on W_z , site sensitivity indices $S_{\{i\}}^{tot}(z)$ do not depend on site $z \in \mathbb{D}_z$ and can simply be denoted by $S_{\{i\}}^{tot}$. For any support $v \subset \mathbb{D}_z$, the block sensitivity indices of \mathbf{X} and W_z over support v verify [37, for a detailed proof]:

$$\frac{S_{W_z}^{tot}(v)}{S_{\mathbf{X}}^{tot}(v)} \simeq \frac{v_c}{|v|} \quad (39.22)$$

where v_c depends on the covariance function $C(\cdot)$. Equation (39.22) shows that the ratio $v_c/|v|$ determines the relative contribution of the model inputs W_z and \mathbf{X} to the output variance $\text{var}(Y_v)$. For a small ratio (i.e., when the area of the support v is large compared with the critical size v_c), the variability of spatial input W_z is mainly *local*, and the spatial correlation of W_z over v is weak. This local variability averages over the support v when the aggregated model output Y_v is computed; hence, spatial input W_z explains a small fraction of the output variance $\text{var}(Y_v)$. This *change of support effect* is of great importance to better understand how the result of a sensitivity analysis may change under model upscaling or downscaling.

4.6 Application on Ceres-Mithra Test Case

The model output of the Ceres-Mithra test case is a discretized spatial map of time-integrated surface activity concentration of *cesium 137* (Bq.s.m^{-3}), at moments $t_0 + 20'$, $t_0 + 40'$, ..., $t_0 + 2h$ where t_0 is the beginning of releases. This output is function of six uncertain inputs: the heights of release (HR1 and HR2), the deposition velocity (DV), the source term activity (STA), and the wind direction and speed (WD and WS). The associated two-dimensional spatial grid is made up of $60 \times 45 = 2700$ points and is the same for all the Ceres-Mithra simulations.

In the following, a global sensitivity analysis is performed on the Ceres-Mithra test case, using first the sensitivity index maps described on page 1344 to get some insight on the local model behavior and then using the aggregated sensitivity indices defined on page 1345 to get a global ranking of model inputs. With these sensitivity measures requiring a high number of evaluations, the surrogate model is necessary because of the important CPU time cost of a Ceres-Mithra run. This

metamodel is parametrized using an n -sample based on a *maximin* Latin hypercube sampling design, with $n = 200$, and validated by cross-validation (see [30] for details). Then, the sensitivity indices are estimated from ten thousand metamodel predictions and using Monte Carlo-based formulas of [39] and pick-and-freeze ones (see Eq. (39.18)) for the sensitivity index maps and aggregated Sobol indices, respectively.

4.6.1 Sensitivity Index Maps

Firstly, Figs. 39.6 and 39.7 represent the time evolution of the primary and total Sobol indices for each pixel of the maps. For the sake of brevity, only the variables with significant Sobol indices are shown and only at three different times. The local analysis of Sobol indices reveals that the source term activity influence is predominant in the central part of the plume, while the wind direction is less influential in this area. On the flip side, the situation is reversed in the limit of the plume: logically, the wind conditions have a strong impact on the plume trajectory.

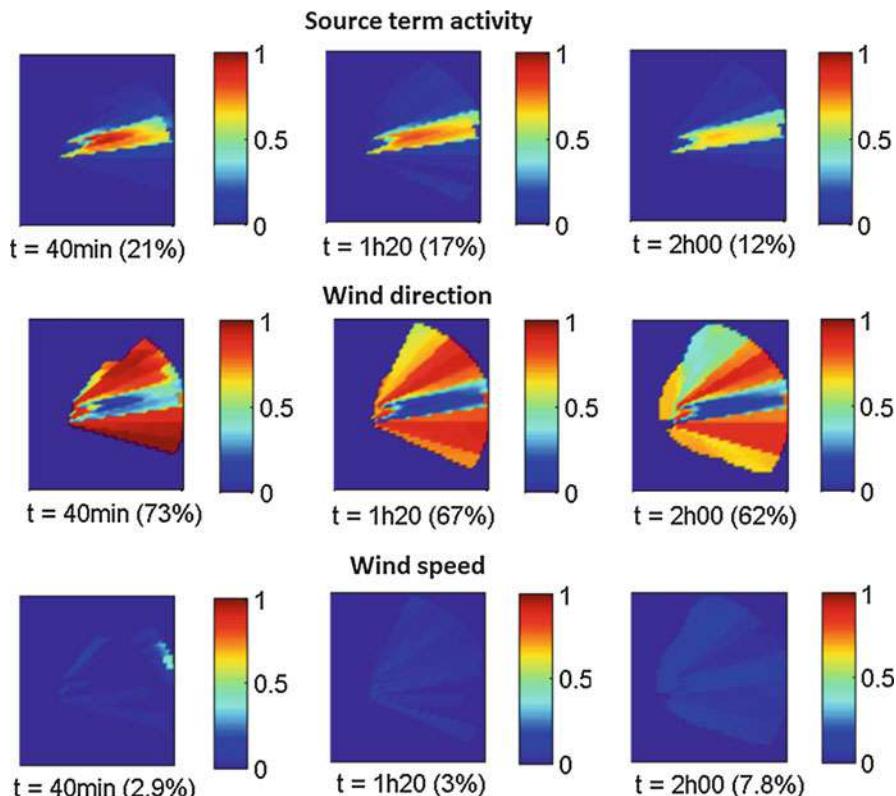

Fig. 39.6 Temporal evolution of the site 1st order Sobol indices for the ^{137}Cs integrated surface activity

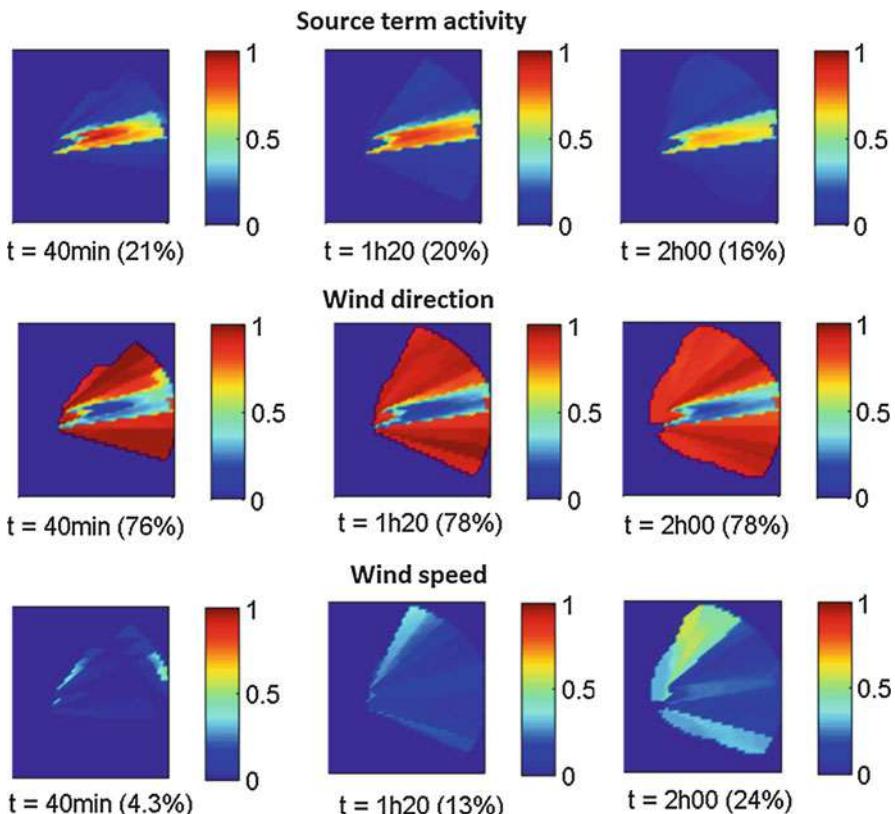

Fig. 39.7 Temporal evolution of the site total Sobol indices for the ^{137}Cs integrated surface activity

From a global point of view, the wind direction is the most influential variable on the surface activity forecast: it explains more than half of the activity variance. The source term activity is the second most influential variable, with on average about 15% of explained variance. The uncertainty on wind speed is less influential, while the deposition velocity and heights of release do not affect the forecast. The sum of the primary effects (i.e., without considering any interactions between variables) explains between 80% and 100% of the variance. Thus, the interactions account for less than 10% of the variance, and the only significant interaction is the one between the wind variables. The estimation of second-order indices shows that this interaction is located at the limit of the plume and increases slightly over time, while the direction wind decreases; see Fig. 39.8.

4.6.2 Aggregated Sensitivity Indices

Secondly, we turn to the aggregated total Sobol indices proposed by [16] in order to summarize previous site information. Figure 39.9 represents the evolution of

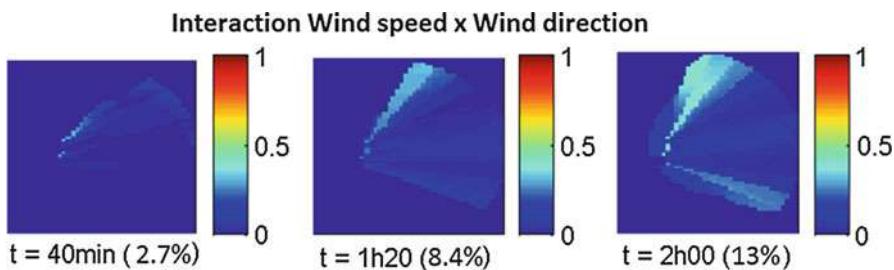

Fig. 39.8 Temporal evolution of the site 2nd order Sobol indices between wind components, for the ^{137}Cs integrated surface activity

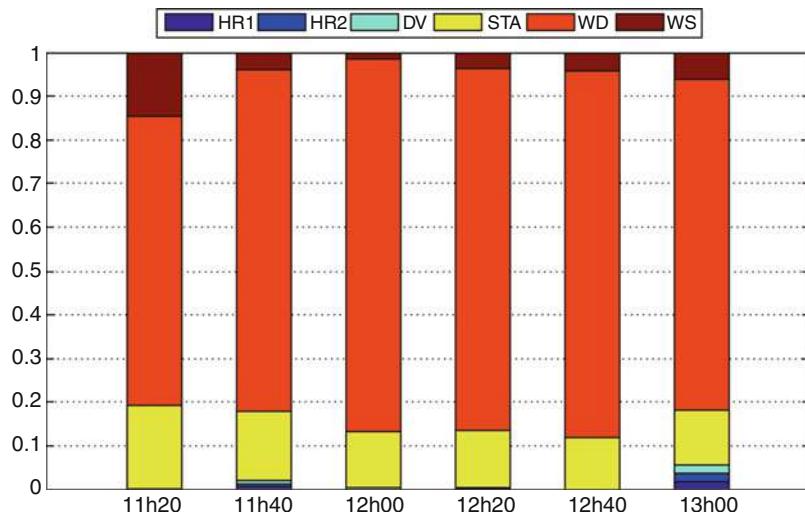

Fig. 39.9 Temporal evolution of the normalized block total Sobol indices for the ^{137}Cs integrated surface activity

these sensitivity indices after a normalization step, in order to sum to one. Clearly, the wind direction is the predominant input, explaining between 66% and 76% of the global output variance, according to the considered moment. Then, the source term activity represents between 12% and 19% of this variability. The wind speed uncertainty is less influential, with a contribution between 6% and 15%.

4.6.3 Conclusion on Ceres-Mithra Test Case

To conclude, the main benefit of the aggregated sensitivity indices is to give a single sensitivity measure for each model input, thus allowing the inputs to be ranked according to their global influence on model output; this leads clearly to easier conclusions in order to reduce the output variability by means of efforts deployed to the control of the most influential inputs. Besides, sensitivity index maps bring complementary information about the local contribution of the inputs to the output

variability, which can be helpful from a physical point of view, to better understand the local model behavior. Consequently, it is recommended to perform both types of sensitivity analyses in parallel, in order to deal with a spatial model output.

5 Conclusions

We discussed in this section how sensitivity analysis can be applied to computer codes with spatiotemporal inputs and/or outputs. The methods presented to deal with spatiotemporal inputs are practice oriented and have already been used in several industrial and environmental case studies. They all focus on the computation of variance-based sensitivity indices, but some of them can easily be adapted to other important measures such as elementary effects (Morris method). However, a homogeneous theoretical framework is still missing to properly define importance measures with respect to spatiotemporal inputs and more generally functional inputs.

Regarding spatiotemporal outputs, we distinguished the use of (i) sensitivity index maps, which scrutinize model behavior at each point of a spatiotemporal output domain; (ii) block sensitivity indices, which analyze the influence of model inputs on the average value of model output over a given subset of the spatiotemporal domain; and (iii) aggregated sensitivity indices, which summarize the influence of a model input over the entire spatiotemporal output domain. All types of indices give valuable insight on model behavior, and we strongly suggest to carry out different analyses whenever possible.

Finally, we tried to emphasize how sensitivity analysis can shed a new light on scale-related questions in spatiotemporal modeling, by analyzing how sensitivity indices and the ranking of uncertain inputs depend on the spatial/temporal support of model output. In spite of these advances, a general framework for sensitivity analysis of spatiotemporal models is still to be developed, and further research in this field is strongly needed.

Decision Analytic and Bayesian Uncertainty Quantification for Decision Support

40

D. Warner North

Abstract

This essay introduces probability in support of decision-making, as a state of mind and not of things. Probability provides a framework for reasoning coherently about uncertainty. According to Cox's theorem, it is the *only* way to reason coherently about uncertainty. Probability summarizes states of information. A basic desideratum is that states of information judged equivalent should lead to the same probability distributions. Some widely used probabilistic models have both sufficient statistics and maximum entropy characterizations. In practice, outside of certain physics and engineering applications, human judgment is usually needed to quantify uncertainty as probabilities. Reality is highly complex, but one can test judgments against what is known, drawing upon many specialized areas of human knowledge. Sensitivity analysis can evaluate the importance of multiple uncertainties in a decision context. When the choice between alternatives is close, what is the value of further information (VOI)? Important concepts discussed in this chapter are the expected value of perfect information and the expected value of further experimental testing.

Practical application is illustrated in two case studies. The first involves assessing the probability for replication of a terrestrial microbe on Mars, in the decision context of a constraint on planetary exploration. The second involves weather modification of hurricanes/typhoons: whether to deploy this technology to reduce damage from hurricanes impacting US coastal areas and valuing experimental testing offshore. The decision context is that of a natural disaster turned political by deployment of new technology where such deployment might be followed by a reduction, or by an increase, in adverse impacts, compared to not deploying the technology.

Decision support should be viewed as an iterative process of working with those with decision responsibility and with experts who are the best available

sources of information. The decision support process includes characterizing uncertainties and values for outcomes in the context of a choice among decision alternatives. Sensitivity analysis and VOI can give insight on whether to act now or to seek more information and more refined analysis. In a public policy decision context, the process can facilitate stakeholders sharing and critiquing information as the basis for characterizing uncertainties and learning which uncertainties and value judgments are most important for decisions.

1 A Viewpoint on Uncertainty Quantification

Introduction and purpose: This chapter of the handbook is a guide to using decision analysis with emphasis on uncertainty quantification. It assumes that the reader is familiar with probability theory as a mathematical structure based on the Kolmogorov axioms, as described in numerous modern textbooks. The emphasis in this chapter is on interpreting and using probability theory for uncertainty quantification as a part of applying decision analysis in a decision support context.

Normative context and the axiomatic basis for probability. Modern decision theory was developed by Abraham Wald [61] and Leonard J. Savage [48] in the mid-twentieth century, building on foundations laid by Ramsey [47] and von Neumann and Morgenstern [59]. Decision analysis, as the application of decision theory to complex practical problems, came about in the 1960s largely through the research and writings of Ward Edwards, Ronald Howard, and Howard Raiffa and their colleagues [2, 3, 15–17, 32, 44–46, 60].

Many people trained in decision analysis view its theoretical basis as the axiomization by Leonard J. Savage in his 1954 book, *The Foundations of Statistics*

[48]. Rational decision-making is based on a combination of the Kolmogorov axioms for probability theory and representation of subjective beliefs by probabilities, plus axioms for utility theory from John von Neumann and Oskar Morgenstern in their book, *Theory of Games and Economic Behavior*, 2nd Edition [59].

In this decision theory framework, probabilities for outcomes, which may depend on a state of nature or may result from a choice among decision alternatives, are described as “subjective.” (For example, note the title *Studies in Subjective Probability*, a book compiling key papers, edited by Kyburg and Smokler [29], including Frank P. Ramsey’s seminal 1926 essay, “Truth and Probability” [47]). A frequent criticism of subjective probabilities has been that they are not based on any type of objective or scientific measurement process. The assessment of subjective probability is carried out by asking a person – someone who has a decision to make or who is to provide judgment as an input into the decision-making process – for a comparison of uncertain situations involving monetary rewards: “Would you be willing to take a particular bet?” Probability assessment methods are explained later. Bayesian probability in decision theory has been pejoratively linked to this subjective aspect, that it involves assessing subjective judgment and personal beliefs, rather than objective measurements, as is the usual practice in science.

The wiki “Probability interpretations” [69] notes that “On most accounts, evidential probabilities are considered to be degrees of belief, defined in terms of dispositions to gamble at certain odds.” This may be an accurate portrayal of views still widely held. The wiki gives historical detail on contributors as the various interpretations of probability were developed. The reader may wish to consult this history, some of which is described later in this chapter, but two key authors, Richard T. Cox and E. T. Jaynes, are not mentioned.

Jaynes’ “logic of science” view seems preferable to the subjective and sometimes pejorative “betting odds” viewpoint on subjective probability. Gamblers are viewed by many scientists as irrational. As illustrated in the case studies later, one should build probability assessments based on data, models, and expert judgment and should use such probability assessments to support decision-making. Review by the experts who have been assessed and peer review by other experts are useful as part of the process. The information base supporting the probability assessment should be made evident.

Many scientists trained in statistics have been inclined to reject the use of subjective probability. If the numerical quantity is not a frequency in experimental data, then it should not be regarded as a legitimate use of the probability concept. An alternative interpretation is due to E.T. Jaynes and his immediate intellectual predecessors, geophysicist Harold Jeffreys [22] and physicist Richard T. Cox [9]: Probability as used in science and in decision theory should not be viewed as the output of an intrinsically personal process of judgment, but rather as a structure for scientific inference about uncertainty.

The viewpoint acquired from Jaynes and his intellectual predecessors (to Harold Jeffreys, add economist John Maynard Keynes and their Cambridge mentor, Professor William E. Johnson) is that probability theory provides the logic for

quantitative reasoning about uncertainty. Jaynes' posthumous text [21] carries the title *Probability Theory: The Logic of Science*. Jaynes' interpretation has other enthusiastic fans, such as Nassim Nicholas Taleb, author of *The Black Swan* ([52], see p. 319, notes on chapter 9), *Fooled by Randomness* ([53], see p. 289, notes on chapter 13), and *Antifragile* [54]. Many practitioners of risk and decision analysis are not familiar with the Jaynes and Jeffreys interpretation, sometimes called the “necessarist” school of probability. A central idea of from Jaynes and his predecessors is that the assessment of a probability reflects a state of information. All probability assessments should be regarded as conditional on this state of information. The state of information is not a physically measurable entity but a mental construct: what an individual has as knowledge, which may include a great deal of observations plus models and mental constructs used to organize this information. While in many applications information is shared, in a specific instance, different individuals may have different information about the same physical event.

As a very simple example, consider a coin toss. The coin is assumed to be “fair” in having a “Head” on one side, a “Tail” on the other, and tossed in such an imprecise way that these two outcomes become equally likely, and one of the two is certain to occur. Individual one (“Tom”) watches individual two (“Bill”) toss the coin high in the air, catch it in the palm of the hand, and then peek at the landed coin, so that Bill knows which side is up. Tom should assign a probability of 0.5 to the outcome of a Head. Individual two, Bill, has seen the result of the toss. (We assume good vision, so Bill will assign a probability of either 0 or 1 to the outcome of a Head.) The event is the same, the time of the probability assessment is the same, and the two individuals may generally agree on most items of information. But one of them has seen the outcome of the coin toss and the other has not. This example illustrates that all probabilities are conditional: Uncertainty can be a matter of who has what knowledge from one or more observations, rather than about the physics of the coin and the coin tossing system. Probability reflects the state of mind, rather than being a measurement of the state of a physical system, such as temperature as a measure of the energy in a material object.

The concepts from philosophy underlying this idea are that probability is the logic for reasoning, and the numerical probabilities we use reflect states of knowledge, not physical states of a system. The ideas come down from Plato through Immanuel Kant to his disciple, Hans Vaihinger, author of “The Philosophy of As-If,” written in 1877, published in German in 1911 and in English in 1924 [57]. We humans think using numbers and models, and we should not confuse these models with reality. They are useful “fictions” in Vaihinger’s writings. Human brains connect to underlying physical reality only through sensory data – observations, which may be numerical measurements. How well can we predict what we do not yet know? The answer lies in the realm of mental processing – in the brain(s) of the predictor(s), who use their state of knowledge to make the prediction. Uncertainty is a lack of knowledge – in the human brain, and not as some sort of objective reality. Probability, as a measure of uncertainty, reflects one’s state of mind, and not a state of things.

Is there another way of reasoning logically about uncertainty other than probability theory? Work by Richard T. Cox [8, 9], now called “Cox’s theorem,” shows that any logically consistent system for quantifying uncertainty based on propositional logic – that is, based on logical combinations of statements each of which is either true or false – must be equivalent to probability theory based on the Kolmogorov axioms, up to the choice of a constant, the number attached to the certain event. The convention is that the certain event has probability one. So we do not have to hunt for a new method for characterizing particularly deep or challenging uncertainties, if we are content to deal with propositional logic augmented by numerical expressions of uncertainty. Standard probability theory based on the Kolmogorov axioms should suffice.

Below is a simplified sketch of the proof of Cox’s theorem, as an application of logic in the form of Boolean algebra.

Let us consider a system for reasoning about uncertainty. We will assume that our measure, called “plausibility,” P , is a *real number*, and that degrees of plausibility are associated with real numbers within some interval range, which by convention we have set to be the interval from 0 to 1, with greater plausibility associated with larger numbers.

We now apply our plausibility system to a set of outcomes/events/propositions (denoted by capital letters) that obey the rules of propositional logic, in particular, Boolean algebra. We want each of the entities, which following Jaynes and others we will call propositions, to have *an unambiguous meaning with two-valued logic*: A proposition can be true or it can be false, but it cannot be inherently ambiguous. For example, consider the cat in Schrödinger’s famous thought experiment. Propositional logic requires that a cat be either alive or dead, so both the Proposition A (the cat is alive) and the denial of A, sometimes denoted A' , are well defined. Because the logic is two valued, the denial of the denial brings us back to the original proposition: If the denial of A' (the cat is not alive, but dead), the denial of the denial, A'' , is that the cat is not dead, but alive. Propositions may depend on information in the form of other propositions, but not on information in the form of “modal” operators of knowledge and belief. (For a discussion on modal operators and modal logic, see Stanford Encyclopedia of Philosophy, Modal Logic [51].) Examples of modal operators are “It is known that p ”; “It is necessarily the case that p ”; “It is possible that p ”; “It is not necessarily the case that not- p ”; “It is not known that not- p ”; “It is more likely than not that p ”; and so forth, where p is a proposition. Modal and other logics for reasoning under uncertainty have been developed, but they will not be further discussed here.

We call a collection of propositions established to be true to be a state of information. The notation $A|B$ denotes the event of A being true given that B is true. $A|BC$ is the event that A is true given that B and C are both true. And when we use the “and” to connect two propositions (denoted AB), we assume that they are not mutually contradictory, so that the conjunction (AB : logical AND) and union (non-exclusive logical OR: $A+B$) of the propositions make sense.

$$(A + B)|CD$$

is the event that at least one of the propositions A and B is true given that C and D are (both) true.

Greater plausibility is represented by a greater number, so we can write

$$P(A|B) > P(C|B)$$

to mean that, given B, A is more plausible than C.

If new information is obtained so that B becomes B' , and this change makes the plausibility of A increase, then we can write

$$P(A|B') > P(A|B)$$

But for another proposition C, the change from B to B' does not change the plausibility, then

$$P(C|AB') = P(C|AB)$$

and if we consider the plausibility of both A and C, it must increase because A is more plausible with B' than B, and C's plausibility has not changed:

$$P(AC|B') > P(AC|B)$$

The plausibility of the combined proposition AB, that A and B are both true, depends on the plausibility of B and of A given B, $A|B$. So the functional form of plausibility for AB must be a function of the plausibilities B and $A|B$. The Cox proof shows that conjunction of plausibilities must be associative, and since all strictly increasing associative binary operations on real numbers are isomorphic to multiplication (Cox [9], pp. 12–16; Jaynes [21], Chapter 2; Wiki, Cox's theorem [64]), then, our plausibility model might as well be ordinary multiplication:

$$P(AB) = P(A|B)P(B)$$

The final stage in the proof, that the functional relationship must be multiplication, is required by *consistency*: If the plausibility of a proposition can be derived in multiple (valid) ways, the numerical results must be equal. Suppose that $A+B$ is equivalent in plausibility to $C+D$. Then we acquire new information on A and then new information on B; the numerical results of conditioning on the new information must be the same as if we have acquired new information on C and then new information on D.

Jaynes [21] devotes most of two chapters to building up to Cox's theorem. The derivations of Cox and successors get into subtleties on the domain of what we have called propositions and descriptions of these propositions using set theory. The wiki on “Cox's theorem” describes relevant literature. The remainder of this chapter assumes that probability theory is the appropriate logic to use in dealing with uncertainty, assuming that two-valued logic applies and that ambiguities have been removed through careful definition. If propositions or outcomes of concern in

a decision context can be described as a set of mutually exclusive and collectively exhaustive propositions with associated numbers, then such ambiguities should be removed. (Difficulties arise when this set is not continuous, or not differentiable. Such difficulties are discussed in advanced probability texts such as Loève [31] and to recent papers such as by van Horn [58] and other scholars concerned with these difficulties in the context of Cox’s theorem. As a practitioner of probabilistic analysis, this author has, as yet, no cause to believe these difficulties pose serious practical impediments to using standard probability theory to characterize uncertainties.)

Other approaches. Many alternatives have been proposed, as opposed to using the standard system of probability to associate one number with an uncertain event. Mostly these alternatives have a behavioral motivation – people have difficulty or refuse to summarize their state of information on an uncertain quantity into a single number. One can use more numbers – a range, perhaps. More complex structures than traditional probability theory have their advocates. This discussion advocates sticking with traditional probability theory and an understanding that probabilities will change with new information: Bayes’ theorem requires consistency between probabilities assigned prior and posterior to the new information. Most people cannot reason consistently about uncertainty without extensive training in probability theory, especially if not trained to apply Bayes’ theorem. That is motivation for introducing some of the examples given below. Many people trained in probability in the tradition that probabilities represent frequencies in data cannot calculate the correct answer, because they were not taught to think about revising probabilities, but only of estimating probabilities from a stream of data from presumably independent, identical experimental trials. When the situation does not involve presumably independent, identical experimental trials, but rather complex influences on an event that is unique, traditional methods taught in statistics courses may seem inadequate. But probability theory does apply.

1.1 Many Problems with Using Probability Theory Remain

Ambiguity. Let us assume that we can apply probability theory to propositions provided they meet a test that the proposition is described at a level of precision so that a finding of true or false is unambiguous. If it is a hypothesis or theory, it can be confirmed or disproved; if it is an event or a numerical outcome such as a measurement, we can say at least conceptually that the result was in an interval (an estimate, plus or minus some amount to account for measurement precision), or it was not. We might invoke a “clairvoyant” test: A description of the event, outcome, or proposition must be sufficiently specific so that if a clairvoyant were to be asked if this event will occur, no further specification is needed: The clairvoyant is able to answer true or false to the question without any unresolved ambiguity.

Poorly supported inputs. If one uses probability theory in the form of a model to calculate probabilities of outcomes from probabilities placed on inputs, including

model structure and assumptions, the resulting probabilities on outcomes are no better in quality than these inputs. An applicable phrase is “garbage in, garbage out,” abbreviated GIGO. Logic in making the probability calculations does not compensate for weaknesses in the inputs. The probability numbers are simply a summary of a state of information about an uncertain event or quantity. They do not have an objective life of their own. In some situations these numbers can be based upon data: a frequency in repetitive situations. These situations are discussed in more detail as the special case of aleatory uncertainty. In other situations, the basis for the probability number may be the judgment of one or more experts. Motivational and cognitive biases and differing states of information among experts, whose judgment is considered appropriate as the best source for a needed input, can make the problem of getting high-quality input data formidably hard. Sensitivity analysis is a key step in achieving insight on how precision (or lack thereof) in the inputs affects the calculated output.

These critical matters of assessing expert judgment about uncertainty are a main focus in the two case studies that form the second half of this essay. The task is done when the experts understand the elicitation process and support the probability numbers. That happened in both case studies, and the process to complete this task took weeks to months.

Relying on expert judgment. When a probability number comes from expert judgment, it is a reflection of the information that this expert has. It is an output from a reasoning process, which may be fast and intuitive, slow with laborious mental processing of available information (e.g., pro and con entries on many pages of a yellow pad of paper), or done with the aid of a computer-implemented mathematical model that performs a large set of detailed calculations. The resulting probability number may, or may not, be a good basis for making a decision. Is this expert well qualified by virtue of training and experience? Is there motivational bias – the expert attempting to influence the output of the analysis in a way that might benefit the expert? More generally, is this expert trustworthy?

Most people, even those trained in probability and statics, are not intuitively good at reasoning about situations that are both complex and uncertain. People are much better at recognizing patterns – situations that offer opportunities or situations that pose danger. There is a large relevant literature in the social sciences on human judgment about uncertainty. An excellent introductory summary is Daniel Kahneman’s 2011 book [26], *Thinking, Fast and Slow*, which is still on the *New York Times* Science Best Seller List as of January 2016. An earlier 1974 paper in *Science* by Kahneman and his colleague Amos Tversky summarizes their early experimental data. This paper was later included in a 1982 book [27] with the same title, *Judgment under Uncertainty: Heuristics and Biases*. Carl Spetzler and Carl Axel Stael von Holstein published a paper based on Kahneman and Tversky’s research on assessing expert judgment about uncertainty [50].

The approach is as follows: Ask the expert to explain in detail on how the outcomes might occur. Make the reasoning, including assumptions/models (and mental models), explicit. When in doubt, construct models and use them as basis

for calculating probabilities on outputs from probability judgments on inputs. The second case study below illustrates how statistical data may be included.

Science and engineering are the “slow” thinking process in the title of Kahneman’s book [26]: Observe and record the data, hypothesize the relationships of how nature works, and check the accuracy of predictions based on these relationships with further experiments. Quantitative analysis is an intrinsic part of the process. As we come to understand cause-and-effect relationships for how nature works, we are enabled to make more accurate predictions. Many authors will refer to this process as the scientific method. Its contributions to improving the state of human knowledge and to the quality of human life have been enormous. But many people resist applying this same process to their own decision-making, in the ways described in Kahneman [26].

This is not to say that intuition based on experience has little value. On the contrary, human intuition and ability to recognize patterns can be of enormous value. But intuition often conflicts with what we can learn through a systematic process of collecting and analyzing the available information. People who have been successful in past decision-making may resist advice from people who have differing experience and backgrounds. People often make errors whose patterns are predictable by those who study human reasoning [26, 27]. Knowledge of these patterns is fundamental in assessment of judgment about uncertainty when this must be done by asking experts to do a mental integration of what they know and provide probability numbers. A good analyst will try to document what the experts know, achieve an understanding of their reasoning process, and check their judgment against that from other experts. This can be a lengthy and expensive process. Those who are used to the scientific method learn the high value of peer review, including careful checking of data quality and analytical methods. The use of probabilistic modeling has, as a major advantage, that the logic of probability theory is well established. There should not be surprises or errors because the logic is flawed. But for many decision situations, analysis must rely on human judgment, because the important uncertainties for the decision have not been resolved by a process of repeated experimental measurements providing frequency data on which to base the probabilities.

Combining the information from diverse sources – experts and data. Characterizing uncertainty in a complex decision context should involve adequate time learning about the uncertainty and how it arises. There may be knowledge about cause and effect. Various areas of science and engineering may apply. An analyst may need to learn new concepts and specialized terminology before engaging in dialogue with experts in the subject area, so as to understand their reasoning and assess their judgment in the form of probabilities. Different people may have knowledge of different aspects or of different events in a causal chain. An analyst may need to invest considerable effort in building a model of “how things work” before beginning to assess the uncertainties.

There are methods for combining the judgment of multiple experts by weighting their probabilities with calibration based on test questions [7]. Such methods can

be useful when a quick assessment is needed on a well-defined uncertainty, with a relatively low budget. But many experienced analysts [33, 34, 72] believe that there is no substitute for a process of in-depth dialogue with the experts – investing the time to learn the experts’ reasoning and, often, to build this reasoning into a model. An excellent process for assessing a complex uncertainty is that developed by Budnitz et al. for assessing probabilities from a set of experts on seismic risk at nuclear power plants [5, 6]. If the analysis budget does not permit such a costly process, information sharing, review by other experts, and documentation of the experts’ reasoning process can supplement assessment of uncertainties by eliciting probabilities from experts.

The best (but often, the slowest) process for reducing uncertainty may be the scientific method. Experts propose a hypothesis and refine it as further information is obtained. Many decisions won’t wait until uncertainty is resolved, through a process of hypothesis generation and then experiments to determine if the hypothesis predicts well, so the hypothesis can be upgraded to confirmed theory. Action may be needed more quickly. Those with decision responsibility may have to choose between taking action now in the face of large uncertainties, or deferring the action, accepting that the action may become more costly and less effective because of waiting until the uncertainties are reduced.

Epistemic versus aleatory uncertainties. Many processes involve variation in repeated occurrences. Statistical knowledge is accumulated in these situations, but not the ability to predict what will happen in a particular occurrence. Coin tossing and rolling of dice were examples used as probability theory was developed historically, as a way of understanding games of chance. These are special cases where, given that the underlying assumptions are valid, probabilities on complex events may be computed with high precision.

There is an important implicit idea here that the input probabilities can be established as true with high precision. This may be a matter of design and reasoning, or of having massive experience so as to test the probability number against the frequency observed in a large number of repeated experiments, or a combination of both.

For coin tossing, games of chance based on rolling dice, roulette wheels or wheels of fortune, and decks of playing cards, one can reason based on symmetry that there is equivalence in the probability among the set of possible outcomes. The coin has two sides, each die has six faces, the wheel is divided into a set of arcs of equal length, and for a very well-shuffled deck, the chance of drawing any particular card is one over the number of cards in the deck. Furthermore, the process either has no dependence on the past, as the coin toss, roll of dice, or spin of the wheel are done with sufficient imprecision in the initial conditions for the physics of the applied forces, so that these situations can be considered as identical, independent experimental trials with no dependence on the results from past trials. Such input probabilities are considered to be known, such as each of the six faces of a die having a probability of 1/6 of being on top when the die comes to rest after rolling. Given the input of 1/6 from the assumption of symmetry and the rolling process being

imprecise by design (e.g., a long toss with a bounce off the side onto the table), one can calculate quite precisely the frequency of winning in a large numbers of repetitions of a dice game such as Craps or a card game such as 21. (One of the founders of decision analysis, Ward Edwards, did such calculations, impressing a gambler sponsor who subsequently funded a series of psychology experiments as games of chance in the Four Queens Casino in Las Vegas [42].)

The same idea can be applied in other contexts. Life insurance is another example, and it illustrates how the process becomes more complicated. The length of a person's life is an uncertain quantity. People of the same age and sex without known health impairments or disabilities may be regarded as having equivalent probabilities of dying after n years. The insurance industry has used mortality data to develop life tables. The current versions are quite sophisticated. (Example: <https://www.johnhancockinsurance.com/life/life-expectancy-tool.aspx>.) Put in information on known health impairments, exercise pattern, alcoholic beverage consumption, driving record, etc., and observe how the expected remaining lifetime changes with these factors. There is an important message here. The probability distribution on a person's lifetime as determined from mortality statistics is dependent on a list of factors influencing life span. As more factors are added in the evaluation, probabilities that were initially equal can become unequal, because the more detailed state of information provides a basis for distinguishing among individuals. That same message applies in many other contexts. It is therefore helpful to consider that ALL probabilities are conditional on a state of information. Outside of games of chance, there are few situations where conditioning can be ignored. Ignoring possible conditioning factors is sensible if one can reasonably assume that, based on symmetry or experience, the probabilities of the uncertain outcomes are known to high precision, so knowledge of these additional factors is not significant for the assessments. But even in the context of games of chance, the simplifying assumptions underlying such "assumed-to-be-precise" probabilities may be absent. Consider flipping bent coins or thumbtacks, rolling loaded dice, or the spin of an unbalanced roulette wheel or wheel of fortune: The outcomes are now not equally likely.

Italian scholar Bruno de Finetti developed the concept of **exchangeable sequences** as the appropriate foundation for uncertain situations in which statistical methods apply. Such situations are often described as **aleatory** uncertainties. The basic idea is that a sequence of numbers X_1, X_2, X_3, \dots , representing experimental data, observations, or outcomes, can be considered as having a joint probability distribution that is invariant to relabeling the indices. In other words, the order of the data elements does not matter in making the probability assignments. Di Finetti's theorem states that the elements of such a sequence are conditionally independent of each other, given one or more latent underlying variables that are uncertain (i.e., described by a probabilistic model). For these variables the term **epistemic** uncertainty applies. Inference or learning about these variables can occur by observing elements of the sequence [10, 65].

Now we have a theory into which probabilistic models such as the Bernoulli process apply. For flipping thumbtacks instead of tossing coins, the probability of

a “Head” (point down, head of tack up) is unknown, but as one flips a thumbtack a large number of times, the observed frequency of heads compared to the number of flips converges to a number which is the probability of heads on a single flip. This is the process of statistical inference described in many texts on probability and statistics.

1.2 Bayes’ Theorem – A Consistency Condition Among Probabilities

How does one revise a probability distribution based on new information, such as the number of heads in additional tosses of a thumbtack? The process is a simple application of the logical consistency requirement in probability theory. Let A and B be two uncertain quantities, and consider how one can write the probability of the joint event A and B:

$$P(A,B) = P(A|B)P(B) = P(B|A)P(A).$$

Then, dividing, with an assumption that $P(A)$ is not zero (which would mean A is not possible),

$$P(B|A) = P(A|B)P(B)/P(A) \quad (40.1)$$

We have a new probability for B given that A is known to have occurred. $P(B|A)$ is often called the posterior probability, and $P(B)$ the prior probability, referring to time periods before and after the resolution of uncertainty on A, which revised the state of information. The expression $P(A|B)/P(A)$ is often called the likelihood function. The relationship works with A and B as random variables as this term is used in probability and statistics texts.

This relationship (40.1) is known as Bayes’ theorem, after the Reverend Thomas Bayes, an English minister, logician, and Fellow of member of Britain’s Royal Society. The relationship was published by a friend in 1763, 2 years after Bayes’ death.

With the combination of exchangeable sequences and Bayes’ theorem, much of traditional statistics can be reinterpreted as using new information to revise probability distributions.

Here is a simple example. A fair coin is flipped four times. You are told that the outcomes included at least one head. What is the probability of all heads?

Many people who have taken classes in probability and statistics fail to get the correct answer. Finding the correct answer is simple for those not trapped in the thought pattern of traditional statistics, where the usual assumption is that probabilities do not change. Draw a “tree” diagram showing the sequence of possible head-tail sequences of four flips. There are 16 different sequences, ranging from HHHH to TTTT. Only the last is eliminated by the information that there was at least one head, and the relative probability of the other 15 outcomes remains

the same. The answer is 1/15. The reasoning is a very simple example of Bayes' theorem.

A more complex application is the “Monty Hall” [68] problem arising from the American television show, “Let’s Make a Deal,” and publicized in Marilyn Savant’s widely read column “Ask Marilyn” in *Parade* magazine.

Suppose you’re on a game show, and you’re given the choice of three doors: Behind one door is a car; behind the others, goats. You pick a door, say No. 1, and the host, who knows what’s behind the doors, opens another door, say No. 3, which has a goat. He then says to you, “Do you want to pick door No. 2?” Is it to your advantage to switch your choice?

The correct answer is to switch the choice of the door, which increases the probability of winning from 1/3 to 2/3. Many readers of the magazine claimed this answer was wrong. It is counterintuitive, and as such, an excellent example of why logical reasoning is needed in complex uncertain decision situations. Apply Bayes’ theorem: The probability of the car being behind door 1 is 1/3. The host now reveals that the car is not behind door 3. So it must be behind either door 1 or door 2. Has the probability on door 1 changed? No, the information from what the host has done should only change the probability on the other two doors. The host is not going to open the door with the car or the door that you chose. He opens the third (No. 3), one with a goat. The other door, No. 2, now has the probability that you would have earlier placed on door 3, plus its earlier probability: $1/3 + 1/3 = 2/3$.

At this point readers who may be unfamiliar or only partially knowledgeable have been introduced to Bayes’ theorem and exchangeable sequences, two key ideas for how uncertainty can be characterized in quantitative form using probability theory. Probabilities reflect a state of information that changes as new information is obtained. Probability illustrated through games of chance is unusual, because in this context people believe they know the input probabilities and can compute with confidence probabilities of complex sequences of events, such as winning at the dice game Craps, drawing a Royal Flush hand in poker, etc.

1.3 A Basic Desideratum: Two States of Information Perceived to be Equivalent Should Lead to the Same Probability Assignments

The basic desideratum is a powerful fundamental principle for testing whether probability assignments are properly done. This principle is quite different than the subjectivist test of whether the person being assessed would be willing to bet using these probabilities. The idea comes from Laplace’s writings from two centuries ago [30], and it has been developed by E.T. Jaynes and others who have followed the idea that probability is a logic that can be applied broadly to uncertain situations and not restricted to repetitive situations that meet the test of exchangeable sequences.

Two applications of this basic desideratum have already been discussed: the assignment of probabilities to symmetrical objects used in games of chance, the fair coin, the die, and equal arcs on the roulette wheel or wheel of fortune. By Laplace’s Principle of Insufficient Reason, if the sides of the coin, the six faces of the die,

or the equal arcs around the wheel are judged equal in the sense that relabeling leads to an equivalent state of information, then the probability assignments should be the same: $1/2$ for each side of the fair coin, $1/6$ for each face of a fair die, and $1/360$ th times the degree of arc for the wheel, (with correction for space taken up by dividers).

The second application is exchangeable sequences. It's the same idea – the probabilities are invariant under rearrangements of the order of the elements in the sequence. Using Bayes' theorem enables observations of sequence elements to revise probability distributions on parameters, which turn out to have meaning as frequencies in the limit when the sequence has a large number of repetitions. The most well-known models from probability theory fit this description: the Bernoulli process, a generalization of the coin-tossing game to binary events where the probability of heads versus tails (or success versus failure) is unknown; the Poisson process where nonnegative numbers come from events such as the time of the next arrival for each of a succession, such as customers at a service center or decays of radioisotopes; and the Gaussian or normal distribution composed of the sum of lots of small independent increments – random walk, velocity of molecules in an ideal gas, or distribution of a characteristic such as height in a male or female human population. Readers may have learned about such processes from a standard text on probability and statistics. But what they may not have learned is that these probability distributions are special cases in which Bayes' theorem can be done by simple arithmetic on parameters, because observations can be characterized by sufficient statistics.

E.T. Jaynes' writings including his 2003 textbook assert maximum entropy as a principle for choosing probability distributions. Is maximum entropy an appropriate principle for this purpose? An answer is provided in North [38]. Maximum entropy turns out to be an application of the Basic Desideratum.

Howard Raiffa, his Harvard colleague Robert Schlaifer, and others noted the special character of probability distributions that have a “conjugate prior,” such that revision from prior to posterior for these distributions by Bayes' theorem can be done within the same family: Bernoulli, Poisson, normal, gamma, and a few others [46]. The relation to sufficient statistics is clear. For example, in the Bernoulli process a prior distribution is used for the parameter ρ , which corresponds to the long-run frequency of heads and the probability of a head on the next flip with current information. The beta prior probability distribution is defined over the interval from 0 to 1, with two parameters u and v :

$$\text{Beta}(u,v) = P(\rho|u,v) = B(u,v)\rho^{(u-1)}(1-\rho)^{(v-1)}$$

where $B(u,v)$ is a normalizing constant (made up of gamma functions) such that the probability density function integrated over $[0,1]$ sums to one. If r heads are observed in n trials, the posterior distribution is beta with $u+r$ and $v+n-r$ as the parameters.

(Detailed discussion can be found in many texts and papers, such as Navarro and Perfors [37]).

Similar discussions are readily found for the Poisson process and exponential distribution with unknown mean inter-arrival time and the Gaussian or normal distribution with unknown mean and variance.

The mathematical proof showing the equivalence of the exponential family of probability distributions with sufficient statistics with the solutions of finding the probability distribution that maximizes entropy subject to constraints that correspond to knowing the mean and/or higher moments of the probability distribution is found in North [38]. Readers interested in these details can find them there. The following is a sketch of the argument, for discrete outcomes (intervals) which become in the usual take-the-limit argument in calculus arbitrarily small with a correspondingly large number of them.

Consider the data from a series of observations from an exchangeable sequence. A histogram of the results summarizes these data. Relabeling the observations does not change the histogram. Count all the sequences that lead to a given histogram, and these sequences are judged to have equivalent probabilities.

Let n be the number of trials and n_k the number in the k th interval, where k runs from 1 to N and N (as well as n) will be large numbers, with $n \gg N$, and for all k , $n_k \gg N$. Let $f_k = n_k/n$, the frequency of the k th interval in the n trials.

The number of ways W to arrange n objects in N categories is the multinomial expression:

$$W = n! / n_1! n_2! \dots n_N!$$

Sterling's approximation gives $n! = e^{-n} n^n \times \sqrt{2\pi n}$

Therefore,

$$\log n! = n \log n - n + O(\log n)$$

where $O(\log n)$ are terms that increase no faster than as $\log n$ as n gets large.

Then

$$\log W = n \log n - n - \sum_{k=1}^N n_k \log n_k + \sum_{k=1}^N n_k + O(\log n)$$

Dividing by n , the number of trials,

$$1/n \times \log W = - \sum_{k=1}^N f_k \log f_k + O((\log n)/n)$$

As we go to the limit of very large n , this goes to the entropy function:

$$H(p_1, \dots, p_N) = - \sum_{k=1}^N p_k \log p_k$$

Essentially, entropy is counting the most likely histograms as the numbers n and N become large. One might think of this as follows: The exchangeable sequence process becomes random, subject to what is known on expected value of functions of the probability distribution, such as its mean, variance, and possibly higher moments. The usual proof of the Central Limit Theorem follows the essentially the same logic.

In case of conjugate prior-posterior families, the insight is that all one needs to do for Bayesian updating is to keep track of statistics such as the sample mean and sample variance, and other aspects of the observational history average out in a randomization process. There are a number of important applications in physics to this line of reasoning. It means one can avoid the need for an ergodic hypothesis, an assumption that time averages equal ensemble averages. Rather, for a system in equilibrium, in assigning probabilities on the state of the system, it should not matter when the experimental observation occurs. So, one can randomize the time of the experiment, and the probabilities on the state of the system should remain the same. Invariance to such randomization leads directly to the probability distributions developed by J. Willard Gibbs for statistical mechanics, without requiring ensemble as an intermediate concept [38].

Here is a summary of applications of the basic desideratum:

- (1) relabel outcomes: Laplace's Principle of Insufficient Reason;
- (2) Rearrange order of experimental results: de Finetti's concept of exchangeability.
- (3) Invariance to transformation – transformation groups. (Not covered here: see Jaynes [20, 21] and North [38])
- (4) Invariance to the time of an experiment to measure a dynamic system: the concept of equilibrium in statistical mechanics.

This brief digression into conjugate prior/posterior families of probability distributions explains why these families of probability distributions have both sufficient statistics and a maximum entropy characterization. These families are special cases where uncertainty can be described as random or having no memory, with relevant information for Bayesian updating very simply characterized, as by a sample mean and variance. With lots of small fluctuations or influencing forces, the Central Limit Theorem applies, and the composite distribution describing the system's behavior as a sum of these fluctuations ("random errors" or "random walk") becomes the normal distribution. Exponential inter-arrival times describe a process in which succeeding events do not depend on the timing of preceding events, but rather a process where the probability of an event in each increment of time is the same.

It seems like excellent intellectual background to think about complicated systems as having "state variables" that describe what information is needed to make good predictions on what will happen to these systems. In physics such state variables often work well to enable predictions: Energy is conserved and evenly distributed in a system at equilibrium. Therefore, knowing the temperature of a volume of gas in a box allows accurate prediction of the distribution of velocities of the gas molecules that compose the volume of gas: The result, due to Maxwell,

is that the velocities follow a normal distribution, and for gases where molecules do not interact (ideal gas assumption), this distribution is experimentally verified as correct [67].

In most applications in risk and decision analysis, we are not dealing with the orderly randomness of the normal or exponential probability distributions. But thinking about what state variables influence the behavior of a complex system will help to identify what variables are important to include in a description of the state of information. Conditioning on these variables may enable describing how one uncertain quantity is linked to another. No linkage, or independence, of one uncertain quantity from another, may be motivated by a lack of any known causal relationship between them. But in a physical, economic, political, or interpersonal situation, it is often the case that there are linkages between uncertain events. Then conditional probabilities should be used to characterize these linkages where the occurrence of predecessor events can make a successor event more, or less, probable. And there may be changes in the probabilities with time – a nonstationary process. An analyst wishing to characterize an uncertain event in terms of a probability should consider carefully how the event probability might change over time or with further information about other, possibly related, events.

It is therefore advisable to consider all probabilities as conditional on one's state of knowledge. Markov models in probability theory consider transitions among states, and such models may be useful. The second case study below included a Markov model, but when probability numbers became established, the complexity of considering multiple transitions among states was judged unnecessary.

Networks of events linked through having the probability of successor events depend on the outcome of predecessor events that have become widely used both in decision analysis as influence diagrams [18] and in computer science as Bayesian networks or Bayesian belief networks [63, 66].

1.4 Decision Analysis

What is decision analysis? This term comes both from Howard Raiffa [45] and Ronald Howard [15]. Decision analysis is as a process, rather than a product. The case studies in the latter part of this chapter can be viewed as products, descriptions of what came out of a process. The National Research Council reports of [35] and [36] emphasize analysis as a process. See also Fischhoff [11].

Decision analysis as a process supports decision-making by those with decision responsibility. It involves characterizing uncertainties, which are usually what make decision-making difficult. Putting the task in the second person with the reader as the decision-maker, the process involves structuring through quantitative analysis your *alternatives* (what you can do); your *information* (what you know, including information relevant to uncertainties), and your *preferences* (what you want) to identify the alternative(s) that are *best* in terms of maximizing expected utility. A good decision is one that is logically consistent with the alternatives, information,

and preferences. It is to be distinguished from a good outcome – ultimately, what you want. In the presence of uncertainty and the absence of clairvoyance or wizardry, is there a better way to get good outcomes than to make good decisions? Such a better way has not yet been identified. Over many decision situations the best way to get good outcomes is to make good decisions. Now make a transition from a personal orientation from you as the decision-maker to providing decision support for other people – an individual, a group, or a government agency trying to act in accordance with law – who have decision responsibility: The “you” becomes “they” – and “they” may not agree among themselves.

The existential reality is that humans, as individuals and in groups, must make choices in the face of uncertainty. This is not usually done well in the sense of logical consistency with what they know, what they can do, and what they want. Is there a better way to get good outcomes than by carefully assessing situations, planning ahead, and otherwise trying to make good decisions in managing resources and opportunities?

As available information changes, one can use an informal analogue to the scientific method: Learn from your mistakes, and use what you learn to improve your judgment and your decision-making. Tetlock and Gardner [55] describe how well this can work for forecasting events of the kind that are of interest to the intelligence community. Learned skill in dealing with uncertain situations enables improved decisions for oneself and support for improved decision-making by others.

Probability theory is not limited to frequencies in repeated measurements or subjective judgments made in the form of choices on whether to accept a bet. Probability theory is a branch of mathematics that facilitates logical reasoning about uncertainty, by associating a numerical measure, on a scale of zero to one. Very small numbers approaching zero imply that an outcome is unlikely to impossible, while numbers approaching one imply the event is highly likely to certain. Especially in recent decades, many people have come to use in common parlance the concept of probability as quantified uncertainty. This handbook chapter discusses how the process of using probability as quantified uncertainty can be done well, as opposed to not so well.

Probability theory facilitates reasoning about uncertainty in a way that is unambiguous and logically consistent. It is the appropriate logic for scientific inference. The “scientific method” is applied to the available information, which implies that analysis should keep track of significant changes in the information.

Preferences. “What you want” is an area of similar complexity to dealing with information and uncertainty. Valuation in the context of making choices is the subject of economics and, more broadly, social sciences – the study of how human beings make choices. What do people want, as individuals and as a group of individuals who share in outcomes? Most individuals will wish to avoid being subject to “Dutch Book” – becoming a “money pump” by a sequence of trades violating transitivity, such that a person gets back to his or her starting point but with less money. It may not be possible to construct transitive preference orderings

for a group from the preference orderings of the individuals in the group, even if individual preference orderings are transitive. Majority voting may not work: The Condorcet paradox on majority voting [71] and the Arrow Impossibility Theorem [1, 62] show that construction of preferences for the group obeying transitivity may not be possible. Cultural change, ethics, and morality may come into play in helping members of a group agree on preferences. To the extent a group or society can agree in the sense of having transitive group preferences; preference measures can be constructed to evaluate outcomes. But obtaining agreement on the ordering of good outcomes in the context of a public policy decision may involve considerable difficulty [14].

Decision analysis involves defining outcome events related to the decisions so that both the answers to questions “What will happen?” and “What do those responsible want?” can have answers that are well defined and not ambiguous. And the process continues, to obtain for each outcome or event a numerical measure of uncertainty (a probability) and a numerical measure of value. (This “numeraire” may be a utility, or in the absence of a nonlinear measure of risk preference, it might be a value assessed with dollars or another currency.) Cost-benefit analysis involves assessing costs and benefits from the outcomes from the choice among the set of decision alternatives. More sophisticated versions examine the distribution of costs and benefits and not just the aggregate amounts of cost and benefit across the population that experiences the outcomes.

Discussion of multi-attribute utility. If the von-Neumann-Morgenstern axioms hold, then one can construct a multi-attribute utility over a set of outcome measures in two stages [12, 13]. (1) Deterministic trade-off valuation: Use one scale as the numeraire. (It is often convenient to do this with a currency – money, such as US dollars.) One can add or subtract monetary value for distributional impacts. A Pareto criterion avoids this judgment, but it may not allow some alternative policies to be distinguished from each other. This is consistent with usual practice for cost-benefit analysis in economics. (2) Use a risk preference measure, constructed as utility function on money. All ways of constructing multi-attribute utility function by trade-offs with risk should give the same result. Often risk preference is not included on public sector decisions: Risks are judged small relative to resources of government, so an expected monetary value criterion is argued to be adequate. Exponential utility with one parameter – constant risk aversion – allows sensitivity analysis for the impact on the decision of choice of risk attitude [43].

2 Two Case Studies

2.1 Case Study #1: Terrestrial Microbes on Mars

In 1972 the author and his colleagues at SRI International received a challenging assignment: to assist the US National Aeronautics and Space Administration (NASA) by making an assessment of the probability that the planned 1976 landing

would result in contamination of the planet Mars by terrestrial microorganisms transported by the spacecraft.

At this time both the USA and the Soviet Union were initiating a program of unmanned exploration of nearby planets. Mars was a particularly important destination, since it was viewed as having the best chance of having indigenous life. After photographs from a flyby mission showed what looked like evidence of past flows by liquid water on the planetary surface, leading scientists questioned whether the planned landing of a spacecraft on the Martian surface might pose an unacceptable risk of introducing living microbes transported from Earth that could proliferate on Mars.

The USA and the Soviet Union then agreed that both nations would carry out their programs so that the risk of planetary contamination, defined as one replication by one microbe in the Martian environment, would not exceed $1/1,000 (10^{-3})$. NASA determined that for the first landing in 1976, Project Viking, the risk would not exceed $1/10,000 (10^{-4})$. It was the job of NASA's Planetary Quarantine Officer (PQO) to veto the mission if the risk exceeded this allowed limit. The author and colleagues carried out an assessment that persuaded the PQO and the distinguished group of scientists advising him that the Viking Lander was below this risk limit.

Given the scant knowledge available about Mars in the early 1970s, how does one deal with the difficulties of assessing the probability that a terrestrial microbe carried aboard the spacecraft could reproduce there? NASA had performed such an assessment, but there were doubts by scientists advising NASA as to whether the results were reasonable. The task was not only to carry out a new assessment but also to communicate with the scientists who had raised these doubts. (This work for NASA is documented in [25] and [41]. A summary is in [39].)

It was well established that the Viking Lander contained a large number of microbes (about 20,000) that were viable in the sense that they were capable of reproducing in a suitable environment. Many were in the form of spores that were encased in the plastic used to protect the spacecraft's solid-state electronics against physical damage from vibration during the mission launch. The scientists believed that microenvironments might be present on Mars where usable water might be present (i.e., in a liquid or near-liquid state, such that microbes could reproduce). The landing site was chosen to be in a dry area, but elsewhere on Mars useable water and nutrients needed for reproduction, such as organic carbon, might be present. Could the microbes get from the place where the spacecraft landed to one of these microenvironments? For example, might dust or sand driven by the high winds on Mars erode the spacecraft, releasing microbes from the plastic in which they were encased? Might a viable microbe then be carried by the Martian winds to a favorable microenvironment in some location, perhaps quite distant from the landing site? For reproduction to occur, the microbe would need to be capable of reproducing in the absence of oxygen (i.e., facultatively anaerobic) and at the extremely low temperature of the Martian surface (facultatively psychrophilic).

The adopted approach used the idea of conditionality and tracked the sequence of events from the landing to a possible reproduction. It is similar to the process for modeling safety issues and the transport process for pollutants emerging from

a source and reaching a receptor area where vulnerable species might be damaged. The model begins with an initiating event, the landing of the spacecraft with its bio-burden of viable terrestrial organisms (VTOs) in different locations on the spacecraft. The next event, release, depends on whether the landing is soft as planned or a hard landing due to equipment malfunction and, also, where on the spacecraft the organisms are located. The analysis team considered three means by which organisms might enter the Martian environment – implantation beneath the surface, such as from being on the bottom of a landing pad or in a buried fragment of the spacecraft that broke up from a hard landing. An organism on the surface of the spacecraft might come off from vibration and land on the soil surface. Wind-driven dust and sand might erode the spacecraft over a long period of time, releasing organisms encased in the plastic or on interior surfaces. The model included all of these modes of release. The next stage is the transport of an organism to a favorable microenvironment. Does such a microenvironment exist, with water near enough the liquid state to be usable for reproduction by the organism? Are the needed nutrients available? Does the organism have the capability to reproduce in the absence of oxygen and at temperatures well below where water normally freezes? The model also included the possibility that the life detection experiment on the spacecraft becomes contaminated, resulting in a large amount of microbial reproduction on the spacecraft and a much larger subsequent release of organisms. This structure for the probabilistic model is shown in Fig. 40.1.

The first box on the left summarized information on the bio-burden: the number of viable terrestrial organisms on board the spacecraft at the time of landing. The estimate took into account the effect of the heat sterilization processes for the components, data on microbial spores in the plastic, estimates on organisms that might be trapped between surfaces as components of the spacecraft were assembled, and recontamination after final assembly, including the potential for contamination of the life detection experiment. The output is the estimated number of organisms in each of five categories of location. The second box includes the outcome for landing, at the planned low velocity with three pads in contact with the Martian soil or a much higher velocity “hard” crash landing that would cause the breakup of the

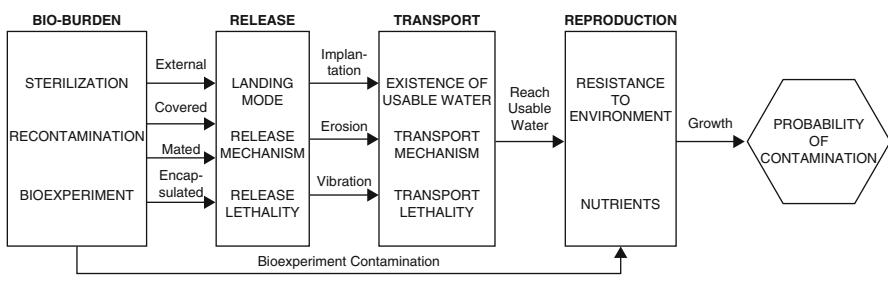

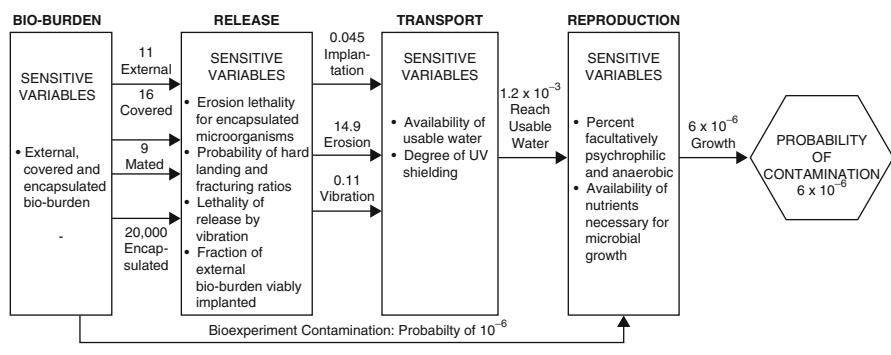

Fig. 40.1 Viking Lander contamination model (Retrieved from <http://ntrs.nasa.gov/archive/nasa/casi.ntrs.nasa.gov/19750005702.pdf>)

spacecraft with pieces buried deep into Martian soil. The outputs are estimates of the expected number of organisms implanted into the soil, released through wind-driven dust or sand erosion into the Martian atmosphere and released via vibration or other nonviolent processes from the spacecraft onto the Martian surface. The third box deals with transport to a possible favorable microenvironment, a location with water near enough the liquid state at some time in the Martian year (i.e., “useable”) so that reproduction might occur. The inputs are the probability that such a microenvironment exists on Mars and the fraction of the surface area that it covers, given it exists. The third box is a relatively elaborate six-state Markov model allowing for multiple transport events (by a series of Martian dust storms) from release from the spacecraft to contact with useable water. (Details are in Judd et al. [25]). The output of the third box is the expected number of organisms that reach useable water. The fourth box considers availability of nutrients and the characteristics needed for the organisms to reproduce in the cold and without oxygen. If these conditions for reproduction are met, the outcome is “growth,” i.e., planetary contamination.

The model then gives a probability for contamination built up from approximately 20 inputs describing the microbial contents on the landing vehicle, the probabilities assigned to the mission outcome (nominal landing and failure modes), and Martian environmental conditions. The scientists who provided these inputs found it relatively easy to understand the structure of the analysis, the judgments they were being asked to make, and how these judgments would be used. When a complete set of inputs was assembled, the assessment was reviewed with these scientists. The nominal results are shown on the arrows in Fig. 40.2. The nominal case result is a probability of 6×10^{-6} , a factor of about 16 below the mission risk limit.

Extensive sensitivity analyses were carried out to see how the calculated probability of contamination changed with changes in the inputs to the calculation, singly and in combination. An illustrative set are shown in Table 40.1.

Numbers on arrows give the expected numbers of VTOs

Fig. 40.2 Viking Lander Mission contamination model with results (Retrieved from <http://ntrs.nasa.gov/archive/nasa/casi.ntrs.nasa.gov/19750005702.pdf>)

Table 40.1 Viking Mission contamination sensitivity analysis

Contamination model variables	Probability of contamination						
	Values				Units: = 10** - 6		
	Extreme Low	Intermed. Low	NOMINAL	Intermed. High	Extreme High	Nominal: Low	5.9 High
Bio-burden variables

2. rep availability of nutrients	0.01	0.02	0.1	0.2	0.5	0.6	29.6

The pattern of numerical results suggested a reason why the calculated risk was more than an order of magnitude below the risk limit of 10^{-4} . Most of the release of viable organisms was through erosion. The Martian atmosphere has no ozone layer to absorb the ultraviolet (UV) radiation in sunlight, so a high UV flux reaches through the Martian atmosphere down to the surface. A terrestrial microorganism would be killed by this UV radiation unless it was protected by shielding, such as being encased in a piece of plastic much larger than the microorganism itself. The density of the Martian atmosphere is well known from observation by telescope from Earth. Only small particles would be transported a significant distance from the spacecraft, even in the periodic Martian dust storms. These small particles would not provide adequate shielding to protect the microbes from the UV radiation. It was therefore highly unlikely that microbes could survive a journey from the Viking landing site to a favorable microenvironment if such microenvironments exist on Mars. This insight was not known previously within NASA and its scientific

advisors, but the scientists advising the Planetary Quarantine Officer and other senior officials at NASA accepted the reasoning. Within a short time the scientists who had expressed concern about the risk of contamination agreed that the objective of holding the risk for the first Viking Mission below 10^{-4} had been met and that the Viking Mission should proceed without the need for further steps to reduce the microbial load on the Viking Lander. The Viking Mission flew on schedule and the landing on Mars in 1976 was successful.

In 2015 more information has become available. Microenvironments have now been observed in the form of dark streaks that appear in several locations on Mars when temperatures are above -23°C . These streaks are thought to be hydrated minerals – a mixture of salts and water. And particles do migrate, even moderately large ones. Sand-grain-size particles have been observed to impact on the solar panels of the Mars Rover vehicles. Theoretical calculations and orbiter photos indicate that sand dunes on Mars move [23, 24, 28].

The authors have not been asked to redo their analysis based on such new information. In 1992 a committee of leading scientists stated, “... it is the unanimous opinion of the task group that terrestrial organisms have almost no chance of multiplying on the surface of Mars and in fact have little chance of surviving for long periods of time, especially if they are exposed to wind and to UV radiation” (Space Science Board [49], page 49). The insight from the analysis had become conventional wisdom. But revisiting the analysis might suggest that NASA should be concerned about the risks of contamination from a rover or a lander near the areas where the streaks that might be liquid water have been observed.

Calculating the probability that a terrestrial microorganism could reproduce on Mars would seem like a situation where there are no data, an example of deep uncertainty and an absence of the information needed for expert judgment. But in this project the analysis team broke the assessment into pieces and assembled judgments from experts via the model described above. Analysis using this model provided a basis for NASA to decide to proceed with the mission.

2.2 Case Study #2: Decision Analysis of Hurricane Modification

The second case study was done a few years earlier. It was on a decision to deploy a new technology in a domain where it was previously assumed that nothing could be done to avert natural disaster but to warn the potentially affected population and, in severe situations, to evacuate them from the area.

Hurricanes are intense cyclonic storms with winds in excess of 74 miles per hour that form over warm ocean water, such as in the Caribbean or adjacent areas of the western Atlantic. In the Pacific and Indian Oceans, these storms are called typhoons, another name for the same natural phenomenon.

In the early 1960s scientists at the National Hurricane Research Center developed a theory that seeding the clouds around the “eye” (the calm circular center) of a hurricane could reduce the intensity of the maximum winds and the storm surge, so that a hurricane impacting a populated coastal area should become less destructive. The theory held that seeding with silver iodide crystals would cause supercooled

water to form into ice crystals, releasing heat that would cause the cloud bank around the eye wall to move outward, reducing the speed of the maximum winds [70]. Small-scale experimental seeding had been carried out on two hurricanes after the theory was proposed, and a computer-implemented model of hurricane dynamics and experiments had been developed. Strong evidence supporting the theory came from cloud seeding on Hurricane Debbie on August 18 and 20 of 1969: After the first day of seeding, a reduction of 31 % in the maximum sustained winds was observed. The hurricane was left alone for a day and then reseeded, with a subsequent wind speed reduction of 15 %.

Our analysis team from SRI International was engaged subsequent to the experiment on Hurricane Debbie. The team was asked by the Assistant Secretary of Commerce for Science and Technology, Myron Tribus, to carry out a decision analysis on whether the government program, Project Stormfury, should be moved from a research project into an “operational” mode that could seed hurricanes threatening coastal areas of the USA.

This analysis was subsequently published in *Science* [19]. The following description is a summary from that publication, with an emphasis on the assessment of uncertainty and the valuation of information from opportunities for further experimental seeding of the kind that had been done for Hurricane Debbie in 1969. While currently available scientific information no longer supports the Stormfury theory, the case study illustrates a number of aspects that apply in other decisions on deploying a new technology in uncertain situations that could evolve negatively as well as positively. The potential for benefit must be weighed against the risk of a negative outcome, and public perceptions become important when a government agency takes responsibility for introducing technology into a natural process that has a potential for harm.

The property damage caused by a hurricane is strongly related to the speed of the maximum sustained winds. These winds do damage directly and through the storm surge, pushing seawater to abnormally high levels as the hurricane impacts a coastal area, causing both flooding and structural damage from wave action.

A simplified view of illustrating the difficulty is shown in Fig. 40.3. Supposing a hurricane is about 12 h away from impacting a populated coastal area. Natural forces might be causing the hurricane to intensify, but with current knowledge the change in the hurricane winds cannot be anticipated. Meteorologists cannot predict accurately how the behavior of the hurricane will evolve over time.

The diagram shows a possible scenario: If the hurricane is seeded, the wind speed is reduced from $w(t_1)$ to $w'(t_1)$, so that seeding has reduced the wind and the property damage. But when the hurricane makes landfall, it has intensified – less if it has been seeded, but the wind speed has increased. Those people suffering property damage might blame a government decision-maker for making the choice to seed.

At the time of our analysis, nearly all the government meteorologists that we questioned said that they would seed a hurricane threatening their homes and families – but only if they could be released from professional liability. The trade-off between accepting the responsibility for seeding and accepting higher probabilities of severe property damage is a crucial issue in this decision. There are many similar

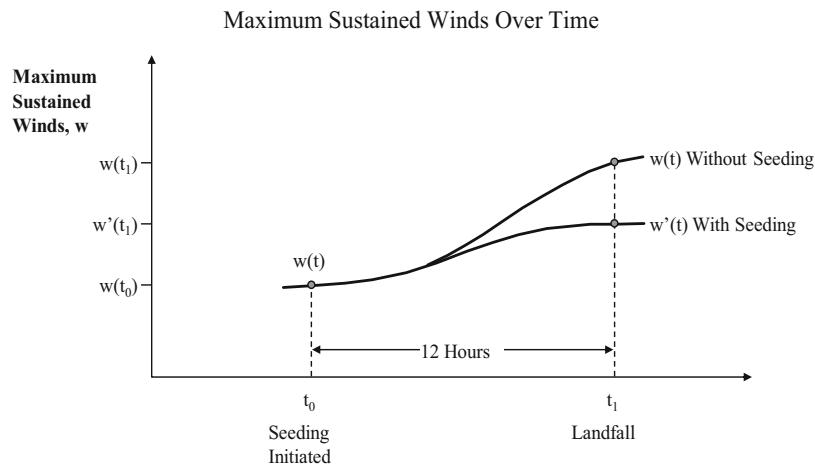

Fig. 40.3 Maximum sustained winds over time

situations where new technology may bring benefits, but not enough is known to assure that there are not substantial risks.

The consequences of seeding and not seeding are characterized with probability distributions. Our team developed these distributions from data on the changes in central pressure of hurricanes, a standard relationship between wind and central barometric pressure used in predicting hurricane winds and verified by wind observations, plus judgment of these government experts on the additional uncertainty introduced by seeding. The team considered three outcomes: (H1) The “beneficial” Stormfury hypothesis: The effect of seeding averaged over many hurricanes is a reduction of the maximum sustained wind speed. (H2) The “null” hypothesis: Seeding on average induces no change in maximum wind speed. (H3) The “detrimental” hypothesis: On average seeding increases the maximum sustained wind speed. These outcomes are mutually exclusive and collectively exhaustive: Only one can be true. Available knowledge is characterized by probabilities over these three hypotheses. Bayes’ theorem allows a logical revision of these probabilities, from before the Debbie experiment, after the results from the Debbie experiment became available (the time of the analysis), and to a future time when more seeding experiments might yield results.

Using the central pressure to wind speed relationship with the available historical data gave a probability distribution for the unseeded and for the “null” hypothesis. This distribution seemed to fit reasonably well to the normal or Gaussian distribution, and to first order, the 12-h wind speed change in percentage terms stayed the same as the initial hurricane wind speed varied. The team decided to stay within the two-parameter normal family of probability distributions for characterizing 12-h wind speed changes, with an important distinction between the average change – the mean – over many hurricanes, and the wind speed change in a specific hurricane, which was estimated with limited precision from the central pressure change data.

Probabilistic Model for 12-Hour Change in Maximum Sustained Wind, Natural Hurricane

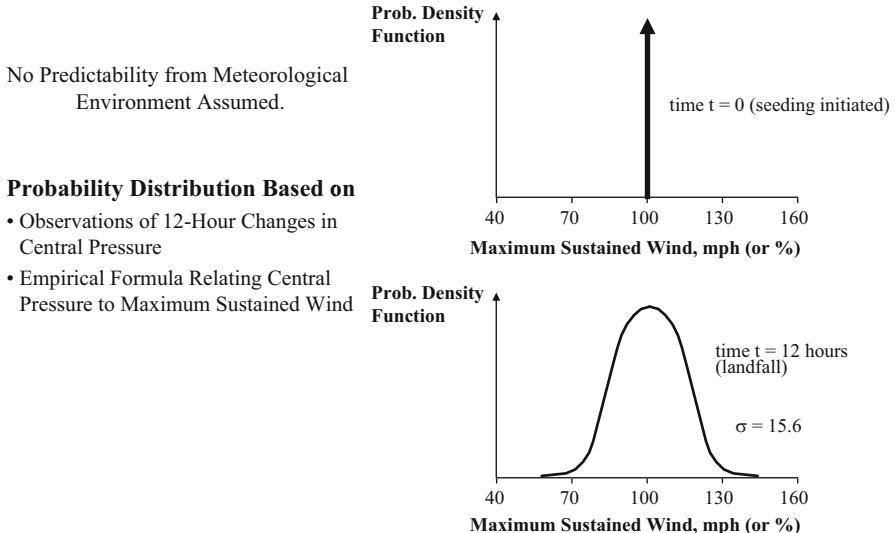

Fig. 40.4 Probabilistic model for 12-h change in maximum sustained wind, natural hurricane

The standard deviation for this unseeded (and “null” if seeded case) was 15.6 %. See Fig. 40.4.

For the “beneficial” seeded case, the team of analysts and experts agreed on a 15 % reduction on average and a standard deviation of 7 % for the effect on individual hurricanes. For the “detrimental” case, the corresponding numbers were a mean increase on 10 % and the same standard deviation, of 7 %. The standard deviation for an individual hurricane under H1 or H3 is the square root of the sum of the squares, 18.6 %.

The team went through an informal process of assessing probabilities on the three hypotheses but using the mathematics of Bayes’ theorem. Establishing probabilities for the three hypotheses was a crucial aspect of characterizing the overall uncertainty on how seeding could reduce wind speed and property damage.

If one starts with equal prior probabilities on the three hypotheses, then using Bayes’ theorem to update after the Debbie results, the posterior probabilities were H1 = 81 %, H2 = 15 %, and H3 = 4 %. The team used a lower value for H1, based on agreement that (1) before Debbie, H1 and H3 were approximately equal but with lower probability than H2, and after Debbie, H1 and H2 were approximately equally likely. The probabilities that met these conditions were H1 = H2 = 0.49 and H3 = 2 %. The government meteorology experts accepted these probabilities as reasonable judgments given the currently available information.

Developing this set of probabilities and probability distributions in Figs. 40.5 and 40.6 was essentially the author’s responsibility as the project leader of the

**Probabilistic Model for 12-Hour Change in Maximum Sustained Wind,
Seeded Hurricane**

Probability Distribution Based on:

- Probability Distribution for 12-Hour Change in Natural Hurricane
- Expert Judgment on Average Effect of Seeding
- Expert Judgment on Fluctuations From Average Effect in Seeding a Particular Storm

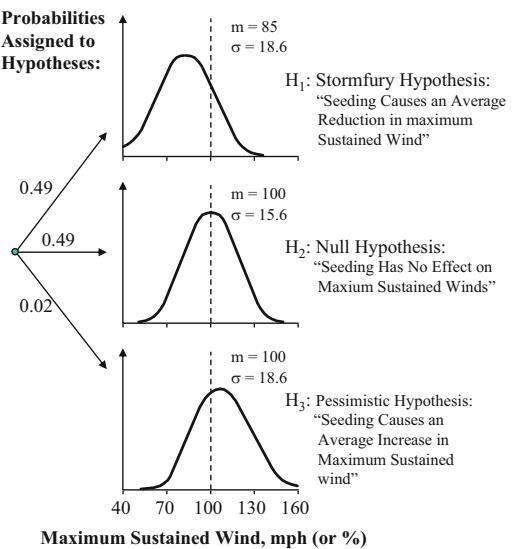

Fig. 40.5 Probabilistic model for 12-h change in maximum sustained wind, seeded hurricane

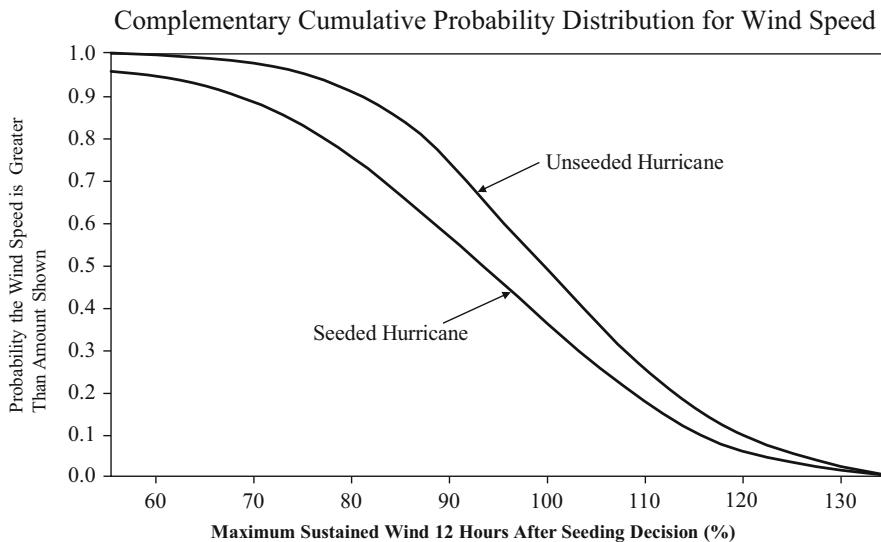

Fig. 40.6 Complementary cumulative probability distribution for wind speed

analysis team. These probabilities provided an imprecise numerical “sketch” designed to give insight on the strategic decision to allow seeding on a hurricane approaching the US coast. A better job of characterizing uncertainty might be done in the tactical situation when seeding became allowed and detailed data on a particular hurricane in a particular location might be available. The sketch was to be used to compare the decision alternatives of seeding and not seeding, with an evaluation on the potential impact on property damage, and of the trade-off between accepting a higher probability on large amounts of property damage and the acceptance of government responsibility, turning a natural disaster into situation modified by the US government action of cloud seeding before the hurricane came ashore. A more refined analysis of the probabilities was left for a later time. As team leader, the author was comfortable that the team had done all that it could do in combining available data and expert judgment within the time and resources of the project.

Early in the project the author learned the following historical anecdote from old hands among the meteorologists. In 1947 the US Navy seeded a hurricane out at sea moving parallel to the coast of Georgia. While the seeding had no apparent effect on its wind intensity, the hurricane made an abrupt left turn and did considerable damage to the city of Savannah. A subsequent investigation determined that the left turn occurred a few hours before the seeding was done. But the accusations that government seeding was responsible for the course change and the resulting property damage lingered in the memories of the scientists. They knew that Dr. Tribus, who had a background that included work on weather modification as well as probabilistic reasoning similar to E.T. Jaynes [56], was eager to go ahead seeding a hurricane threatening the US coast if seeding offered a prospect of reducing property damage. The meteorologists’ preference was for the equivalent of a massive clinical trial; seed about a hundred hurricanes far from shore and get much more experimental data, in addition to the 2 days of observation from seeding Hurricane Debbie. But carrying out such experimental seeding might take many decades, and hurricane damage to the USA was averaging \$400 million per year in 1970.

Wind speed changes needed to be translated into property damage changes. The quantitative methods used provided the equivalent of a sketch. The data available at the time of our project on wind speed versus property damage was assembled, with a correction on property damage for price inflation, and then plotted, as shown in Fig. 40.7. The relationship was steeply nonlinear. A log-log regression gave an exponent of about four and a half (4.363) for property damage as a function of maximum sustained surface wind speed. (For a sensitivity range 3–6 was used.)

With this relationship wind changes could be translated into property damage changes. There was no attempt to establish a baseline in dollars or specify a location such as New Orleans or Miami, but rather to calculate the percentage change in damage. The probability distribution on damage was scaled to 100 for the initial wind speed 12 h from landfall: A “nominal” hurricane had property damage of \$100 million if winds were unchanged, and damage changes estimated based on this exponential relationship of damage to wind speed. Estimates could be scaled

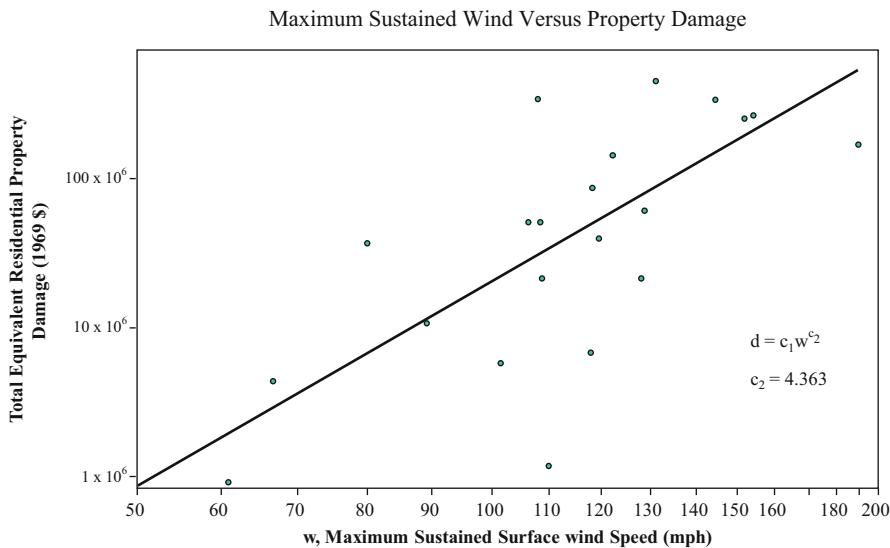

Fig. 40.7 Maximum sustained wind versus property damage

based on property values for different coastal areas. Such adjustment was not done in estimating the exponent from the data on historical hurricanes, but it could be done in a site-specific analysis.

The probability distributions on wind changes and the relationship of wind changes to property damage permitted computation of the expected damage with and without seeding, shown in Fig. 40.8. This calculation could have been done on a computer with great precision. At the time of this analysis, computers were large and took time for access, while handheld calculators were common, as cell phones with calculators have become today. The quantitative characterizations were not precise – they were the equivalent of sketches summarizing the available information. For convenience in explaining and ease for others to reproduce the calculations, the wind speed change outcomes were divided into five intervals: increase of 25 % or more, increase of 10 % to 25 %, little change, +10 % to –10 %, decrease of 10 % to 25 %, and a decrease of more than 25 %. The corresponding representative values for the five intervals are +32 %, +16 %, 0, –16 %, and –34 %. The decision on whether to seed is shown in Fig. 40.9.

Expected values for the wind speed change and property damage were calculated for each of the intervals and then the expected damage, multiplying probability times damage and summing over the five intervals, with and without seeding. This is readily done on a hand calculator. The expected property damage loss was reduced 18.7 % by seeding, a result that pleased Dr. Tribus and confirmed his intuition. The comparison of the alternatives is shown below in decision tree form in Fig. 40.9, with the decision shown as a box, and the resolution of uncertainty on damage from the first seeded hurricane shown with five discrete outcomes. A cost of \$250,000 for seeding was assumed, small compared to damage in the \$100 million range.

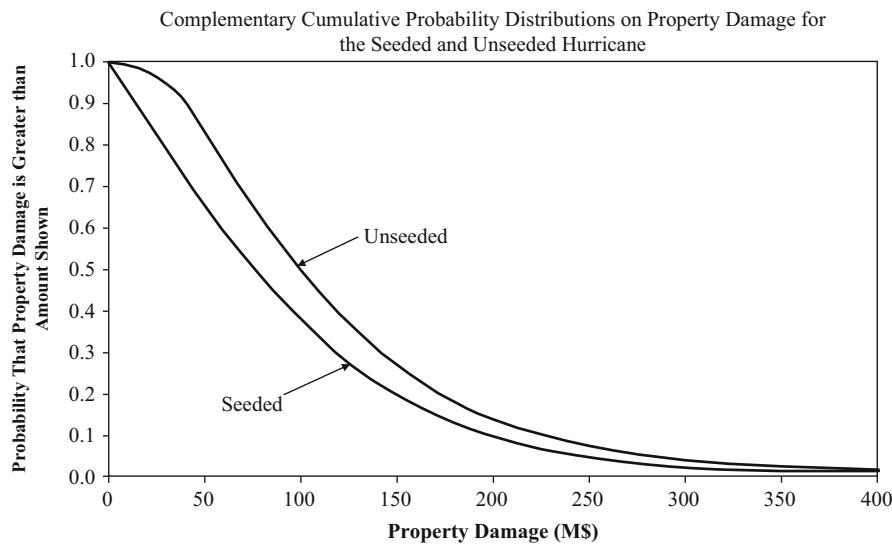

Fig. 40.8 Complementary cumulative probability distributions on property damage for the seeded and unseeded hurricane

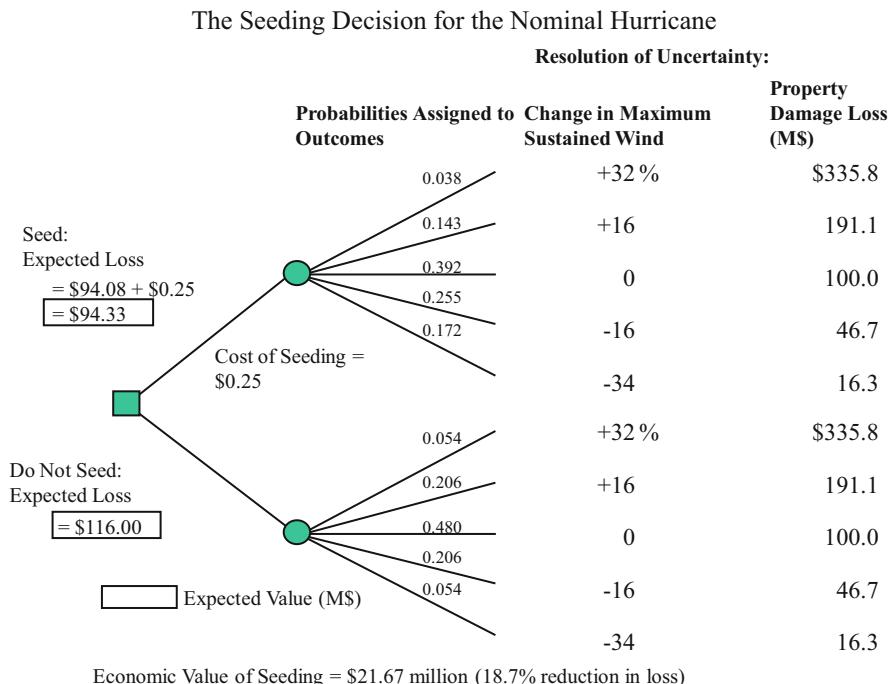

Fig. 40.9 The seeding decision for the nominal hurricane

Consider the government responsibility issue: What if a seeded hurricane intensifies after seeding – or does something else unexpected, such as a sudden change in direction? (The team did not calculate the latter. The meteorologists believed that seeding would not alter the path of the hurricane.) The team calculated that the probability that a seeded hurricane would intensify as 36 % and that it would intensify by at least 10 % as 18 %. (These numbers can be read from the complementary cumulative distribution on wind speed changes, Fig. 40.6.) Would there be public outrage or lawsuits brought against the federal government? The Port of New York Authority communicated informally that it might choose to sue if the US government did not seed a hurricane headed toward New York City.

The author, with responsibility as project leader, was unsure how to get numbers to define this trade-off. The opportunity came after a long day of meetings, having drinks in a hotel bar with a senior career civil servant serving as an advisor to Dr. Tribus. This advisor agreed to give his assessment of what he thought were reasonable trade-off values for the five outcomes. (The drinks and a pledge not to reveal his identity may have helped obtain his agreement.) The discussion went like this: Suppose you as a decision-maker for the federal government had to make a choice between two outcomes: a seeded hurricane that intensifies 16 % between seeding and landfall and an unseeded hurricane intensified even more causing x percent more property damage. Now if x is near zero, I expect you will choose the unseeded alternative. But if x is very large, you might choose to assume the political consequences for taking the responsibility in return for a lot less property damage inflicted on the local population. We want to find the level of x where the choices become equal, your point of indifference. The source gave judgments of $x = 30\%$ for $+16\%$ in wind speed, $x = 50\%$ for $+32\%$ in wind speed, $x = 5\%$ for no change, and $x = 0$ for wind speed reductions. Putting these values into the calculation of expected net value for each alternative makes the results very close, less than a 5 % difference in expected monetary value. The decision tree is shown in Fig. 40.10.

The analysis had now been expanded to include both the property damage minimization objective and the concern over assuming government responsibility for seeding. No one argued that the responsibility costs used in the analysis, obtained from a single source, were unreasonable and should be changed.

The project team decided to hire an experienced law school professor to investigate further. Gary Widman, then with Hastings College of the Law, University of California, wrote what became appendix material for the final report [4]. His findings were as follows:

With respect to Sovereign Immunity, the principle that citizens need a legal basis before they can bring suit against their sovereign government:

In conclusion, existing immunity law provides only partial and unpredictable protection at best. There are also grounds for recognizing that immunity defenses may be avoided in most cases if the plaintiff carefully chooses his remedy, his legal theory, and his forum. Only specific Congressional action offers a prospect of substantial, predictable immunity protection.

The Seeding Decision for the Nominal Hurricane (Government Responsibility Cost Included)

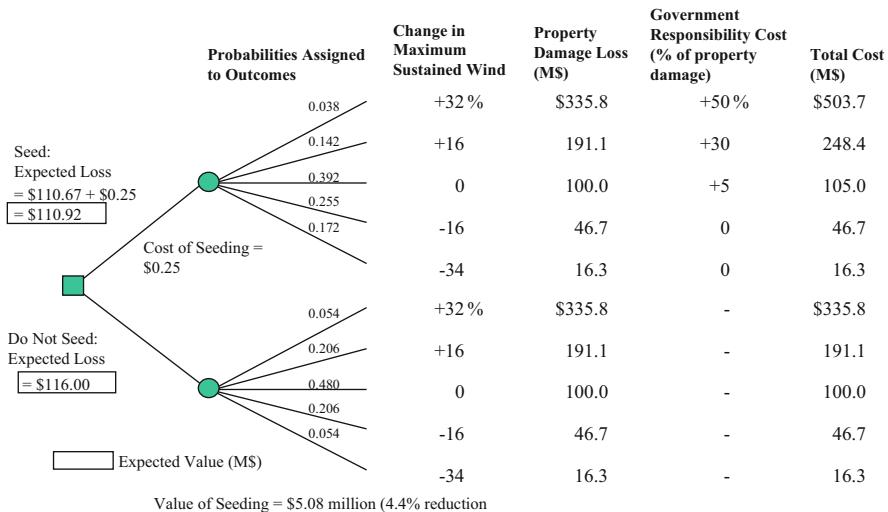

Fig. 40.10 The seeding decision for the nominal hurricane (government responsibility cost included)

And there appeared to be ample potential grounds for bringing a lawsuit:

In conclusion, existing immunity law provides only partial and unpredictable protection at best. There are also grounds for recognizing that immunity defenses may be avoided in most cases if the plaintiff carefully chooses his remedy, his legal theory, and his forum. Only specific Congressional action offers a prospect of substantial, predictable immunity protection.

This legal research persuaded Dr. Tribus and others in the leadership of the National Hurricane Research Laboratory and the National Weather Service that the decision to move to operational seeding would need to be made by the US President or under new legal authority provided by Congress.

There was a further issue to be addressed, and that was getting attention on the opportunities for further seeding experiments such as had been done on Hurricane Debbie. What would it be worth to resolve the uncertainty on which of the three hypotheses were true before a seeding decision needed to be made? Consider that an alternative to resolve this uncertainty by hiring a hypothetical clairvoyant who knows the answer. But the clairvoyant must be paid before we get the clairvoyant's information. What is the clairvoyant's information worth, in the context of the nominal \$100 million hurricane? The calculation of the expected value of information is relatively straightforward once a decision tree has been constructed with values on the outcomes. In the case of perfect information, complete resolution of the uncertainty on which hypothesis is correct, one needs only reverse the sequence, resolution of the uncertainty on which hypothesis before making the choice of whether to seed. The decision tree is shown in Fig. 40.11.

Expected Value of the Clairvoyant's Information: Which Hypothesis Describes the Effect of Seeding?

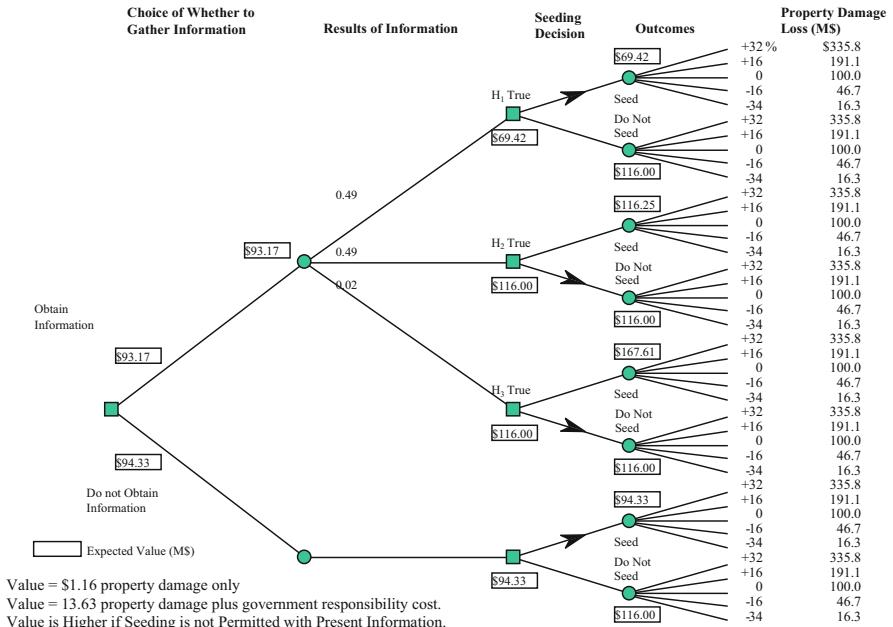

Fig. 40.11 Expected value of the clairvoyant's information: which hypothesis describes the effect of seeding?

A more complex calculation with a decision tree shows the decision to carry out an experimental seeding of the type that was done for Hurricane Debbie. Probabilities are calculated for the outcomes for a seeded hurricane, and Bayes' theorem is used to update the posterior probabilities of the three hypotheses. The overall result, shown in Fig. 40.12, is that for one \$100 million hurricane, the expected value of an experimental seeding is on the order of ten times the cost.

The project final report [4] includes calculated values for multiple seeding experiments and extrapolated to US hurricane seasons. Opportunities for seeding in the Pacific were more plentiful, and both the analysis team and the government sponsors believed that seeding experiments in the Pacific should be done. The analysis was presented to Dr Edward David, the Science Advisor to President Nixon, and the President's Science Advisory Committee (PSAC). President Nixon himself was briefed by Dr. David. The President's reaction is interesting, especially in view of later events in the Nixon Administration. President Nixon considered that if a severe hurricane threatened a US city such as New Orleans, he might wish to go onto television and ask for a plebiscite from affected citizens as to whether, as Commander in Chief, he should order a seeding.

Value of A Seeding Experiment (Government Responsibility Cost Included)

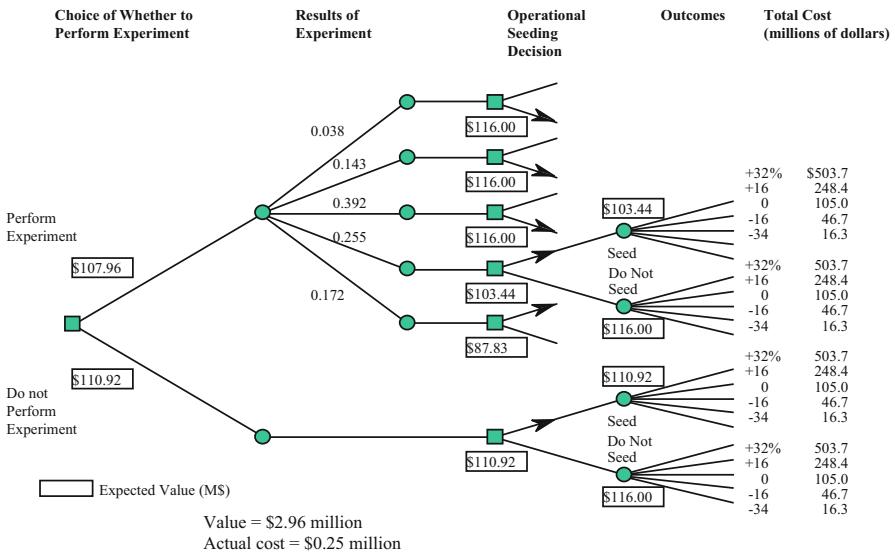

Fig. 40.12 Value of a seeding experiment (government responsibility cost included)

This analysis is believed to be the first use of value of information analysis in a public policy decision context at the Presidential level and the publication in *Science* [19], the first publication of this type on the application of decision analysis with value-of-information results.

In subsequent years, no further seeding experiments were carried out. As a consequence of weather modification activities in connection with the War in Vietnam, relations between the US Navy and the Department of Commerce on cloud seeding became troubled. Further research identified flaws in the Project Stormfury hypothesis: The measured abundance of supercooled water was insufficient to give the needed changes in hurricane structure, and the structural changes observed in Hurricane Debbie were observed to occur in unseeded hurricanes. Project Stormfury was officially cancelled in the early 1980s [70].

3 Conclusions

The reader is reminded again of the importance of process, as opposed to analytical product. In both case studies an analytical team had the task of learning about uncertainties in a highly complex area of emerging science. The teams learned what was needed to structure available knowledge into a quantitative analysis that was accepted by the government scientists and their managers and which subsequently underwent extensive review. There was not extensive public involvement in either case.

The author takes considerable pride in the way the Mars analysis team learned about the importance of UV radiation and particle shielding and the way the hurricane analysis team included government responsibility cost into the hurricane analysis as a way of bringing attention to the importance of the legal issues related to trying to change a weather phenomenon. Both teams dealt with the complexity and uncertainty under time and resource constraints and with difficulties to overcome in getting cooperation from government scientists. Some of the government scientists in the hurricane case study were initially hostile to what they thought was an effort to take seeding operational as part of coastal defense before the technology had been established as acceptably safe. The team learned their concerns and tried to address them openly. The hurricane seeding decision analysis was presented to the committee of leading scientists who advised the President, and the (at the time) innovative Bayesian probability and value of information calculations were well received by these scientists and published in *Science* [19]. The results analysis encouraged support for seeding in the Pacific, which seemed like a very good alternative at the time.

The author has learned over many applications of decision analysis in addition to these two case studies the importance of proper framing: What are the decisions, and what are the consequences that the stakeholders care about? [35, 36].

It is disappointing that there have not been more applications of decision analysis to major public policy problems. There is opportunity: The tools of probabilistic analysis are there, and efforts are ongoing to apply these tools to a range of problems, including the safety of nuclear power plants and the global decisions to deal with the threats posed by greenhouse-gas-induced climate change [40].

Many corporations are now using decision analysis routinely; Chevron received the first Raiffa-Howard Award (named for Howard Raiffa and Ronald Howard) for excellence in decision quality at the 2014 INFORMS meeting in San Francisco. Opportunities to carry out analysis in support decisions depend on the leadership with the decision responsibility. These leaders can ask for the support that decision analysis can provide.

Acknowledgements This chapter draws from presentations on the two case studies at the November 2014 meeting of INFORMS (Institute for Operations Research and the Management Sciences) in San Francisco, on the occasion of the 50th Anniversary of Decision Analysis honoring its founders, Stanford University Professor Ronald Howard and Harvard University Professor Howard Raiffa. The author wishes to acknowledge the collaboration with colleagues in the two case studies, and appreciation to Tony Cox for detailed comments on the initial draft of this chapter. The author expresses gratitude to these and other colleagues over 50 years in decision and risk analysis for the many insights learned about assessing uncertainties and values in a decision support context.

Validation, Verification, and Uncertainty Quantification for Models with Intelligent Adversaries

41

Jing Zhang and Jun Zhuang

Abstract

Model verification and validation (V&V) are essential before a model can be implemented in practice. Integrating model V&V into the process of model development can help reduce the risk of errors, enhance the accuracy of the model, and strengthen the confidence of the decision-maker in model results. Besides V&V, uncertainty quantification (UQ) techniques are used to verify and validate computational models. Modeling intelligent adversaries is different from and more difficult than modeling non-intelligent agents. However, modeling intelligent adversaries is critical to infrastructure protection and national security. Model V&V and UQ for intelligent adversaries present a big challenge. This chapter first reviews the concepts of model V&V and UQ in the literature and then discusses model V&V and UQ for intelligent adversaries. Some V&V techniques for modeling intelligent adversaries are provided which could be beneficial to model developers and decision-makers facing with intelligent adversaries.

1 Introduction

Models have been extensively used in research when describing systems and predicting scenarios. Model verification and validation (V&V) can quantify confidence in the accuracy of model-based predictions under certain assumptions.

Verification refers to building the system right, while validation refers to building the right system [47]. Verification is conducted before validation. The verification process includes assessing code verification and calculation verification. Validation consists of conceptual model validity and operational validity. There are many approaches to validation, such as validation by assumption, validation by results, and validation by common sense. Validation techniques include animation, comparison to models, degenerate tests, event validity, extreme condition, face validity, fixed values, historical data validation, historical methods, internal validity, multistage validation, operational graphics, parameter variability, predictive validation, traces, and turning tests [58]. See the explanations of the techniques in Table 41.1.

Academia, industry, and government have been interested in model validation. Some terms related to the model, such as “reliability,” “credibility,” “confidence,” and “applicability,” have become common in academic and industrial studies, as well as government reports and implementations. A Standards Committee for the development of model V&V procedures for computational solid mechanics models has been formed by the American Society of Mechanical Engineers (ASME); a V&V model for all safety-related nuclear facility design, analyses, and operations has been supported by the Defense Nuclear Facilities Safety Board (DNFSB); and validation of complex models has been a key concern of the military simulation community for over three decades [39].

Considerable attention has been paid to model verification and validation. Numerous articles have appeared in the literature expressing different concerns of the validity of the models that have been proposed. The advances in the techniques of modeling and solution have impacted how people perceive model validation. For details about model V&V and about computational simulation models [57–59], see [44]. Validation methods, procedures for economic and financial models, urban and transportation models, government and criminology models, and medical and physiological models have also been studied [16].

The V&V approach quantifies degree of the accuracy and confidence inferred from the comparison of the prediction from the model with the results from reality

Table 41.1 Common model validation techniques (Source: [58])

Techniques	Explanation
Animation	Use graphs to show the model's behavior through time
Comparison to models	Compare model results to the results of other valid models
Degenerate test	Test model behavior using appropriate values of input/internal parameters
Event validity	Compare model event to real system to see the similarity
Extreme condition	Check model plausibility in extreme and unlikely levels of the system
Face validity	Ask knowledgeable people about the reasonability of the model
Fixed values	Fix values for variables/parameters to check against easily calculated values
Historical data validation	Use part of the data to build model, and the rest of data to test model
Historical methods	Three historical methods: rationalism, empiricism, positive economics
Internal validity	Implement several runs to determine the amount of variability in the model
Multistage validation	Combine the three historical methods into a multistage process
Operational graphics	Display values of various performance measures
Parameter variability	Use sensitivity analysis to determine the parameters' effect
Predictive validation	Check the prediction of the model with the system behavior
Traces	Trace entities in the model to see whether the model logic is correct
Turning tests	Ask people to discriminate the outputs of the model and system

or experiments. There can be no validation if there is no experimental data with which to compare the result of the model [6]. However, for intelligent adversaries, deficiencies of data and the incompleteness of understanding adversaries' behavior hinder the modeler from building the model and obtaining credible predictions. Taking the characteristics of the intelligent adversaries into consideration, is it possible to obtain sufficient data to build and validate such models? If not, is model validation even possible for intelligent adversary analysis in the absence of outcome data? These questions will be discussed in this chapter.

2 Model Verification vs. Validation

2.1 Terminology

We first introduce the terms of “verification” and “validation” before discussing the relationships between them. Model V&V methods and procedures have been defined by multiple organizations. In the development of fundamental concepts and

Table 41.2 Definitions of verification and validation by DMSO and IEEE (Source: [7, 24])

	Verification	Validation
DMSO	The process of determining that a model implementation accurately represents the developer's conceptual description and specifications	The process of determining the degree to which a model is an accurate representation of the real world from the perspective of the intended uses of the model
IEEE	The process of evaluating a system or component to determine whether the products of a given development phase satisfy the conditions imposed at the start of that phase	The process of evaluating a system or component during or at the end of the development process to determine whether it satisfies specified requirements

terminology for V&V, the Department of Defense (DoD) Modeling and Simulation Office (DMSO) has been the leader and played a major role in attempting to standardize the definitions of V&V [7, 8]. In addition, DMSO developed the US fundamental concepts and terminology for model V&V applied to high-level systems such as ballistic missile defense and battle management simulations [71].

There is a variety of formal definitions. The Defense Modeling and Simulation Organization (DMSO) of the Department of Defense (DoD) and the Institute of Electrical and Electronics Engineers (IEEE) give the most widely used definitions of the terms of verification and validation [44]; see Table 41.2.

Software engineering and software quality assurance use the IEEE definitions [44]. By contrast, computational simulations in science and engineering and operation research use the DMSO definitions. The DMSO definitions are widely adopted by [1, 32, 33, 55, 63, 71] as well as in this chapter. Thacker et al. [71] states “Software V&V is fundamentally different from model V&V. Software V&V is required when a computer program or code is the end product. Model V&V is required when a predictive model is the end product. A code is the computer implementation of algorithms developed to facilitate the formulation and approximate solution of a class of models.”

Different papers have defined model V&V differently according to specific contexts. For example, [59] defines model validation as “substantiation that a computerized model within its domain of applicability possesses a satisfactory range of accuracy consistent with the intended application of the model”; according to [15], model validation refers to activities “to establish how closely the model mirrors the perceived reality of the model use/developer team”; [36] defines model as “activities designed to determine the usefulness of a model; i.e., whether it is appropriate for its intended use(s); whether the benefits of improving model usefulness exceed the costs; whether the model contributes to making “better” decisions; and possibly how well the particular model performs compared to alternative models”; [46] defines verification and validation as “the process of determining the accuracy with which a computational model can produce results deliverable by the mathematical model on which it is based: code verification and solution verification” and “the process of determining the accuracy with which a model can predict observed physical events (or the important features of a physical reality)” respectively.

2.2 Relationships Between Verification and Validation

Model verification and validation (V&V) are the primary processes for quantifying and building credibility in numerical models and essential parts of the model development process if models are accepted and used to support decision-making. Verification and validation are often mentioned together in requirements to test models, yet they are fundamentally different.

Verifying a model means checking if the model produces the intended output as a function of the inputs, and whether it is mathematically correct. The focus here is on the model implementation and coding [18]. Verification is a critical activity, but is not the same as validation. Fundamentally, model validation is subjective and different perspectives on model validation could have very different meanings. The assertion “the model was judged valid” can mean almost anything, since the modelers choose “the validity tests, the criteria for passing those tests, what models outputs to validate, what setting to test in, what data to use, etc.”[37].

Verification is a matter of asking “Did I build the thing right?” and “Have the model and the simulation been built so that they fully satisfy the developer’s intent?”. By contrast, validation asks “Did I build the right thing?” and “Will the model be able to adequately support its intended use?” “Is its fidelity appropriate for that?” [49].

The purpose of model verification and validation is to assess and improve credibility, accuracy, and trustworthiness. Model verification and validation cannot certify a model to be accurate for all scenarios; but can provide evidence that a model is sufficiently accurate for its intended use [71].

3 Validation, Verification, and UQ in the Literature

3.1 Validation, Verification, and UQ in Model Development Process

U.S. GAO [76] introduces basic steps in the modeling process, which includes (1) describing problem, (2) isolating system, (3) adopting supporting theory, (4) formulating model, (5) analyzing data requirements, collecting data, (6) developing computer program, (7) debugging computer program, (8) developing alternative solutions, (9) evaluating model output/results, (10) presenting results/plans, (11) developing model maintenance procedures, and (12) transferring system to users. According to [76], steps (1)–(7) are covered by model verification, and steps (1)–(11) are covered by model validation. Yet, the absence of the necessary information often makes it hard to follow the steps to validate models. Gass [15] adopts this modeling process which aims at indicating how “the research community concerned policy models is attempting to develop and test procedures for improving the role of models as decision aids.”

Over the past three decades, new dimensions have been brought to the notion of model V&V by large-scale computer-based mathematical and simulation models

[30]. The “Sargent Circle” in simulation validation is one of the earliest and most influential among all the paradigms of the relationships among V&V activities [56].

In the Sargent Circle [56], conceptual model validation is defined as “determining that the theories and assumptions underlying the conceptual model are correct and that the model representation of the problem entity is reasonable for the intended purpose of the model”; computerized model verification is defined as “assuring that the computer programming and implementation of the conceptual model is correct”; and operational validation is defined as “determining that the model’s output behavior has sufficient accuracy for the model’s intended purpose over the domain of the model’s intended applicability.” Most validation takes place in operational validation. In order to obtain a high degree of confidence in the model and its results, the model developers need to compare the input-output behaviors of the model and the system. There are three basic comparison approaches: (1) graphs of the model and system behavior data, (2) confidence intervals, and (3) hypothesis tests. For details of the methodologies, see [2, 4, 31, 33].

A detailed schematic of the model V&V in model development process is given by [71]. There are two branches in the procedure of model V&V: the first is to obtain relevant and high-quality experimental data via physical testing; and the second is to develop and exercise the model.

Because of inherent randomness, uncertainties cannot be ignored. Uncertainty quantification (UQ) exists in the processes of both performing experiments and developing models, which emphasizes the importance of UQ in improving confidence in both the experiment and model outcomes.

By comparison with experimental data, validation is able to quantify the confidence in the predictive capability of the model. For more definitions, uncertainties, and model explanations, see [1, 45, 52, 53, 70, 71].

3.2 Quantitative Model Validation Techniques

With the development of computing capacity, computational models become extensively used to solve practical problems in various disciplines and play an important role as predictive models for complex systems. Imprecise data and model assumptions could impact the quality of the model prediction. It is important to quantify the uncertainty in the model prediction [55]. Although qualitative validation methods such as graphical comparison between model prediction and experimental data are widely used, statistics-based quantitative methods are essential to systematically account for the uncertainty in both model prediction and experimental observation [43]. Hemez and Doebling [21] claims that the ability to quantify uncertainty is essential for the success of any model validation.

Many previous papers have studied the application of statistical hypothesis testing methods in the context of model validation [22, 51], as well as the validation metrics, which provide quantitative measures of agreement between a predictive model and physical/experimental observations [13, 33, 42]. Yet there remain some unclear issues in the practice of model validation. Ling and Mahadevan [32] studies

the quantitative model validation techniques from the perspectives of both hypothesis testing-based and non-hypothesis testing-based methods and gives a systematic procedure for quantitative model validation. The quantitative model validation techniques include classical hypothesis testing, Bayesian hypothesis testing, confidence intervals, reliability-based metric, and area metric-based method. For details and examples of these quantitative model validation techniques, see [13, 26, 32].

4 Validation for Intelligent Adversary Models

4.1 Difficulties in Validating Intelligent Adversary Models

Model validation, together with verification, is critical for models intended to be used in practice. They are required by many organizations such as the US Department of Defense that uses adversary models [18]. After the attacks on September 11, 2001, billions of dollars have been spent on homeland security. To better understand intelligent adversary behaviors and to better study the strategic interactions between defenders and adversaries (e.g., attackers and terrorists), numerous models have been developed. Unfortunately, because of the deficiency of empirical data, few (if any) such models have yet been validated, which limits the application of those models in practice.

In defense and homeland security, decisions are made about allocating resources to prevent attacks by adversaries and protect the public. Risks from such intelligent adversaries, like terrorists, must be assessed prior to guiding defensive resource allocation; otherwise the effectiveness of resource allocation would be unreliable. Intelligent adversary risk assessment aims to prevent adversary attacks or mitigate the effects of adversary attacks by allocating resource efficiently. The risk assessment has significant importance in protecting the public safety. When a model is adopted to predict the adversaries' behavior and to instruct resource allocations, decision-makers should be confident that the model adequately represents the real situation. Poor risk assessment could lead to ineffective resource allocations and vulnerable targets.

Intelligent adversary risk assessment models are increasingly being developed and studied. Those models need to be validated. Probabilistic risk assessment (PRA)/ event-tree-based methods [12, 74], decision-analytic methods [14, 50], game-theoretic methods [20, 28, 79], and statistical machine-learning methods [11, 35] have been proposed for modeling intelligent adversaries. However, these models are complex and may not be directly tested by comparing model predictions with the outcome of events in the real world, since there are too few comparable adversary attack data to support statistical inferences about the model validity. The Committee on Methodological Improvements to the Department of Homeland Security's Biological Agent Risk Analysis cautions that "there may be insufficient scientific knowledge to verify or validate these models" [41]. When modeling the intelligent adversary, the modeler needs to consider the strategy and the rationality of the adversaries; in addition, it is difficult to model the consequences

resulting from terrorist incidents, since it is hard to assess when, where, and how the terrorists would strike. Meanwhile, as technologies evolve, adaptive terrorists could mount new types of attacks. In the reality of counterterrorism, there are lots of uncertainties; and throughout the built models, there are assumptions and dubious parameters. Unless the models are validated, the model results may not be trustworthy.

It is possible to make empirical observations to compare with the prediction results from the corresponding models. For example, [75] proposes a prospect theory model of coaches's utility and estimates the models' parameters using the data from the 2009 NFL season; [19] studies parking choice models, which are first calibrated based on the collected data from video-recorded observations from a set of parking lots on the University at Buffalo north campus and then used to predict the drivers' behavior. Intelligent adversaries are more difficult to model, since they are adaptive, and may have unknown preferences, beliefs, and capabilities. Guikema [17] indicates that "the key difference between risk assessment for situations with intelligent adversaries and traditional risk assessment problems is that intelligent adversaries adapt. They adapt to observed, perceived, and imputed likely future actions by those defending the system they are attempting to damage. This adaptive behavior must be considered if risk assessment models are to provide accurate estimates of future risk from intelligent adversaries and appropriately support risk management decision making."

Also, [3] claims that adversary risk analysis has three special uncertainties: (1) aleatory uncertainty (randomness of outcomes), (2) epistemic uncertainty (strategic choices of an intelligent adversary), and (3) concept uncertainty (beliefs about how the problems are framed).

Validating models for the probable behaviors of intelligent adversaries may not mean comparing the model results with existing data or experimental data as is in validating traditional models. This is because the data, if any, is often incomplete and sometimes classified. In terms of validating counter-terrorism models, [65] states that "for terrorist acts, validation is only possible in a limited sense and may be more correctly characterized as ensuring the models are reasonable or credible, performing sanity checks, ensuring consistency with what is known about terrorist groups, and not being able to invalidate the model. Validity, in this case is viewed as a range, not a binary valid/invalid assessment."

4.2 Verification and Validation Methods for Intelligent Adversary Models

4.2.1 Basic Necessary Conditions for Intelligent Adversary Risk Analysis

Guikema [17] proposes four basic necessary conditions for intelligent adversary risk analysis:

1. Adversary models must be descriptively accurate representations of future adversary actions to the best of the then-current knowledge of the defender;

2. Adversary models must be computationally tractable to support risk management decisions in the particular situations being addressed;
3. Adversary models must explicitly address uncertainty and represent any uncertainty in the predicted adversary actions;
4. There must exist one or more defensible methods for gaining confidence in the models for practical use.

The methods for gaining confidence in [17] include “validation by common sense” and “limited case-based validation for historic situation when data is available.”

4.2.2 Conceptual Processes to Provide Increased Confidence in Intelligent Adversary Models

Streetman [65] presents three conceptual processes that may be used to provide increased confidence in intelligent adversary models, but may fall short of traditional validation:

1. Minimally required components, which include terrorist objectives, attack logistics, decision criteria, and adaptation. Models that fail to address these key factors are considered less credible or valid;
2. Use of analogy. To obtain the real data could be hard or even impossible. However, we may infer something about the likely future behaviors of intelligent adversaries through appropriate use of existing databases, and historical attacks may be helpful in validating current models. Validating through analogy rather than using direct data is a reasonable approach. “Adversaries that are influenced by bias or have philosophical or religious perspectives will apply those perspectives to all their planning.”
3. Use of uncertainty. In modeling intelligent adversaries, we should consider the uncertainties in the structure and/or parameters. Parameter values should be evaluated and measured properly.

4.2.3 Transparent Risk Assessment to Improve Confidence

“Risk assessment transparency improves confidence” is suggested by [41], where the bioterrorism risk assessment (BTRA) model [10] is reviewed. The current use of the word “transparency” is summarized by [48] as “letting the truth be available for others to see if they so choose, or perhaps think to look, or have the time, means, and skills to look” and involving “active disclosure.”

In establishing confidence and trust in the methods of outputs from risk assessment models, transparency is a major factor. Achieving transparency requires the assumptions, model’s mathematical and structural foundations, and the sources of data used in the analysis to be made explicit. In [41], it is emphasized that “the accuracy of quantitative bioterrorism risk assessment models and the confidence placed in them depend on the validity of the assumptions and the availability of sound data for each of the biological agents being analyzed.”

4.2.4 Importance of Sensitivity Analysis for Validation

NRC [41] suggests that “sensitivity analysis is important for validation.” Saltelli and Tarantola [54] defines sensitivity analysis as the determination of how “uncertainty in the output of a model (numerical or otherwise) can be apportioned to different sources of uncertainty in the model input.”

There exist a lot of uncertainties or even errors in the model variables and parameters. The decision- maker needs to know how the uncertainties would impact the outputs of the model and therefore the confidence in the model. Many researchers have used sensitivity analysis to test uncertainties and evaluate the validity of the proposed models [60, 61, 80]. Sensitivity analysis has become an important approach to the testing and validation of risk assessment models of complex systems [5].

Recent studies [60, 61, 81] use sensitivity analysis for risk assessment to show how the results of a certain strategy would change when the parameter values change. In the future, it would be important to use more sensitivity analysis in risk management. This would be helpful to see, for example, what countermeasure strategy would be adopted if the modeler knew more about the intelligent adversaries’ behavior.

4.2.5 Comparing Models to Obtain Validity

Many models have been developed to study intelligent adversaries, and there are many variants and examples of these models in the literature [27, 60, 61, 66, 79, 81]. If some model has been proved to be valid, comparing other models with the validated model may be an effective way to do model verification and validation.

In [38], a comparative analysis of probabilistic risk analysis (PRA) and intelligent adversary methods for counterterrorism risk management is conducted. Defender event tree and Bayesian network, attacker event tree and Bayesian network, defender decision tree, attacker decision tree, sequential games, intelligent adversary risk analysis, adversary risk analysis, and simulation games are reviewed. Merrick and Parnell [38] considers each application on the same two illustrative example decisions. With respect to risk assessment, [38] states “Defender event trees and decision trees that represent attacker decisions as probabilities estimate lower expected consequences than attacker event trees and decision trees for the highest expected consequence attack, that is, the one that the attacker would choose.” As for risk communication, it is concluded “Event trees, influence diagrams with just probability nodes, and Bayesian networks with only probability nodes are all equivalent as they are following the laws of probability even though they use different solution algorithms.” At last, in terms of risk management, [38] gets the same conclusion with [41] that “event trees are less useful for assessing the risk posted by intelligent, adaptive adversaries.”

4.2.6 Simulation Validation with Intelligent Adversary Models

Simulation is a powerful tool for the analysis of complex process and systems. A growing number of simulation systems have been created to analyze the threats that terrorist attacks pose for public safety [34].

A National Research Council report [40] urges the Department of Homeland Security (DHS) to better validate its terrorism risk models. Morral et al. [39] reports the RAND's approach to validating the Risk Management Analysis Tool, or RMAT, which is one of the Transportation Security Administration's (TSA) principal terrorism risk modeling tools developed by the TSA and Boeing Company. RMAT is one of the growing class of quantitative models which are complex and could not be validated by comparing model predictions to the outcome of events in the real world, since the reference statistical data is limited. According to [39], "RMAT simulates terrorist behavior and success in attacking vulnerabilities in the domestic commercial air transportation system, drawing on estimates of terrorist resources, capabilities, preferences, decision processes, intelligence collection, and operational planning" and "to estimate the terrorism risk-reduction benefits attributable to new and existing security programs, technologies, and procedures."

Complex simulation is used to test the validity of the RMAT model [39]. In validating the defender model in RMAT, four areas are addressed [39]:

1. Identifying and evaluating the validity of key assumptions implicit in the overall system design;
 2. Comparing the world representation in RMAT to external sources;
 3. Assessing the completeness of the attack scenarios considered in RMAT, including both weapon-target pairings and pathways by which attacks are carried out;
 4. Comparing the attack consequences modeled in RMAT to external sources."
- Regarding the data, diverse forms of evidence are used to validate the data, such as "logic, subject matter expert judgments, and literature searches.

4.2.7 Using Experimental Data to Validate Intelligent Adversary Models

Validation includes comparing the model output with the real data or experimental results. In traditional models, experiments usually mimic the real situation and obtain reliable data. However, for intelligent adversary models, it is typically impossible to find data from experiments in which the conditions correspond exactly to the scenario because of the uncertain and adaptive nature of intelligent adversaries. It may also risk people's lives and public property to do some of such experiments. However, data gained based on laboratory experiments could provide insights into the behaviors of both the defender and attacker during certain hazard and emergency situations, which could be used to validate models.

An experiment was conducted in [23] to assess the extent to which individual decisions are consistent with theoretical predictions of misaligned profiling. The experiments are motivated, in part, by the counterintuitive nature of equilibrium patterns of the randomized strategies. In particular, the theory produces a paradox of misaligned profiling: in equilibrium the high reliability categories are searched more intensively, even though they are used less intensively by the terrorist organization. Field experiments with professional security officials to test these model predictions would be expensive and controversial, if possible at all. The results would be classified. Instead, [23] relies on laboratory experiments, which provide the ability

to replicate and control the environment. The results of the experiment reveal behavioral patterns that are consistent with the predicted patterns. Holt et al. [23] provides theoretical analysis and experimental validation to guide policy makers to improve the effectiveness of targeted profiled screening and investigates the efficient profiling and counterterrorism policy.

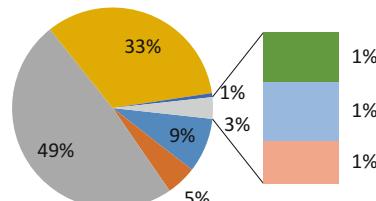

4.2.8 Using Historical Data to Conduct Validation

In addition to experimental data, historical data, which may have been recorded in databases and government reports, can provide other opportunities to validate intelligent adversary models.

In terms of terrorism, there are some databases available that recorded the terrorists' attacks, such as the Global Terrorism Database (GTD) [64], the International Terrorism: Attributes of Terrorist Events (ITERATE) [25], and Terrorism in western Europe: Events Data (TWEED) [69]. Among them, the GTD records incidents from 1970 and includes both domestic and international terror incidents. LaFree and Dugan [29] states that the GTD "have by far the largest number of events than any of the other data sets." Reports from the governments, such as the Federal Emergency Management Agency (FEMA) [72], the National Research Council (NRC) [73], and US Government Accountability Office (U.S. GAO) [77], could also provide useful data to do research on intelligent adversaries.

Zhang and Zhuang [78] presents a class of multi-period and multi-target attacker-defender games where the attackers have multiple attacking options. The attack types considered in [78] include assassination, armed assault, bombing/explosion, facility/infrastructure attack, hijacking, hostage taking, and unarmed assault, which is summarized based on the GTD categories. The percentage of the attack types used by the attackers is shown in Fig. 41.1. Different attack types would impact the attack success probabilities, consequences, as well as the effectiveness of defensive resource allocation. Sequential games are studied when the defender is faced with multiple attack types and adaptive attackers and how the defender would distribute a limited amount of resources to protect multiple urban areas. The objective of the defender is to minimize the total expected loss.

Fig. 41.1 Percentage of attack types in the USA
(Source: [64])

Based on the historical data from the GTD and UASI (the Urban Area Security Initiative, a Department of Homeland Security grant program), the parameter values are estimated in [78], such as the economic loss, fatality loss, success probability, and the defense cost-effectiveness for different attack types and targets. The authors estimate that basing defensive planning on the proposed model results in the lowest expected loss, having an expected loss which is 8–57% lower than the single attack-type model and 82–96% lower than the results of the real allocation [78].

4.3 Validate Intelligent Adversary Models Using Proxy Models

When modeling intelligent adversaries, it is important to construct a representation of preferences. However, sometimes it is difficult or even impossible to get direct elicitation from adversaries. Therefore, we could use indirect elicitation to construct and infer adversary motivations, objectives, preferences, capabilities, and beliefs. Proxy models are used by [27] to infer and validate models of adaptive adversaries. In [27], an adversary objective hierarchy and multi-attribute utility (MAU) models are constructed by proxy, using judgments from an adversary value expert (AVE). Past adversary behavior, public statements by the adversary, adversary web sites, and intelligence could be useful sources for the proxy to validate the behavior of the adversaries.

The proxy MAU models provide a relatively complete and accurate representation of the adversaries' values, including objectives, trade-offs, risk attitudes, and beliefs about consequence impacts. John and Rosoff [27] conducts two validation studies; good convergence between the proxy model and the model assessed by direct contact is demonstrated in both cases, which indicate that the proxy model may provide insights on intelligent adversaries if constructed and implemented properly.

4.3.1 Evaluating Effectiveness of Real-World Deployments to Validate Intelligent Adversary Models

Game theory has been playing an important role in modeling adversary behaviors, and Stackelberg games have been widely used to study terrorism and are in active use for resource deployment scheduling systems by law enforcements around the USA. In a Stackelberg game, there are two players, a leader (defender) and a follower (attacker); the leader chooses a strategy first and the follower subsequently decides his own strategy after observing the leader's strategy. According to [62, 66, 67], “the Stackelberg games models have been used to assist the LAX Airport police in scheduling airport entrance checkpoints and canine patrols of the terminals, the Federal Air Marshals Service (FAMS) to schedule marshals on international flights, the United States Coast Guard (USCG) in scheduling patrols around Boston Harbor, Ports of NY/NJ, and Ports of LA/LB, the Los Angeles Sheriff’s Department (LASD) for patrolling of the Metro trains, and (in-discussion) the patrolling of the Gulf of Mexico for illegal fishing for the USCG.” This system has been expanded to all ports in the USA due to the success of the patrolling schedules [67].

Despite the fact that Stackelberg game-based applications have been deployed in practice, measuring the effectiveness of the applications remains a difficult problem. And the data available about the deterrence of real-world terrorist attacks is very limited. Tambe and Shieh [67] suggests several methods to evaluate the effectiveness of Stackelberg games in real-world deployments, including:

1. Computer simulations of checkpoints and canine patrols;
2. Tests against human subjects, including USC students, an Israeli intelligence unit, and on the Internet Amazon Turk site (which provides some insights into adversary bounded rationality);
3. comparative analysis of predictability of schedules and methodologies before and after implementation of a Stackelberg strategy;
4. Red team/adversary team;
5. Capture rates of guns, drugs, outstanding arrest warrants, and fare evaders;
6. User testimonials.

4.3.2 Validation With Subject Matter Experts

According to [9], the Department of Defense's Modeling and Simulation Coordination Office defines a subject matter expert (SME) as "an individual who, by virtue of position, education, training, or experience, is expected to have a greater-than-normal expertise or insight relative to a particular technical or operational discipline, system or process." However, [68] shows that many SMEs make very poor predictions "at predicting elections, wars, economic collapses, and other events" and are not accountable enough for the accuracy of the forecasts, but the forecasting skills could be improved through learning and practicing.

Experts may offer help to do subjective (and possibly mistaken) model V&V. Experts may have a relatively high level of knowledge about what, when, where, and how the intelligent adversaries may behave. In general, experts may have better knowledge or more plausible-sounding guesses and narratives about the variables and parameters than others and know where the potential uncertainties may exist. Using experts to do model verification and validation is a qualitative technique, and the judgments made by an expert may be subjective and error prone. Also, each expert may have a different understanding of the model and could use different approaches to validate the same model. The benefit of using SME is that the decision-maker may gain different perspectives on the model and would have a comprehensive idea of the situation being modeled.

Louisa and Johnson [34] discusses the validation of a counterterrorism simulation of improvised explosive device (IED) incidents using the SME and concludes "it important to use the expertise of domain experts not only to compare the simulations to previous attacks of which they have knowledge, but also to use their knowledge to create new scenarios that explore the ways in which terrorist attacks could evolve."

Furthermore, the review process of the bioterrorism risk assessment (BTRA) model [10] is an example of using subject matter experts to verify and validate a model. Many good recommendations are given to make the model better [41], such as "The Department of Homeland Security should use an explicit risk analysis

lexicon for defining each technical term appearing in its reports and presentations,” and “To assess the probabilities of terrorist decisions, DHS should use elicitation techniques and decision-oriented models that explicitly recognize terrorists as intelligent adversaries who observe U.S. defensive preparations and seek to maximize the achievement of their own objectives.” DHS [10] concludes that the BTRA is not valid and suggests the DHS not to continue the development of that model.

5 Conclusion

Modeling plays an important role in guiding exploration in scientific research. This chapter has reviewed the concepts of model verification and validation (V&V), illustrated and compared model V&V in the developing process of models, and also discussed techniques for conducting a successful model V&V. Model V&V steps should be integrated with the modeling process and not be separated or treated after the model has been built. In the long run, using a validated model to support decision-making can sometimes improve decisions and make preferred outcomes more likely.

Because of inherent randomness of the systems, uncertainties in the model parameters, and the process of modeling framing, may impact the accuracy of results. Uncertainty quantification (UQ) should be considered in both the modeling process and the experiment process. Having a better understanding of the uncertainties can help the modeler build a more accurate model and thus make the model more effective in practice. This chapter has also illustrated some quantitative model validation techniques in dealing with uncertainty and deciding whether or not to accept the model prediction.

Intelligent adversary model V&V and UQ are different from V&V and UQ for traditional models in literature, where experimental/physical data could be obtained to compare with the model results. Unlike traditional models, the behavior of intelligent adversaries cannot be fully understood, and due to the lack of data and incomplete information about intelligent adversaries’ behavior, it is often the case that neither models nor experimental studies of adversarial behavior can be truly validated. This is a new and challenging area in the literature of model V&V. The model V&V techniques that have been discussed in this chapter include basic necessary conditions for intelligent adversary risk analysis, conceptual processes to provide more confidence in intelligent adversary models, risk assessment transparency, comparing models, simulation, experimental data, historical data, proxy models, evaluating effectiveness of real-world deployments, and using subject matter experts. These techniques attempt to take the uncertainties and adaptiveness of the intelligent adversaries into account, which may be helpful in tackling the dilemma of validating intelligent adversary models.

Many intelligent adversary models have appeared in the literature recently, but research on model V&V and UQ with intelligent adversaries is in many ways still in its infancy, with difficult challenges and limited options for overcoming them. More accurate adversarial models and more sophisticated V&V and UQ procedures with respect to adversarial models should be addressed to better understand the risks from intelligent adversaries and to better assist in surveillance and decision-making.

Robust Design and Uncertainty Quantification for Managing Risks in Engineering

42

Ron Bates

Abstract

Methods for uncertainty quantification lie at the heart of the robust design process. Good robust design practice seeks to understand how a product or process behaves under uncertain conditions to design out unwanted effects such as inconsistent or below-par performance or reduced life (and hence increased service or total life cycle costs). Understanding these effects can be very costly, requiring a deep understanding of the system(s) under investigation and of the uncertainties to be guarded against.

This chapter explores applications of UQ methods in an engineering design environment, including discussions on risk and decision, systems engineering, and validation and verification. The need for a well-aligned hierarchy of high-quality models is also discussed. These topics are brought together in an Uncertainty Management Framework to provide an overall context for embedding UQ methods in the engineering design process. Lastly, some significant challenges to the approach are highlighted.

1 Introduction

Applying UQ methods in design is a core robust design activity and can be difficult. Here we discuss the issues around the use of UQ in the design process and the challenges faced by the practitioner. Engineering design is the process of applying science to create a system or process that converts resources to meet desired needs. Typical engineering applications are inherently complex, with many dynamic, nonlinear interactions and multiple objectives and constraints derived from requirements that express those needs. When considering the design and analysis of engineering systems, one needs to consider attributes that are multifaceted. Studies often contain multiple:

- Objectives and constraints,
- Behaviors and failure modes,
- Physical disciplines,
- Scales or levels of fidelity.

Product design involves teams of specialists developing subsystems in parallel with an inherent need to communicate ideas, models, and results between them. Too much focus on individual aspects of a design (single discipline, single objective) will ultimately lead to overall suboptimal performance.

Addressing these issues requires a holistic, systems engineering view. Experience has shown that without a structured approach to product design and development, the inherent complexity of engineering systems can result in undesired emergent behavior, with adverse consequences from significant project cost overrun to much worse, the classic examples being the collapse of the Tacoma Narrows Bridge or the NASA Challenger disaster. Conversely, adopting a systems approach can simplify complex situations, identify key issues, and reduce risk and cost. Examples of this can be seen in the adoption of “lean” methods in manufacturing, construction, and other sectors, where a focus on alignment of requirements and objectives can help drive out waste. A systems approach can also foster innovation by encouraging both revolution and incremental improvement, or the “aggregation of marginal gains”, which is particularly valuable in mature fields where many of the major advances in design and technology have already been made. Importantly for robust design,

this approach provides a natural framework for dealing with uncertainty in the system itself, in the network of models that represent the system, in model form, and in model inputs and in model outputs, which is the main focus of uncertainty quantification methods in engineering.

The rest of this section will describe in more detail the application of UQ in the engineering design environment, followed by a set of challenges that need to be overcome for application to complex engineering systems. The topics to be discussed are:

- Risk and decision
 - Systems engineering and validation and verification
 - Uncertainty management framework
 - Challenges
-

2 Risk and Decision

The relationship between quality, risk, and uncertainty is worth exploring. Robust design has its roots in the quality revolution in postwar Japan (Ishikawa/Deming) where the connection was made between statistical methods applied to industry and management, leading to the famous “14 key principles for management” later embraced by the total quality management revolution. The point here is that we undertake UQ studies to improve our understanding of the effect of uncertainty on the system (or subsystem, or component) in order to make a decision as part of the product development process (PDP). It is all about those decisions. There is a strong hierarchical link between probabilistic analysis, UQ, uncertainty management, and risk (Fig. 42.1).

Taken in isolation, UQ studies on complex engineering systems are costly and time-consuming to conduct. High cost can make it difficult to justify their use, particularly in low-volume industries. Long-running studies may take weeks or even months to complete, which may be too late to influence the design. However, the design process itself is not a linear process, and in general, neither is innovation. Instead ideas are generated, tested, and broken in an iterative process, and design studies need to keep pace with this. Mapping this process to hierarchical models of the system (integrated, multi-scale, multi-fidelity) may facilitate detailed UQ studies early in the PDP, reducing the risk of costly design modifications later. This will be discussed further in later sections.

When considering uncertainty, there are three main categories:

1. Randomness: aleatory uncertainty, or intrinsic randomness,
2. Incompleteness: epistemic uncertainty, or lack of knowledge,
3. Ineptitude, incomprehension, or incompetence.

The field of UQ is most often concerned with (1) and (2). Probabilistic studies can provide a natural framework for dealing with aleatory uncertainty. Probability

Fig. 42.1 From Risk to probabilistic analysis

distributions can be used to model uncertainty as variation, and the impact of variation can be assessed using models of systems. The issue then becomes one of distinguishing between error in model inputs and error in the models themselves (model discrepancy with the physical system).

Where there are deeper uncertainties, it may be difficult to frame that uncertainty in a probabilistic sense. There may be a lack of data, there may not be a sufficiently credible model of the system, or there may not be sufficient knowledge of cause and effect to produce any kind of model. In these cases, knowledge management and systems engineering can help blend qualitative and quantitative information to express these uncertainties in a way that aids decision-making (see Fig. 42.2).

Where there is complexity, or even chaos, it is likely that there is no credible causal model of the system. There may be deep uncertainty about the system and its inputs, with no model, and no well-defined expressions of uncertainty. One way of trying to address this type of problem is to develop parallel plausible scenarios that illustrate these uncertainties and then to analyze their effects. This can be seen, for example, in weather forecasting where several alternative (but equally likely) storm paths may be shown to communicate the uncertainty in the forecast (see, e.g., [5]).

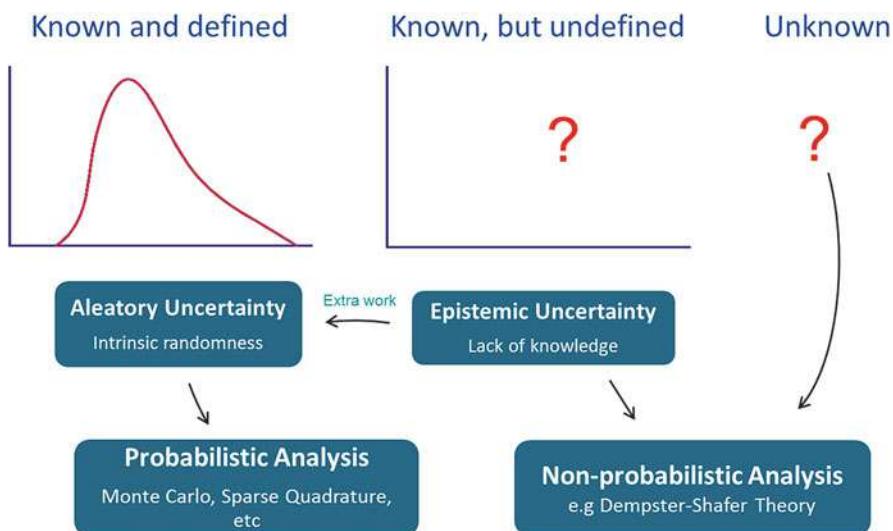

Fig. 42.2 Levels of uncertainty

The Cynefin model [1] provides a framework for integrating and expanding these levels of uncertainty to encompass the wider system view and related decision-making processes and appropriate modes of behavior for dealing with uncertainty. Figure 42.3 shows an attempt at mapping the levels of uncertainty defined in Fig. 42.2 into this framework. Where there is deep uncertainty, one is firmly on the left-hand side of the Cynefin model.

In addition to facilitating UQ studies by helping with the quantification problem, systems engineering can also help to address the issue of ineptitude or incompetence, for example, by providing a framework, or checklist, to facilitate the implementation of best practice or simply by having a structured approach that minimizes data transfer, data processing, model sharing, and model integration. The issue of incomprehension is also worth considering at this point. A proposed solution to a problem may not be adequate if the initial specifications are misunderstood or if the specified system is not correctly modeled. A systems engineering approach can help guard against these problems by checking for inconsistencies and unexpected behavior, which will be explored in the next section. Ultimately, managing uncertainty helps to speed up implementation, reduce error, and reduce cost.

3 Systems Engineering and Verification & Validation

Systems engineering is an approach used to develop complex engineering products. It emphasizes a top-down approach, embracing the whole product life cycle, and is naturally multidisciplinary. Importantly it also places a heavy emphasis on defining requirements (both customer and system) before developing solutions. Why is this

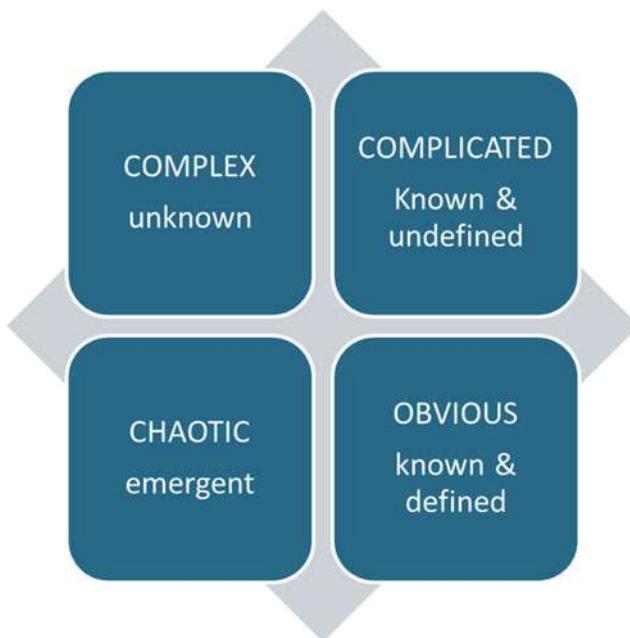

Fig. 42.3 Mapping uncertainty and systems thinking to the Cynefin model

important? Because as systems become more complex, it becomes more difficult to design solutions without encountering undesirable emergent behavior.

Systems engineering promotes a hierarchical approach, embodied in the “V-diagram” shown in Fig. 42.4.

The basic “V” can be applied hierarchically and can operate at many scales in a fractal sense. A typical generic decomposition would be system, subsystem, component, and material. The overall systems engineering framework provides a hierarchical structure to frame UQ studies in the context of risk and decision, as discussed in the previous section. The final step in the system V-diagram is verification, where the system is tested against the original requirements to confirm if it fulfills those requirements: “did we build the thing right?” This is in contrast to system validation which confirms that the requirements are correct and complete: “did we build the right thing?”

System verification and validation (V&V) combines experience, judgment, physical test, and mathematical modeling (simulation). If simulation models are to be used in a V&V context, then they need to be subject to a simulation V&V process, e.g., [4] integrated with the structured systems view.

3.1 Simulation Verification & Validation

In a general sense, a model can be described as a set of assumptions about a given system [2]. Models are used to describe behavior, both static and dynamic, for the

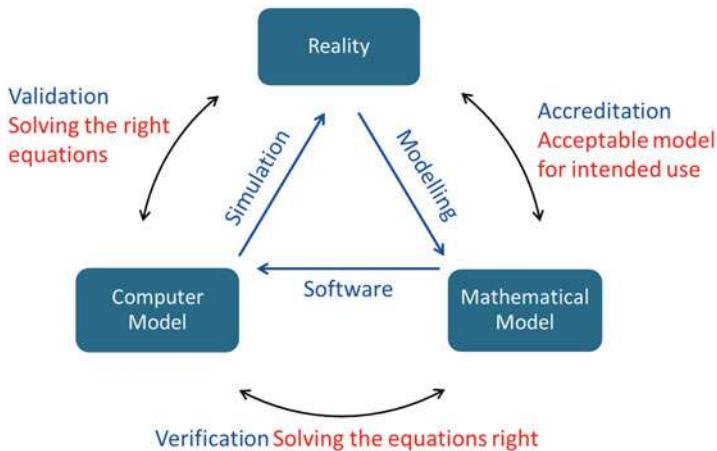

Fig. 42.5 Simulation V&V (A simplified version of the Sargent Cycle [4])

purpose of understanding and controlling (designing) the system. Simulation then is the evaluation of those models to mimic the relevant features of a real process. Once a simulation model is built, it needs to be verified and validated.

In line with the fractal nature of the systems engineering V-diagram, simulation V&V can be viewed as a subsystem of systems V&V (Fig. 42.5), where the goal is to verify the models against experience, judgment, and test data and to validate those models against requirements.

Simulation therefore has multiple roles as it is used throughout the product development process, from design to system validation. Validation can involve testing the simulation model against physical test data for the right physics, the right geometry, the right mesh, the right boundary conditions, etc. This can be achieved with an integrated test and simulation strategy. In the end, the simulation model must be shown to be fit for purpose, and this of course means that the validation process very much depends on the purpose. At this stage one must be mindful of the bounds within which the model is shown to be valid. A model representing a particular design configuration may be calibrated against test data at a particular operating point, but that does not necessarily mean it is a valid model at other design configurations or operating points. If the model is to be used for a design trade study, or for optimization, then the validity of the model over the whole of the defined design space needs to be considered. The discrepancy between model and observed behavior can be modeled, either explicitly or by considering the plausibility of the model as it is evaluated at different locations in the design space.

Where simulation models are used in the early stages of design, they will often need to be evaluated many times, and with many different input configurations (e.g., changes in geometry), it may be possible to use simplified models that are faster to run where less accuracy is required, for example, to detect design trends. Where detailed optimization studies are needed, a more accurate but slower-running model may be necessary to accurately capture behavior. Thus a multi-fidelity approach to modeling may be required, where there are several models of the same system, with different blends of speed and accuracy, used as the situation dictates. Such models need to be aligned with each other, so that they can be interchanged at will. Considering finite element models, this could be achieved by varying the size of the FE mesh, with coarse meshing for faster models and finer meshing for more detailed analysis, subject to model validation. Alternatively, linearized or reduced-order models (ROM) may be used.

4 Uncertainty Management Framework

As previously mentioned, the engineering system can be represented by a network of models. In order to propagate variation through this network, a common parametric model framework is required. The models must be able to represent variation as it is experienced in manufacturing and use. This requires that uncertainty in manufacture and use be defined, measured, and expressed as variation and then propagated as efficiently as possible. The general framework for uncertainty management in analysis is shown in Fig. 42.6.

There are four key pillars to this framework.

1. Quantify input uncertainty (identify sources, elicit, measure)
2. Model the system (validated models, including representation of uncertainty)
3. Propagate uncertainty using a suitable method (see below)
4. Analyze/optimize (sensitivity, objectives, constraints, algorithms)

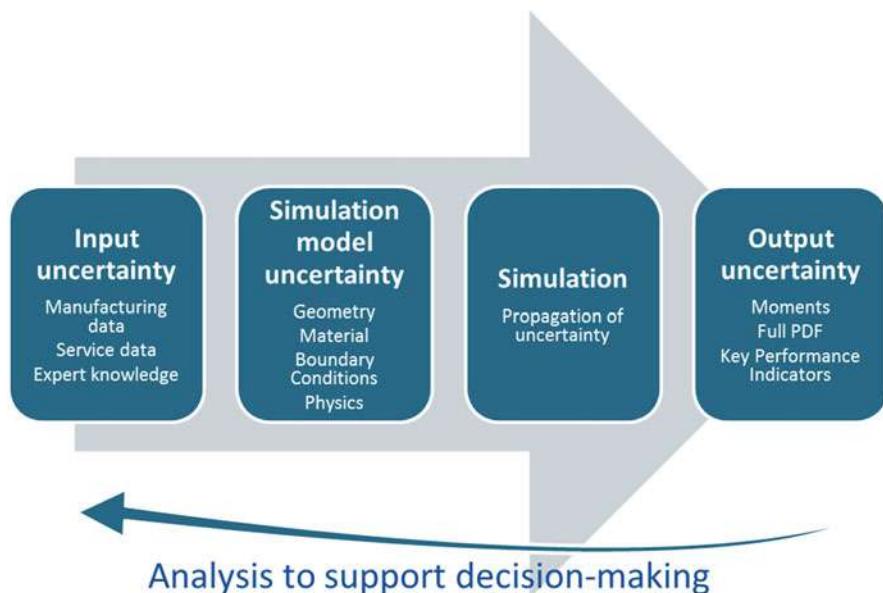

Fig. 42.6 General simulation framework

This simulation framework can be used to solve the forward problem (what is the variation in outputs, given variation in inputs?) and the inverse problem (what input variation caused the observed output variation?). There are significant challenges associated with each pillar of the framework, and these will be further discussed now.

4.1 Quantification of Input Uncertainty

Standard robust design and systems engineering tools can be used to identify sources of input uncertainty, and once identified, these need to be quantified. This usually involves gathering data, although interval-based methods do exist; they are not usually associated with UQ studies, which concentrate on probabilistic analysis. Where deeper uncertainty exists (i.e., uncertainty that cannot be quantified), one can take a scenario-based approach, as previously mentioned. Different types of input uncertainty related to engineering analysis include:

1. Physics. This defines the nature of the problem, e.g., find displacements given forces on objects.
2. Geometry. This defines the domain over which the problem will be solved. This may not necessarily be the fully featured part geometry but could be a simplification.

3. Meshing. The geometry domain needs to be discretized with a mesh as part of the FEM formulation of the problem.
4. Boundary conditions. These define the initial conditions for the model.
5. Solver. In general, the problem needs to be solved numerically, and hence any solution is approximate.
6. Computer hardware. Decomposition of a large problem into subproblems that can be solved with available computing resource (memory, CPU power, bus bandwidth).

4.2 Modeling and Simulation Framework

A system model or network of models that represents the system needs to be:

1. Representative of the relevant system responses,
2. Flexible enough to represent the design space and input uncertainties,
3. Able to run automatically (in “batch mode”), to facilitate design studies and computer experiments.

These modeling and simulation requirements demand flexible, parametric models that can be integrated into workflows containing several simulation codes with data being shared automatically between them. In the case of finite element models, this means automatic generation of geometry, automatic meshing of that geometry, and automatic application of forces and boundary conditions, which are all nontrivial tasks.

Automation is needed for propagation of variation, for example, by using computer experiments [3] where design of experiments (DoE) methods are used to fit empirical models (variously known as emulators, meta-models, surrogates, response surface models) that approximate the behavior of the simulation models, but run much faster and can be used more effectively for design space exploration and optimization. An additional benefit of workflow automation that includes empirical model fitting is that block DoEs can be run in parallel and, in addition, sequential modeling strategies can minimize the number of costly simulation runs needed to fit a good-quality model.

The model network should also be aligned with the broader “systems” view, so that changes to the model can be evaluated by other subsystems (e.g., cost of manufacture) and also so that any resulting design changes can be implemented. Alignment of model networks also facilitates multi-fidelity analysis, where there are multiple models of the same system. Where computational costs are high, a multi-fidelity model framework can be used to achieve accuracy in design search and optimization while reducing the overall computational burden.

4.3 Representation of Uncertainty in Simulation Models

Promoting the parameters of a simulation model from deterministic to stochastic can be very costly from a numerical simulation perspective. Even the most sophisticated propagation methods currently struggle to deal with more than around 20 random variables, when applied to nonlinear systems. Where data exists, variation in individual parameter values can be characterized by standard univariate distributions. Accounting for correlation can be more problematic, but is no less important. Where there is a spatial aspect to the parameters (e.g., boundary conditions along an edge, or a face, material properties, or even geometry), then random fields may be used.

4.4 Propagation of Uncertainty

Methods for the propagation of uncertainty through the model framework include:

- Monte Carlo methods
- Sparse quadrature
- Sigma point methods
- gPC: generalized polynomial chaos
- Stochastic reduced basis methods (for stochastic PDEs)
- Adjoint solvers (for efficient computation of derivatives)

These methods are discussed in detail in other chapters. It is interesting to note that many of these methods are intimately bound to the statistical models that represent the uncertainty, which can make it difficult to develop and deploy generic solutions to the engineering design community.

4.5 Decision Analysis

Evaluation of the model framework provides insight into system performance and design. Specific applications include sensitivity studies, general search in the design space, and numerical optimization. Design information gathered using these techniques can be used to inform decisions during the product development process and to confirm (validate) system behavior as part of a systems V&V process and also for product certification by external authorities. Where information exists on variation in system response (e.g., in-service data, or operational data), then an inverse problem formulation of the model network can attempt to identify the likely variation in system inputs that led to the variation in outputs.

4.5.1 Sensitivity Studies

If one considers the model network as a transfer function, mapping inputs (design parameters) to outputs (system responses), then at its simplest, a sensitivity study can be used to rank the inputs according to their effect on the outputs. The model network evaluates the change in output for a fixed (e.g., unit, or 1%) change in inputs. This does not take into account different levels of uncertainty that each of the inputs may have, which in turn will change the amount by which the outputs will vary. Therefore, in order to be useful, the likely variation of input values must be used. Where these are not known, sensitivity studies are of limited use.

4.5.2 Robust Optimization

Numerical optimization algorithms can be applied to the model network to optimize performance. The lower and upper bounds of the model (input) parameters define a design space which can be explored. If variation in the input parameters is ignored, there is the danger that optimal designs are identified that are at constraint boundaries or that are highly sensitive to small changes in input parameter values (cliff-edge designs). Therefore the robustness of the design to variation in inputs needs to be evaluated, which of course is a prime motivator for UQ studies.

Robust optimization imposes a significant computational burden because a UQ study is potentially needed at every iteration of the optimizer, creating the requirement for fast, efficient UQ methods. The number of objectives is higher for robust optimization as there may well be multiple attributes (e.g., mean, variance), for each response.

5 An Example Application: Jet Engine Disc and Blade Design

The design and development of a new engine is supported by analysis and test operations that rely on models at system, subsystem, and component level. The impact of variation at component level needs to be assessed not only at that level but also at higher levels. This can create a significant challenge for the practical application of UQ methods.

A generic example problem, which is nonetheless based on a real engineering design problem, is presented to illustrate some of the issues that have been discussed. The problem is to design a blade and disc assembly for a jet engine. The idea behind the example is to show the hierarchy of design systems and the multifaceted nature of the design problem.

The disc and blade design problem is addressed at component level, but also needs to be considered at subsystem level (compressor or turbine) and at system (whole engine) level. Figures 42.7, 42.8, and 42.9 show these three levels of design geometry. These geometry models form the basis of the set of analysis models used to inform both design and the verification and validation of the system.

Figure 42.7 shows a schematic of a Rolls-Royce Plc Trent engine. At the core of the engine lies the compressor-combustor-turbine arrangement, where air is compressed, heated, and expanded to produce work. The detailed designs of

Fig. 42.7 Rolls-Royce next-generation advance engine (© Rolls-Royce Image Library)

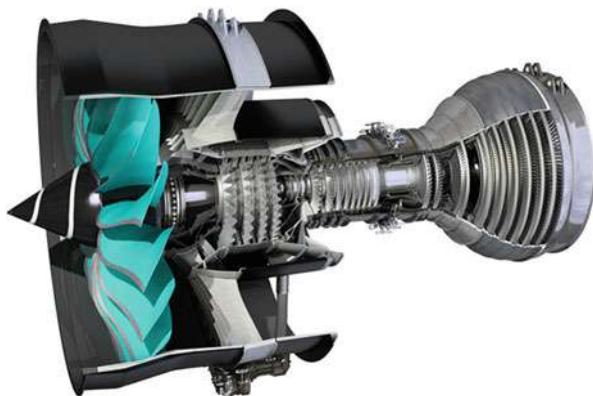

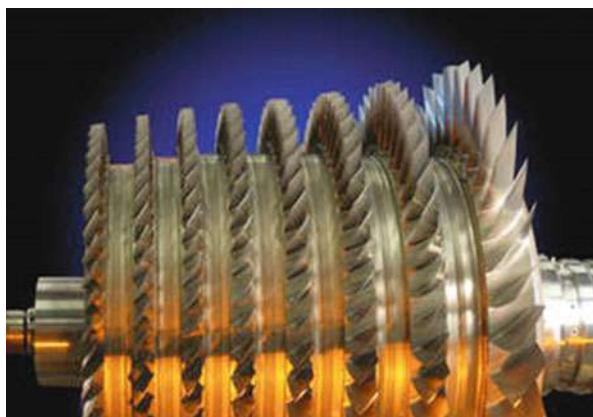

Fig. 42.8 Engine compressor system (©Rolls-Royce Image Library)

the blade and disc arrangements of the compressor and turbine are critical in determining overall engine performance and are subject to multiple design criteria. Performance is evaluated over a full flight profile, with hundreds of complex thermomechanical loading conditions. The blade and disc components need to be evaluated for strength (stress, strain), fatigue, and vibration, requiring the model to be able to represent nonlinear physical phenomena such as creep, plasticity, fatigue, and contact and friction, all in a coupled thermomechanical model.

Not all of these conditions and physics-based models need to be evaluated at the whole engine level. Whole engine analysis is extremely costly – more can be done with available resources if the physical phenomena that drive individual design criteria are modeled at appropriate scale and fidelity. This however creates an overhead in managing the hierarchy of analysis models. The models need to be kept in alignment via common geometry definitions and consistent boundary conditions, all while allowing them to flex to take uncertainty into account and to allow for larger design changes in the search for a good design solution.

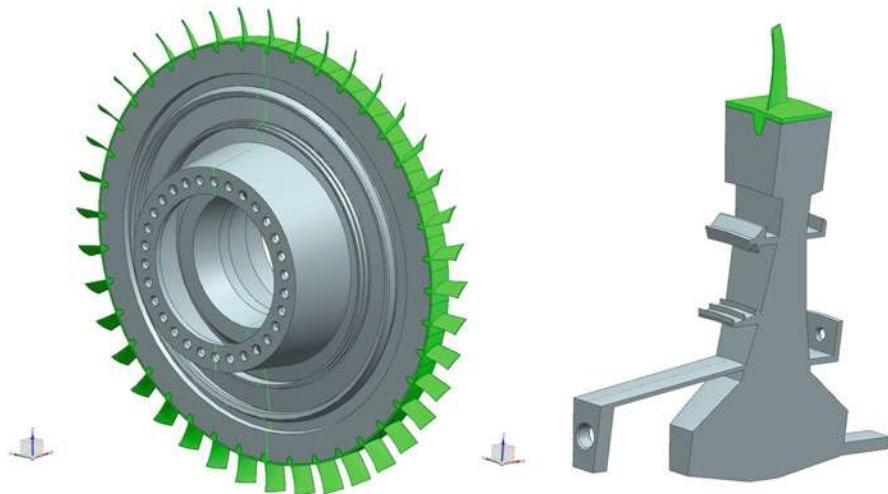

Fig. 42.9 A generic disc and blade model arrangement (*left*) and section thereof (*right*)

The disc and blade arrangement of the compressor subsystem is shown in Fig. 42.8. This subsystem can be modeled and analyzed to determine key performance characteristics, which may involve more detailed modeling at the individual blade and disc level, as depicted in Fig. 42.9

At this detailed level, effects such as contact and friction between blade and disc can be modeled. Thus there is a well-defined modeling pathway from engine to subsystem to component.

6 Challenges For the Application of UQ

In summary, the application of UQ methods to the design of engineering systems poses the following challenges:

1. Simulation
 - a. Multidisciplinary: common parametric models to enable flow of data
 - b. Aligned models: systems of multi-fidelity models
 - c. Fully stochastic simulation models
2. Uncertainty quantification
 - a. Data-led quantification of sources of uncertainty
 - b. Methods for UQ where data are sparse (expensive) and multi-scale
 - c. Propagation methods integrated with simulation models
3. Optimization
 - a. Improved automated geometry creation and meshing (morph geometry or mesh?)
 - b. Increase in the number of objectives considered during optimization

4. Robust design

- a. Tools and methods able to cope with large nonlinear problems
 - b. Hierarchy of variable fidelity models from component to subsystem to system
 - c. Full “System view” of uncertainty quantification and management: decision-making in the face of uncertainty
 - d. Validation: calibration at a test point, extrapolation to a new design vs interpolation
 - e. “Close the loop”: how well did we predict the variation that we see in the field?
-

7 Conclusion

Several aspects of managing uncertainty in engineering design have been discussed. Uncertainty, risk, and decision-making are closely related to each other and also to the process of design and development of new products. By classifying uncertainty into different types (randomness, incompleteness, ineptitude), one can begin to define effective strategies for managing uncertainty. These strategies should be integrated with a systems engineering approach and should ultimately define a hierarchy of models that includes functional models, static and dynamic simulation models, and data, all of which are verified to accurately represent the (sub) systems in question and validated against the original design requirements. This network of models forms the foundation of a framework for managing uncertainty that can be exploited to develop an understanding of how the many forms of variation (randomness) impact design performance.

There are many challenges to making this vision a reality. UQ studies can be costly, both in terms of generating models that are fit for purpose and in evaluating those models to understand how randomness is propagated through them. It can be difficult to develop well-aligned hierarchies of models, and it can also be difficult to understand how the results of a probabilistic simulation study can be used upstream to aid the design decision-making process.

Despite these challenges, the main argument remains that managing risk and uncertainty in engineering design can be achieved using a well-organized, well-structured approach. This can help to minimize risk and create an understanding of uncertainty which can then be used to inform designers on how to make products more robust to variation and more resilient to change.

Quantifying and Reducing Uncertainty About Causality in Improving Public Health and Safety

43

Louis Anthony Cox, Jr.

Abstract

Effectively managing uncertain health, safety, and environmental risks requires quantitative methods for quantifying uncertain risks, answering the following questions about them, and characterizing uncertainties about the answers:

- Event detection: What has changed recently in disease patterns or other adverse outcomes, by how much, when?
- Consequence prediction: What are the implications for what will probably happen next if different actions (or no new actions) are taken?
- Risk attribution: What is causing current undesirable outcomes? Does a specific exposure harm human health, and, if so, who is at greatest risk and under what conditions?
- Response modeling: What combinations of factors affect health outcomes, and how strongly? How would risks change if one or more of these factors were changed?
- Decision making: What actions or interventions will most effectively reduce uncertain health risks?
- Retrospective evaluation and accountability: How much difference have exposure reductions actually made in reducing adverse health outcomes?

These are all causal questions. They are about the uncertain causal relations between causes, such as exposures, and consequences, such as adverse health outcomes. This chapter reviews advances in quantitative methods for answering them. It recommends integrated application of these advances, which might collectively be called causal analytics, to better assess and manage uncertain risks. It discusses uncertainty quantification and reduction techniques for causal modeling that can help to predict the probable consequences of different policy

choices and how to optimize decisions. Methods of causal analytics, including change-point analysis, quasi-experimental studies, causal graph modeling, Bayesian Networks and influence diagrams, Granger causality and transfer entropy methods for time series, and adaptive learning algorithms provide a rich toolkit for using data to assess and improve the performance of risk management efforts by actively discovering what works well and what does not.

1 Introduction

Politically contentious issues often turn on what appear to be technical and scientific questions about cause and effect. Once a perceived undesired state of affairs reaches a regulatory or policy agenda, the question arises of what to do about it to change things for the better. Useful answers require understanding the probable consequences caused by alternative policy actions. For example,

- A century ago, policy makers might have asked whether a prohibition amendment would decrease or increase alcohol abuse.
- A decade ago, policy makers might have wondered whether an invigorated war on drugs would increase or decrease drug abuse.
- Do seatbelts reduce deaths from car accidents, even after accounting for “risk homeostasis” changes in driving behaviors?
- Does gun control reduce deaths due to shootings?
- Does the death penalty reduce violent crime?
- Has banning smoking in bars reduced mortality rates due to heart attacks?
- Do sex education and birth control programs in schools decrease teen pregnancy rates and prevalence of sexually transmitted diseases?
- Has the Clean Air Act reduced mortality rates, e.g., due to lung cancer or coronary heart disease (CHD) or to all causes?
- Will reformulations of childhood vaccines reduce autism?
- Would banning routine antibiotic use in farm animals reduce antibiotic-resistant infections in people?

Policy makers look to epidemiologists, scientists, and risk analysts to answer such questions. They want to know how policy actions will change (or already have changed) outcomes and by how much – how much improvement is caused how

quickly and how long does it last? They want to know what will work best and what has (and has not) worked well in reducing risks and undesirable outcomes without causing unintended adverse consequences. And they want to know how certain or uncertain the answers to these questions are.

Developing trustworthy answers to these questions and characterizing uncertainty about them requires special methods. It is notoriously difficult to quickly and accurately identify events or exposures that cause adverse human health outcomes, quantify uncertainties about causal relations and impacts, accurately predict the probable consequences of a proposed action such as a change in exposure or introduction of a regulation or intervention program, and quantify in retrospect what effects an action actually did cause, especially if other changing factors affected the observed outcomes. The following section explains some limitations of association-based epidemiological and regulatory risk assessment methods that are often used to try to answer these questions. These limitations suggest that association-based methods are not adequate for the task [21], contributing to an unnecessarily widespread prevalence of false positives in current epidemiology that undermines the credibility and value of scientific studies that should be providing trustworthy, crucial information to policy makers [22, 56, 70, 102]. New and better ideas and methods are needed, and are available, to provide better answers. The remaining sections review the current state of the art of methods for answering the following causal questions and quantifying uncertainties about their answers:

1. *Event detection: What has changed recently in disease patterns or other adverse outcomes, by how much, when, and why?* For example, have hospital or emergency room admissions or age-specific mortalities with similar symptoms recently jumped significantly, perhaps suggesting a disease outbreak (or a terrorist bio-attack)?
2. *Consequence prediction: What are the implications for what will probably happen next if different actions (or no new actions) are taken?* For example, how many new illnesses are likely to occur and when? How quickly can a confident answer be developed and how certain and accurate can answers be based on limited surveillance data?
3. *Risk attribution: What is causing current undesirable outcomes? Does a specific exposure harm human health? If so, who is at greatest risk (e.g., children, elderly, other vulnerable subpopulations) and under what conditions (e.g., for what exposure concentrations and durations or for what co-exposures)?* Answering this question is the subject of *hazard identification* in health risk assessment. For example, do ambient concentrations of fine particulate matter or ozone in air (possibly in combination with other pollutants) cause increased incidence rates of heart disease or lung cancer in one or more vulnerable populations? Here, “cause” is meant in the specific sense that reducing exposures would reduce the risks per person per year of the adverse health effects. (The following section contrasts this with other interpretations of “exposure causes disease Y,” such as “exposure X is strongly, consistently, specifically, temporally, and statistically

significantly associated with Y , and the association is biologically plausible and is stronger for greater exposures” or “the fraction of cases of Y attributable to X , based on relative risks or regression models, is significantly greater than zero.” These interpretations do *not* imply that reducing X will reduce Y , as positive associations and large attributable risks may reflect modeling choices or p-hacking, biases, or confounding rather than genuine causation.)

4. *Response modeling: What combinations of factors affect health outcomes and how strongly? How would risks change if one or more of these factors were changed?* For example, what is the quantitative causal relationship between exposure levels and probabilities or rates of adverse health outcomes for individuals and identifiable subpopulations? How well can these relationships be inferred from data, and how can uncertainties about the answers be characterized?
5. *Decision making: What actions or interventions will most effectively reduce uncertain health risks?* How well can the effects of possible future actions be predicted, such as reducing specific exposures, taking specific precautionary measures (e.g., flu shots for the elderly), or other interventions? This is the key information needed to inform risk management decisions before they are made.
6. *Retrospective evaluation and accountability: How much difference have exposure reductions actually made in reducing adverse health outcomes?* For example, has reducing particulate matter air pollution reduced cardiovascular mortality rates over the past decade, or would these reductions have occurred just as quickly without reductions in air pollution (i.e., are these coincident historical trends, or did one cause the other?)

These questions are fundamental in epidemiology and health and safety risk assessment. They are mainly about how changes in exposures affect changes in health outcomes and about how certain the answers are. They can be answered using current methods of causal analysis and uncertainty quantification (UQ) for causal models if sufficient data are available.

The following sections discuss methods for drawing valid causal inferences from epidemiological data and for quantifying uncertainties about causal impacts, taking into account model uncertainty as well as sampling errors and measurement, classification, or estimation errors in predictors. UQ methods based on model ensemble methods, such as Bayesian model averaging (BMA) and various forms of resampling, boosting, model cross validation, and simulation, can help to overcome over-fitting and other modeling biases, leading to wider confidence intervals for the estimated impacts of actions and reducing false-positive rates [50]. UQ has the potential to restore greater integrity and credibility to model-based risk estimates and causal predictions, to reveal the quantitative impacts of model and other uncertainties on risk estimates and recommended risk management actions, and to guide more productive-applied research to decrease key remaining uncertainties and to improve risk management decision-making via active exploration and discovery of valid causal conclusions and uncertainty characterizations.

2 Some Limitations of Traditional Epidemiological Measures for Causal Inference: Uncertainty About Whether Associations Are Causal

Epidemiology has a set of well-developed traditional methods and measures for quantifying associations between observed quantities. These include regression model coefficients and relative risk (RR) ratios (e.g., the ratio of disease rates for exposed and unexposed populations) as well as various quantities derived from them by algebraic rearrangements. Derived quantities include population attributable risks (PARs) and population attributable fractions (PAFs) for the fraction of disease or mortality cases attributable to a specific cause, global burden of disease estimates, etiologic fractions and probability-of-causation calculations, and estimated concentration-response slope factors for exposure-response relations [27, 98]. Although the details of calculations for these measures vary, the key idea for all of them is to observe whether more-exposed people suffer adverse consequences at a higher rate than less-exposed people and, if so, to attribute the excess risks in the more-exposed group to a causal impact of exposure. Conventional statistical methods for quantifying uncertainty about measures of association, such as confidence intervals and *p*-values for RR, PAF, and regression coefficients in logistic regression, Cox proportional hazards, or other parametric or semi-parametric regression models, are typically used to show how firmly the data, together with the assumptions embedded in these statistical models, can be used to reject the null hypothesis of independence (no association) between exposures and adverse health responses. In addition, model diagnostics (such as plots of residuals and formal tests of model assumptions) can reveal whether modeling assumptions appear to be satisfied; more commonly, less informative goodness-of-fit measures are reported to show that the models used do not give conspicuously poor descriptions of the data, at least as far as the goodness-of-fit test can determine. However, goodness-of-fit tests are typically very weak in detecting conspicuously poor fits to data. This is often illustrated by the notorious “Anscombe’s quartet” of qualitatively very different scatter plots giving identical least-squares regression lines and goodness-of-fit test values.

The main limitation of these techniques is that they only address associations, rather than causation. Hence, they typically do not actually quantify the fraction or number of illnesses or mortalities per year that would be prevented by reducing or eliminating specific exposures. Unfortunately, as many methodologists have warned, PAF and probability of causation, as well as regression coefficients, are widely misinterpreted as doing precisely this (e.g., [98]). Large epidemiological initiatives, such as the World Health Organization’s Global Burden of Disease studies, make heavy use of association-based methods that are mistakenly interpreted as if they indicated causal relations. This has become a very common mistake in contemporary epidemiological practice. It undermines the validity, credibility, and practical value of many (some have argued most) causal claims now being published using traditional epidemiological methods [70, 88, 102]. To what extent associations correspond to stable causal laws that can reliably predict future consequences of

policy actions is beyond the power of these traditional epidemiological measures to say [98] doing so requires different techniques.

2.1 Example: Exposure-Response Relations Depend on Modeling Choices

A 2014 article in *Science* [21] noted that “There is a growing consensus in economics, political science, statistics, and other fields that the associational or regression approach to inferring causal relations – on the basis of adjustment with observable confounders – is unreliable in many settings.” To illustrate this point, the authors cite estimates of the effects of total suspended particulates (TSPs) on mortality rates of adults over 50 years old, in which significantly positive associations (regression coefficients) are reported in some regression models that did not adjust for confounders such as age and sex, but significantly negative associations are reported in other regression models that did adjust for confounders by including them as explanatory variables. The authors note that the sign, as well as the magnitude, of reported exposure concentration-response (C-R) relations depends on details of modeling choices about which variables to include as explanatory variables in the regression models. Thus, the quantitative results of risk assessments presented to policy makers as showing the expected reductions in mortality risk per unit decrease in pollution concentrations actually reflect specific modeling choices, rather than reliable causal relations that accurately predict how (or whether) reductions in exposure concentrations would reduce risks.

A distinction from econometrics between structural equations and reduced-form equations [65] is helpful in understanding why different epidemiologists can estimate exposure concentration-response regression coefficients with opposite signs from the same data. The following highly simplified hypothetical example illustrates the key idea. Suppose that cumulative exposure to a chemical increases in direct proportion to age and that the risk of disease (e.g., the average number of illness episodes of a certain type per person per decade) also increases with age. Finally, suppose that the effect of exposure at any age is to decrease risk. These hypothesized causal relations are shown via the following two *structural equations*:

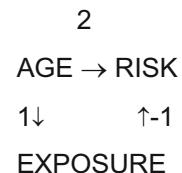

$$\text{EXPOSURE} = \text{AGE}$$

SEM equations

$$\text{RISK} = 2 * \text{AGE} - \text{EXPOSURE}.$$

These are equations with the explicit causal interpretation that a change in the variable on the right side causes a corresponding change in the variable on the left side to restore equality between the two sides (e.g., increasing age increases cumulative exposure and disease risk, but increasing exposure decreases risk at any age). These two structural equations together constitute a *structural equation model* (SEM) that can be diagrammed as in Fig. 43.1:

Fig. 43.1 SEM causal graph model

In this diagram, each variable depends causally only on the variables that point into it, as revealed by the SEM equations. The weights on the arrows (the coefficients in the SEM equations) show how the average value of the variable at the arrow's head will change if the variable at its tail is increased by one unit, for example, increasing AGE by 1 decade (if that is the relevant unit) increases RISK directly by 2 units (e.g., 2 expected illnesses per decade, if that is the relevant unit), increases EXPOSURE by one unit, and thereby decreases RISK indirectly by 1 unit, via the path through EXPOSURE, for a net effect of a 1 unit increase in RISK per unit increase in AGE.

By contrast to such causal SEM models, what is called a *reduced-form model* is obtained by regressing RISK against EXPOSURE. Using the first SEM equation, $\text{EXPOSURE} = 1\text{*AGE}$, to substitute EXPOSURE for AGE in the second SEM equation, $\text{RISK} = 2\text{*AGE} - \text{EXPOSURE}$, yields the following reduced-form equation:

$$\text{RISK} = \text{EXPOSURE}$$

Reduced-form equation

This reduced-form model is a valid *descriptive statistical* model: it reveals that in communities with higher exposure levels, risk should be expected to be greater. But it is not a valid *causal* model: a prediction that reducing exposure would cause a reduction in risk would be mistaken, as the SEM equations make clear. The reduced-form equation is not a structural equation, so it cannot be used to predict correctly how changing the right side would cause the left side to change. The coefficient of EXPOSURE in the linear regression model relating exposure to risk is +1 in the reduced-form model, but is -1 in the SEM model, showing how different investigators might reach opposite conclusions about the sign of “the” exposure-response coefficient based on whether or not they condition on age (or, equivalently, on whether they use structural or reduced-form regression equations).

In current epidemiological practice, the distinction between structural and reduced-form equations is often not clearly drawn. Regression coefficients of various signs and magnitudes, as well as various measures of association based on relative risk ratios, are all presented to policy makers as if they had valid causal interpretations and therefore important implications for risk management policy-making. In air pollution health effects epidemiology, for example, it is standard practice to present regression coefficients as expected reductions in elderly mortality rates (or as expected increases in life span) per unit reduction in air pollution concentrations [24, 28], thereby conflating associations between historical levels

(e.g., pollutant levels and mortality rates both tend to be higher on cold winter days than during the rest of the year, and both have declined in recent decades) with a causal, predictive relation that implies that future reductions in pollution would cause further future reductions in elderly mortality rates. Since such association-based studies are often unreliable indicators of causality [21] or simply irrelevant for determining causality, as in the examples for Fig. 43.1, policy makers who wish to use reliable causal relations to inform policy decisions must seek elsewhere.

These limitations of association-based methods have been well discussed among methodological specialists for decades [98]. Key lessons, such as that the same data set can yield either a statistically significant positive exposure-response regression coefficient or a statistically significant negative exposure-response regression coefficient, depending on the modeling choices made by the investigators, are becoming increasingly appreciated by practitioners [21]. They illustrate an important type of uncertainty that arises in epidemiology, but that is less familiar in many other applied statistical settings: *uncertainty about the interpretation of regression coefficients* (or other association-based measures such as RR, PAF, etc.) as indicating causal relations *vs.* confounded associations or modeling biases *vs.* some of each. This type of uncertainty cannot be addressed by presenting conventional statistical uncertainty measures such as confidence intervals, p-values, regression diagnostics, sensitivity analyses, or goodness-of-fit statistics, since the uncertainty is not about how well a model fits data or about the estimated parameters of the model. Rather, it is about the extent to which the model is only descriptive of the past *vs.* predictive of different futures caused by different choices. Although this is not an uncertainty to which conventional statistical tests apply, it is crucial for the practical purpose of making model-informed risk management decisions. Policy interventions will successfully increase the probabilities of desired outcomes and decrease the frequencies of undesired ones only to the extent that they act causally on drivers of the outcomes and not necessarily to the extent that the models used describe past associations.

One way to try to bridge the gap between association and causation is to ask selected experts what they think about whether or to what extent associations might be causal. However, research on the performance of expert judgments has called into question the reliability of expert judgments, specifically including judgments about causation [61]. Such judgments typically reflect qualitative “weight of evidence” (WoE) considerations about the strength, consistency (e.g., do multiple independent researchers find the claimed associations?), specificity, coherence (e.g., are associations of exposure with multiple health endpoints mutually consistent with each other and with the hypothesis of causality?) temporality (do hypothesized causes precede their hypothesized effects?), gradient (are larger exposures associated with larger risks?), and biological plausibility of statistical associations and the quality of the data sources and studies supporting them. One difficulty is that a strong confounder (such as age in Fig. 43.1) with delayed effects can create strong, consistent, specific, coherent, temporal associations between exposure and risk of an adverse response, with a clear gradient associating larger risks with larger exposures, without providing any evidence that exposure actually causes increased risk.

Showing that an association is strong, for example, does not address whether it is causal, although many WoE systems simply assume that the former supports the latter without explicitly addressing whether the strong associations are instead explained by strong confounding, strong biases, or strong modeling assumptions. Similarly, showing that different investigators find the same or similar association does not necessarily show whether this consistency results from shared modeling assumptions, biases, or confounders. Conflating causal and associational concepts, such as evidence for the strength of an association and evidence for causality of the association, too often makes assessments of causality in epidemiology untrustworthy compared to methods used in other fields, discussed subsequently [51, 83]. Most epidemiologists are trained to treat various aspects of association as evidence for causation, even though they are not, and this undermines the trustworthiness of expert judgments about causation based on WOE considerations [83].

In addition, experts are sometimes asked to judge the *probability* that an association is causal (e.g., [25]). This makes little sense. It neglects the fact that an association may be partly causal and partly due to confounding or modeling biases or coincident historical trends. For example, if exposure does increase risk, but is also confounded by age, then asking for the probability that the regression coefficient relating exposure to risk is causal overlooks the realistic possibility that it reflects both a causal component and a confounding component, so that the probability that it is partly causal might be 1 and the probability that it is completely causal might be 0. A more useful question to pose to experts might be what *fraction* of the association is causal, but this is seldom asked. Common noncausal sources of statistical associations include model selection and multiple testing biases, model specification errors, unmodeled errors in explanatory variables in multivariate models, biases due to data selection and coding (e.g., dichotomizing or categorizing continuous variables such as age, which can lead to residual confounding), and coincident historical trends, which can induce statistically significant-appearing associations between statistically independent random walks – a phenomenon sometimes dubbed as spurious regression [17, 98].

Finally, qualitative subjective judgments and ratings used in many WoE systems are subject to well-documented psychological biases. These include confirmation bias (seeing what one expects to see and discounting or ignoring evidence that might challenge one's preconceptions), motivated reasoning (finding what it benefits one to find and believing what it pays one to believe), and overconfidence (not sufficiently doubting, questioning, or testing one's own beliefs and hence not seeking potentially disconfirming information that might require those beliefs to be revised) [61, 102].

That statistical associations do not in general convey information sufficient for making valid causal predictions has been well understood for decades by statisticians and epidemiologists specializing in technical methods for causal analysis (e.g., [31, 36]). This understanding is gradually percolating through the larger epidemiological and risk analysis communities. Peer-reviewed published papers and reports, including those relied on in many regulatory risk assessments, still too often make the fundamental mistake of reinterpreting empirical exposure-response (ER)

relations between historical levels of exposure and response as if they were causal relations useful for predicting how future changes in exposures would change future responses. Fortunately, this confusion is unnecessary today: appropriate technical methods for causal analysis and modeling are now well developed, widely available in free software such as R or Python, and readily applicable to the same kinds of cross-sectional and longitudinal data collected for association-based studies. Table 43.1 summarizes some of the most useful study designs and methods for valid causal analysis and modeling of causal exposure-response relations.

Despite the foregoing limitations, there is much of potential value in several WoE considerations, especially consistency, specificity, and temporality of associations, especially if they are used as part of a relatively objective, quantitative, data-

Table 43.1 Some formal methods for modeling and testing causal hypotheses

Method and References	Basic Idea	Appropriate study design
Conditional independence tests [31, 32]	Is hypothesized effect (e.g., lung cancer) statistically independent of hypothesized cause (e.g., exposure to chemical), given values of other variables (e.g., education and income)? If so, this undermines causal interpretation.	Cross-sectional data Can also be applied to multi-period data (e.g., in dynamic Bayesian networks)
Panel data analysis [2, 109]	Are changes in exposures followed by changes in the effects that they are hypothesized to help cause? If not, this undermines causal interpretation; if so, this strengthens causal interpretation. Example: Are changes in exposure levels followed (but not preceded) by corresponding changes in mortality rates?	Panel data study: Collect a sequence of observations on same subjects or units over time
Granger causality test [23], transfer entropy [81, 91, 99, 118]	Does the history of the hypothesized cause improve ability to predict the future of the hypothesized effect? If so, this strengthens causal interpretation; otherwise, it undermines causal interpretation. Example: Can lung cancer mortality rates in different occupational groups be predicted better from time series histories of exposure levels and mortality rates than from the time series history of mortality rates alone?	Time series data on hypothesized causes and effects
Quasi-experimental design and analysis [12, 40, 41]	Can control groups and other comparisons refute alternative (noncausal) explanations for observed associations between hypothesized causes and effects? For example, can coincident trends and regression to the mean be refuted as possible explanations? If so, this strengthens causal interpretation.	Longitudinal observational data on subjects exposed and not exposed to interventions that change the hypothesized cause(s) of effects.

Table 43.1 (continued)

Method and References	Basic Idea	Appropriate study design
Intervention analysis, change-point analysis [45], Gilmour et al. 2006	<p>Does the best-fitting model of the observed data change significantly at or following the time of an intervention? If so, this strengthens causal interpretation.</p> <p>Do the quantitative changes in hypothesized causes predict and explain the subsequently observed quantitative changes in hypothesized effects? If so, this strengthens causal interpretation.</p> <p>Example: Did lung disease mortality rates fall significantly faster or sooner in workplaces that reduced exposures more or earlier than in workplaces that did not?</p>	<p>Time series observations on hypothesized effects and knowledge of timing of intervention(s)</p> <p>Quantitative time series data for hypothesized causes and effects</p>
Counterfactual and potential outcome models, including propensity scores and marginal structural models (MSMs) [82, 96]	Do exposed individuals have significantly different response probabilities than they would have had if they had not been exposed? Example: Do workers have lower mortality risk after historical exposure reductions than they would have had otherwise?	Cross-sectional and/or longitudinal data, with selection biases and feedback among variables allowed
Causal network models of change propagation [19, 39]	Do changes in exposures (or other causes) create a cascade of changes through a network of causal mechanisms (represented by equations), resulting in changes in the effect variables?	Observations of variables in a dynamic system out of equilibrium
Negative controls (for exposures or for effects) [73]	Do exposures predict health effects better than they predict effects that cannot be caused by exposures more (e.g., reductions in traumatic injuries)?	Observational studies

driven approach to inferring probable causation. The following sections discuss this possibility and show how such traditional qualitative WoE considerations can be fit into more formal quantitative causal analyses.

3 Event Detection and Consequence Prediction: What's New, and So What?

In public health and epidemiology, surveillance data showing changes in hospital or emergency department admission rates for a specific disease or symptom category may provide the first indication that an event has occurred that has caused changes in health outcomes. Initially, the causes of the changes may be uncertain, but if the date of a change can be estimated fairly precisely and matches the date of an event that might have caused the observed effects, then the event might have caused the change

in admissions rates. This causal hypothesis is strengthened if occurrences of the same or similar event in multiple times and places are followed by similar changes in admission rates (consistency and temporality of association) and if these changes in admissions rates do not occur except when the event occurs first (specificity of association). To make this inference sound, the event occurrences must not be triggered by high levels of admissions rates, since otherwise interventions that respond to these high rates might be followed by significant reductions in admission rates due solely to *regression to the mean*, i.e., the fact that exceptionally high levels are likely to be followed by lower levels, even if the interventions have no impact [12].

The technical methods used to estimate when admission rates or other effect have changed significantly, such as counts of accidents or injuries or fatalities per person per week in a population, include several different statistical anomaly-detection and change-point analysis (CPA) algorithms (e.g., [108]). The key idea of these algorithms is to determine whether, for each point in time (e.g., for each week in a surveillance time series), the series is significantly different (e.g., in distribution or trend) before that time point than after it. If so – if a time series jumps at a certain time – that time is called a change point.

3.1 Example: Finding Change Points in Surveillance Data

As an example of change-point detection in surveillance data, consider the following example. Since 2001, when a letter containing anthrax led to 5 deaths and 17 infections from which the victims recovered, the US Environmental Protection Agency (EPA), the Centers for Disease Control and Prevention (CDC), and the Department of Health Services have invested over a billion dollars to develop surveillance methods and prevention and preparedness measures to help reduce or mitigate the consequences of bioterrorism attacks should they occur again [38]. Detecting a significant upsurge in hospital admissions with similar symptoms may indicate that a bioterrorism attack is in progress. The statistical challenge of detecting such changes against the background of normal variability in hospital admissions has motivated the development of computational intelligence methods that seek to reduce the time to detect attacks when they occur, while keeping the rates of false positives acceptably small [11, 106].

Well-developed, sophisticated techniques of statistical uncertainty quantification are currently available for settings in which the patterns for which one is searching are well understood (e.g., a jump in hospitalization rates for patients with similar symptoms that could be caused by a biological agent) and in which enough surveillance data are available to quantify background rates and to monitor changes over time. Figure 43.2 presents a hypothetical example showing weekly counts of hospital admissions with specified symptoms in a certain city. Given such surveillance data, the risk assessment inference task is to determine whether the hospitalization rate increased at some point on time (suggestive of an attack) and, if so, when and by how much. Intuitively, it appears that counts are greater on the

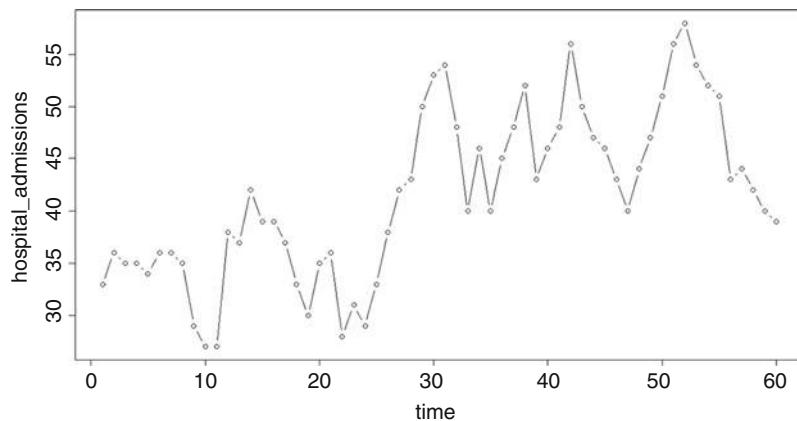

Fig. 43.2 Surveillance time series showing a possible increase in hospitalization rates

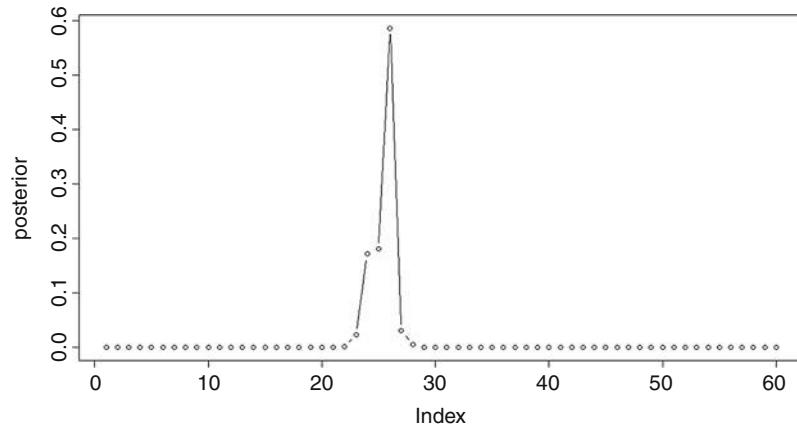

Fig. 43.3 Bayesian posterior distribution for the timing of the increase in Fig. 43.2 if one has occurred

right side of Fig. 43.2 than the left, but might this plausibly just be due to chance, or is it evidence for a real increase in hospitalization rates?

Figure 43.3 illustrates a typical result of current statistical technology (also used in computational intelligence, computational Bayesian, machine learning, pattern recognition, and data mining technologies) for solving such problems by using statistical evidence, together with risk models, to draw inferences about what is probably happening in the real world. The main idea is simple: the highest points indicate the times that are computed to be most likely for when a change in hospitalization rate occurred, based on the data in Fig. 43.2. (Technically, Fig. 43.3 plots the likelihood function of the data, assuming that at most one jump from one level to a different level has occurred for the hospitalization rate. The

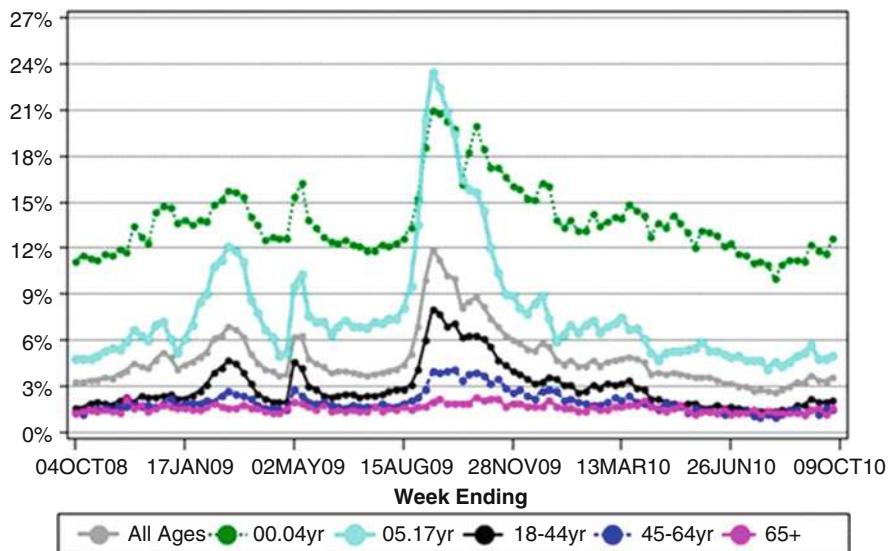

Fig. 43.4 Proportion of emergency department visits for influenza-like illness by age group for October 4, 2008–October 9, 2010, in a US Department of Health and Human Services region (Source: [62], <http://jamia.oxfordjournals.org/content/19/6/1075.long>)

likelihoods are rescaled so that their sum for all 60 weeks is 1, so that they can be interpreted as posterior probabilities if the prior is assumed to be uniform. More sophisticated algorithms are discussed next.) The maximum likelihood-based algorithm accurately identifies both the time of the change (week 25) and the magnitude of its effect to one significant decimal place (not shown in Fig. 43.3). The spread of the likelihood function (or posterior probability distribution) around the most likely value in Fig. 43.3 also shows how precise is the estimation of the change-point time.

Figure 43.4 shows a real-world example of a change point and its consequences for emergency department visits over time. Admissions for flu-like symptoms, especially among infants and children (0–4 and 5–17 year olds), increased sharply in August and declined gradually in each age group thereafter. Being able to identify the jump quickly and then applying a predictive model – such as a stochastic compartmental transition model with susceptible, infected, and recovered subpopulations (SIR model) for each age group – to predict the time course of the disease in the population can help forecast the care resources that will be needed over time for each age group.

More generally, detecting change points can be accomplished by testing the null hypothesis of no change for each time step and correcting for multiple testing bias (which would otherwise inflate false-positive rates, since testing the null hypothesis for each of the many different possible times at which a change might have occurred multiplies the occasions on which an apparently significant change occurs

by chance). Many CPA algorithms use likelihood-based Bayesian methods, as in Fig. 43.3, to identify when a change is most likely to have occurred and whether the hypothesis that it did provides a significantly better explanation (higher likelihood) for the observed data than the null hypothesis of no change. Likelihood-based techniques are fundamental for a wide variety of statistical detection and estimation algorithms. Practitioners can use free, high-quality algorithms available in the R statistical computing environment (e.g., <http://surveillance.r-forge.r-project.org/>; [57]), Python, and other statistics programs and packages to perform CPA analyses.

Algorithms for change-point detection have recently been extended to allow detection of multiple change points within multivariate time series, i.e., in time series containing observations of multiple variables instead of only one [57]. These new algorithms use nonparametric tests (e.g., permutation tests) to determine whether the distributions of the observations before and after the change point differ significantly, even if neither distribution is known, and hence no parametric statistical model can be specified [57]. The development of powerful nonparametric (“model-free”) methods for testing the null hypothesis of no change in the (unknown) distribution enables CPA that is much more robust to uncertainties in modeling assumptions than was possible previously. Assumptions that remain, such as that observations following a change point are drawn from a new distribution, independently of the observations preceding the change point, are statistically testable and weaker than the assumptions (such as approximately normally distributed observations) made in older CPA work.

The use of CPA to search for significant changes in surveillance time series, showing that the number of undesirable events per person per week in a population underwent significant changes at certain times, has allowed the probable causes of observed changes in health and safety to be identified in many applications, providing evidence for or against important causal relations between public policy measures and resulting health and safety effects. For example,

- Nakahara et al. [85] used CPA to assess the impact on vehicle crash fatalities of a program initiated in Japan in 2002 that severely penalized drunk driving. Fatality rates between 2002 and 2006 (the end of the available data series) were significantly lower than between 1995 and 2002. However, the CPA revealed that the change point occurred around the end of 1999, right after a high-profile vehicle fatality that was much discussed in the news. The authors concluded that changes in drunk-driving behavior occurred well before the new penalties were instituted.
- In Finland in 1981–1986, a nationwide oral poliovirus vaccine campaign was closely followed by, and partly overlapped with, a significant increase in the incidence of Guillain-Barré syndrome (GBS). This temporal association raised the important question of whether something about the vaccine might have caused some or all of the increase in GBS. Kinnunen et al. [63] applied CPA to medical records from a nationwide Hospital Discharge Register database. They found that a change point in the occurrence of GBS had probably already taken place before the oral poliovirus vaccine campaign started. They concluded that

there was a temporal association between poliovirus infection and increased occurrence of GBS, but no proof of the suspected causal relation between oral poliovirus vaccines and risk of GBS. This example shows how a precise investigation of the details of temporal associations can both refute some causal hypotheses and suggest others – in this case, that an increase in polio in the population was a common cause of both increased GBS risk and the provision of the vaccine. It also illustrates why a temporal association between an adverse effect and a suspected cause, such as the fact that administration of vaccines preceded increases in GBS risk, should not necessarily be interpreted as providing evidence to support the hypothesis of a causal relation between them.

4 Causal Analytics: Determining Whether a Specific Exposure Harms Human Health

Table 43.2 lists seven principles that have proved useful in various fields for determining whether available data provide valid evidence that some events or conditions cause others. They can be applied to epidemiological data to help determine whether and how much exposures to a hazard contribute causally to subsequent risks of adverse health outcomes in a population, in the sense that reducing exposure would reduce risk – for example, whether and by how much a given reduction in air pollution would reduce cardiovascular mortality rates among the elderly, whether and by how much reducing exposure to television violence in childhood would reduce propensity for violent behavior years later, or whether decreasing high-fat or high-sugar diets in youth would reduce risks

Table 43.2 Principles of causal analytics

1. **Conditional independence principle:** Causes and effects are informative about each other. Technically, there should be positive mutual information (measured in bits and quantified by statistical methods of information theory) between the random variables representing a cause and its effect. This positive mutual information cannot be removed by conditioning on the levels of other variables.
 2. **Granger principle:** Changes in causes should precede, and help to predict and explain, changes in the effects that they cause.
 3. **Transfer entropy principle:** Information flows from causes to their effects over time.
 4. **Counterfactual principle:** Changes in causes make future effects different from what they otherwise would have been.
 5. **Causal graph principle:** Changes in causes produce changes in effects by propagation via one or more paths (sequences of causal mechanisms) connecting them.
 6. **Mechanism principle:** Valid causal mechanisms are lawlike, yielding identically distributed outputs when the inputs are the same.
 7. **Quasi-experiment principle:** Valid causal relations produce differences (e.g., compared to relevant comparison groups) that cannot be explained away by noncausal explanations.
-

of heart attacks in old age. The following sections explain and illustrate these principles and introduce technical methods for applying them to data. They also address the fundamental questions of how to model causal responses to exposure and other factors, how to decide what to do to reduce risk, how to determine how well interventions have succeeded in reducing risks, and how to characterize uncertainties about the answers to these questions.

5 Causes and Effects Are Informative About Each Other: DAG Models, Conditional Independence Tests, and Classification and Regression Tree Algorithms

A key principle for causal analytics is that causes and their effects provide information about each other. If exposure is a cause of increased disease risk, then measures of exposure and of response (i.e., disease risk) should provide *mutual information* about each other, in the sense that the conditional probability distribution for each varies with the value of the other. Software for determining whether this is the case for two variables in a data set is discussed at the end of this section. In addition, if exposures are direct causes of responses, then the mutual information between them cannot be eliminated by conditioning on the values of other variables, such as confounders: a cause provides unique information about its effects. This provides the basis for using statistical *conditional independence tests* to test the observable statistical implications of causal hypotheses: *An effect should never be conditionally independent of its direct causes, given (i.e., conditioned on) the values of other variables.*

As a simple example, if both air pollution and elderly mortality rates are elevated on cold winter days, then if air pollution is a cause of increased elderly mortality rate, the mutual information between air pollution and elderly mortality rates should not be eliminated (“explained away”) by temperature, even though temperature may be associated with each of them. If both temperature and air pollution contribute to increased mortality rates (indicated in causal graph notation as $temperature \rightarrow mortality_rate \leftarrow pollution$), then conditioning on the level of temperature will not eliminate the mutual information between pollution and mortality rate. On the other hand, if the correct causal model were that temperature is a confounder that explains both mortality rate and pollution (e.g., because coal-fired power plants produce more pollution during days with extremely hot and cold weather, and, independently, these temperature extremes lead to greater elderly mortality), diagrammed as $mortality_rate \leftarrow temperature \rightarrow pollution$, then conditioning on the level of temperature would eliminate the mutual information between pollution and mortality rate. Thus, tests that reveal conditional independence relations among variables can also help to discriminate among alternative causal hypotheses.

The notation in these graphs is as follows. Each node in the graph (such as *temperature*, *pollution*, or *mortality_rate* in the preceding example) represents a random variable. Arrows between nodes reveal statistical dependencies (and,

implicitly, conditional independence relations) among the variables. The arrows are usually constrained to form a directed acyclic graph (DAG), meaning that no node can be its own predecessor in the partial ordering of nodes determined by the arrows. The probability distribution of each variable with inward-pointing arrows depends on the values of the variables that point into it, i.e., the conditional probability distribution for the variable at the head of an arrow is affected by the values of its direct “parents” (the variables that point into it) in the causal graph. Conversely, a random variable represented by a node is conditionally independent of all other variables, given the values of the variables that point into it (its parents in the DAG), the values of the variables into which it points (its children), and the values of any other parents of its children (its spouses) – a set of nodes collectively called its Markov blanket in the DAG model.

To illustrate these ideas, suppose that X causes Y and Y causes Z , as indicated by the DAG and $X \rightarrow Y \rightarrow Z$, where X is an exposure-related variable (e.g., job category for an occupational risk or location of a residence for a public health risk), Y is a measure of individual exposure, and Z is an indicator of adverse health response. Then even though each variable is statistically associated with the other two, Z is conditionally independent of X given the value of Y . But Z cannot be made conditionally independent of Y by conditioning on X . One way to test for such conditional independence relations in data is with classification and regression tree algorithms (see, e.g., <https://cran.r-project.org/web/packages/rpart/rpart.pdf> for a free R package and documentation). In this example, a tree for Z would not contain X after splitting on values of Y , reflecting the fact that Z is conditionally independent of X given Y . However, a tree for Z would always contain Y , provided that the data set is large and diverse enough so that the tree-growing algorithm can detect the mutual information between them.

For practitioners, algorithms are now freely available in R, Python, and Google software packages to estimate mutual information, the conditional entropy reduction in one variable when another is observed, and related measures for quantifying how many bits of information observations of one variable provide about another and whether one variable is conditionally independent of another given the values of other variables ([74]; Ince et al. 2009). For example, free R software and documentation for performing these calculations can be found at the following sites:

<https://cran.r-project.org/web/packages/entropy/entropy.pdf>

<https://cran.r-project.org/web/packages/partykit/vignettes/partykit.pdf>.

6 Changes in Causes Should Precede, and Help to Predict and Explain, Changes in the Effects that They Cause

If changes in exposures always precede and help to predict and explain subsequent corresponding changes in health effects, this is consistent with the hypothesis that exposures cause health effects. The following methods and algorithms support formal testing of this hypothesis.

6.1 Change-Point Analysis Can Be Used to Determine Temporal Order

The change-point analysis (CPA) algorithms already discussed can be used to estimate when changes in effects time series occurred. These times can then be compared to the times at which exposures changed (e.g., due to passage of a regulation or to introduction or removal of a pollution source) to determine whether changes in exposures are followed by changes in effects. For example, many papers have noted that bans on public smoking have been followed by significant reductions in risks of heart attacks (acute myocardial infarctions). However, Christensen et al. [14], in a study of the effects of a Danish smoking ban on hospital admissions for acute myocardial infarctions, found that a significant reduction in admissions was already occurring a year *before* the bans started. Thus, the conclusion that bans caused the admissions reductions may be oversimplified. The authors suggest that perhaps some of the decline in heart attack risk could have been caused by earlier improvements in diets or by gradual enactment of smoking bans. Whatever the explanation, checking when reductions began, rather than only whether post-intervention risks are smaller than pre-intervention risks, adds valuable insight to inform potential causal interpretations of the data.

6.2 Intervention Analysis Estimates Effects of Changes Occurring at Known Times, Enabling Retrospective Evaluation of the Effectiveness of Interventions

How much difference exposure reductions or other actions have made in reducing adverse health outcomes or producing other desired outcomes is often addressed using *intervention analysis*, also called *interrupted time series* analysis. The basic idea is to test whether the best description of an effects time series changes significantly when a risk factor or exposure changes, e.g., due to an intervention that increases or reduces it [47, 48, 68]. If the answer is yes, then the size of the changeover time provides quantitative estimates of the sizes and timing of changes in effects following an intervention. For example, an intervention analysis might test whether weekly counts of hospital admissions with a certain set of diagnostic codes or cardiovascular mortalities per person per year among people over 70 fell significantly when exposures fell due to closure of a plant that generated high levels of air pollution. If so, then comparing the best-fitting time series models (e.g., the maximum-likelihood models within a broad class of models, such as the autoregressive integrated moving average (ARIMA) models widely used in time series analysis) describing the data before and after the date of the intervention may help to quantify the size of the effect associated with the intervention. If not, then the interrupted time series does not provide evidence of a detectable effect of the intervention. Free software for intervention analysis is available in R (e.g., [80]; CausalImpact algorithm from Google 2015).

Two main methods of intervention analysis are *segmented regression*, which fits regression lines or curves to the effects time series before and after the intervention and then compares them to detect significant changes in slope or level, and *Box-Tiao analysis*, often called simply intervention analysis, which fits time series models (ARIMA or Box-Jenkins models with models of intervention effects, e.g., jumps in the level, changes in the slope, or ramp-ups or declines in the effects over time) to the effects data before and after the intervention and tests whether proposed effects of interventions are significantly different from zero. If so, the parameters of the intervention effect are estimated from the combined pre- and post-intervention data (e.g., [47, 48]). For effects time series that are stationary (meaning that the same statistical description of the time series holds over time) both before and after an intervention that changes exposure, but that have a jump in mean level due to the intervention, quantifying the difference in effects that the intervention has made can be as simple as estimating the difference in means for the effects time series before and after the intervention, similar to the CPA in Fig. 43.2, but for a known change point. The top panel of Fig. 43.5 shows a similar comparison for heart attack rates before and after a smoking ban. Based only on the lines shown, it appears that

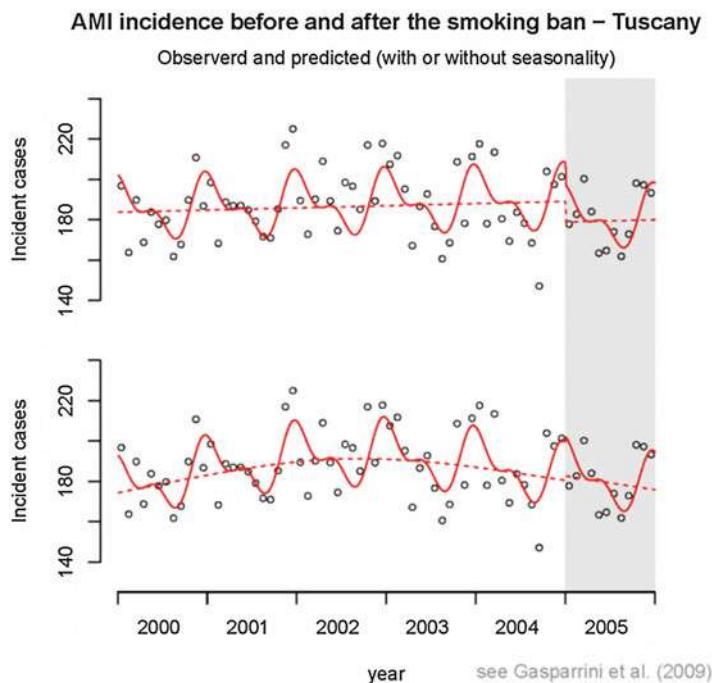

Fig. 43.5 Straight-line extrapolation of the historical trend for heart attack (AMI) rates over-predicts future AMI rates (upper panel) and creates the illusion that smoking bans were followed by reduced AMI rates, compared to more realistic nonlinear extrapolation (lower panel), which shows no detectable benefit from a smoking ban (Source: [33])

heart attack rates dropped following the ban. (If the effects of a change in exposure occur gradually, then distributed-lag models of the intervention's effects can be used to describe the post-intervention observations [47].) In nonstationary time series, however, the effect of the intervention may be obscured by other changes in the time series. Thus, the bottom panel of Fig. 43.5 considers nonlinear trends over time and shows that, in this analysis, any effect of the ban now appears to be negative (i.e., heart attack rates are increased after the ban compared to what is expected based on the nonlinear trend extrapolated from pre-ban data).

Intervention analyses, together with comparisons to time series for comparison populations not affected by the interventions, have been widely applied, with varying degrees of justification and success, to evaluate the impacts caused by changes in programs and policies in healthcare, social statistics, economics, and epidemiology. For example, Lu et al. [75] found that prior authorization policies introduced in Maine to help control the costs of antipsychotic drug treatments for Medicaid and Medicare Part D patients with bipolar disorder were associated with an unintended but dramatic (nearly one third) reduction in initiation of medication regimens among new bipolar patients, but produced no detectable switching of currently medicated patients toward less expensive treatments. Morriss et al. [84] found that the time series of suicides in a district population did not change significantly following a district-wide training program that measurably improved the skills, attitudes, and confidence of primary care, accident and emergency, and mental health workers who received the training. They concluded that “Brief educational interventions to improve the assessment and management of suicide for front-line health professionals in contact with suicidal patients may not be sufficient to reduce the population suicide rate.” [55] used intervention analysis to estimate that the introduction of pedestrian countdown timers in Detroit cut pedestrian crashes by about two thirds. Jiang et al. [59] applied intervention analysis to conclude that, in four Australian states, the introduction of randomized breath testing led to a substantial reduction in car accident fatalities. Callaghan et al. [10] used a variant of intervention analysis, regression-discontinuity analysis, to test whether the best-fitting regression model describing mortality rates among young people changed significantly at the minimum legal drinking age, which was 18 in some provinces and 19 in others. They found that mortality rates for young men jumped upward significantly precisely at the minimum legal drinking, which enabled them to quantify the impact of drinking-age laws on mortality rates. In these and many other applications, intervention analysis and comparison groups have been used to produce empirical evidence for what has worked and what has not and to quantify the sizes over time of effects attributed to interventions when these effects are significantly different from zero.

Intervention analysis has important limitations, however. Even if an intervention analysis shows that an effects time series changed when an intervention occurred, this does not show whether the intervention *caused* the change. Thus, in applications from air pollution bans to gun control, initial reports that policy interventions had significant beneficial effects were later refuted by findings that equal or greater beneficial changes occurred at the same time in comparison populations not affected

by the interventions [44, 64]. Also, more sophisticated methods such as transfer entropy, discussed later, must be used to test and estimate effects in nonstationary time series, since both segmented regression models and intervention analyses that assume stationarity typically produce spurious results for nonstationary time series. For example, as illustrated in Fig. 43.5, Gasparrini et al. [33] in Europe and Barr et al. [8] in the United States found that straight-line projections of what future heart attack (acute myocardial infarction, AMI) rates would have been in the absence of an intervention that banned smoking in public places led to a conclusion that smoking bans were associated with a significant reduction in AMI hospital admission rates following the bans. However, allowing for nonlinearity in the trend, which was significantly more consistent with the data, led to the reverse conclusion that the bans had no detectable impact on reducing AMI admission rates. As illustrated in Fig. 43.5, the reason is that fitting a straight line to historical data and using it to project future AMI rates in the absence of intervention tend to overestimate what those future AMI rates would have been, because the real time series is downward-curving, not straight. Thus, estimates of the effect of an intervention based on comparing observed to model-predicted AMI admission rates will falsely attribute a positive effect even to an intervention that had no effect if straight-line extrapolation is used to project what would have happened in the absence of an intervention, ignoring the downward curvature in the time series. This example illustrates how model specification errors can lead to false inferences about effects of interventions. The transfer entropy techniques discussed later avoid the need for curve-fitting and thereby the risks of such model specification errors.

6.3 Granger Causality Tests Show Whether Changes in Hypothesized Causes Help to Predict Subsequent Changes in Hypothesized Effects

Often, the hypothesized cause (e.g., exposure) and effect (e.g., disease rate) time series both undergo continual changes over time, instead of changing only once or occasionally. For example, pollution levels and hospital admission rates for respiratory or cardiovascular ailments change daily. In such settings of ongoing changes in both hypothesized cause and effect time series, *Granger causality tests* (and the closely related Granger-Sims tests for pairs of time series) address the question of whether the former helps to predict the latter. If not, then the exposure-response histories provide no evidence that exposure is a (Granger) cause of the effects time series, no matter how strong, consistent, etc., the association between their levels over time may be. More generally, a time series variable X is not a Granger cause of a time series variable Y if the future of Y is conditionally independent of the history of X (its past and present values), given the history of Y itself, so that future Y values can be predicted as well from the history of Y values as from the histories of both X and Y . If exposure is a Granger cause of health effects but health effects are not Granger causes of exposures, then this provides evidence that the exposure time series might indeed be a cause of the effects time

series. If exposure and effects are Granger causes of each other, then a confounder that causes both of them is likely to be present. The key idea of Granger causality testing is to provide formal quantitative statistical tests of whether the available data suffice to reject (at a stated level of significance) the null hypothesis that the future of the hypothesized effect time series can be predicted no better from the history of the hypothesized cause time series together with the history of the effect time series than it can be predicted from the history of the effect time series alone. Data that do not enable this null hypothesis to be rejected do not support the alternative hypothesis that the hypothesized cause helps to predict (i.e., is a Granger cause of) the hypothesized effect.

Granger causality tests can be applied to time series on different time scales to study effects of time-varying risk factors. For example, [76] identified a Granger-causal association between fatty diet and risk of heart disease decades later in aggregate (national level) data. Cox and Popken [16] found a statistically significant historical association, but no evidence of Granger causation, between ozone exposures and elderly mortality rates on a time scale of years. Granger causality testing software is freely available in R (e.g., <http://cran.r-project.org/web/packages/MSBVAR/MSBVAR.pdf>).

Originally Granger causality tests were restricted to stationary linear (autoregressive) time series models and to only two time series, a hypothesized cause and a hypothesized effect. However, recent advances have generalized them to multiple time series (e.g., using vector autoregressive (VAR) time series models) and to nonlinear time series models (e.g., using nonparametric versions of the test or parametric models that allow for multiplicative as well as additive interactions among the different time series variables) ([6, 7, 111, 122]; Diks and Wolski 2014). These advances are now being made available in statistical toolboxes for practitioners ([7]). For nonstationary time series, special techniques have been developed, such as vector error-correction (VECM) models fit to first differences of nonstationary variables or algorithms that search for co-integrated series (i.e., series whose weighted averages show zero mean drift). However, these techniques are typically quite sensitive to model specification errors [91]. Transfer entropy (TE) and its generalizations, discussed next, provides a more robust analytic framework for identifying causality from multiple nonstationary time series based on the flow of information among them.

7 Information Flows From Causes to Their Effects over Time: Transfer Entropy

Both Granger causality tests and conditional independence tests apply the principle that causes should be informative about their effects; more specifically, changes in direct causes provide information that helps to predict subsequent changes in effects. This information is not redundant with the information from other variables and cannot be explained away by knowledge of (i.e., by conditioning on the values of) other variables. A substantial generalization and improvement of this information-

based insight is that information flows over time from causes to their effects, but not in the reverse direction. Thus, instead of just testing whether past and present exposures provide information about (and hence help to predict) future health effects, it is possible to quantify the rate at which information, measured in bits, flows from the past and present values of the exposure time series to the future values of the effects time series. This is the key concept of *transfer entropy* (TE) [81, 91, 99, 118]). It provides a nonparametric, or model-free, way to detect and quantify rates of information flow among multiple variables and hence to infer causal relations among them based on the flow of information from changes in causal variables (“drivers”) to subsequent changes in the effect variables that they cause (“responses”). If there is no such information flow, then there is no evidence of causality.

Transfer entropy (TE) is model-free in that it examines the empirically estimated conditional probabilities of values for one time series, given previous values of others, without requiring any parametric models describing the various time series. Like Granger causality, TE was originally developed for only two time series, a possible cause and a possible effect, but has subsequently been generalized to multiple time series with information flowing among them over time (e.g., [81, 91, 99]). In the special case where the exposure and response time series can be described by linear autoregressive (AR) processes with multivariate normal error terms, tests for TE flowing from exposure to response are equivalent to Granger causality tests (Barnett et al. 2009), and Granger tests, in turn, are equivalent to conditional independence tests for whether the future of the response series is conditionally independent of the history of the exposure series, given the history of the response series. Free software packages for computing the TE between or among multiple time series variables are now available for MATLAB [81] and other software (<http://code.google.com/p/transfer-entropy-toolbox/downloads/list>). Although transfer entropy and closely related information-theoretic quantities have been developed and applied primarily within physics and neuroscience to quantify flows of information and appropriately defined causal influences [58] among time series variables, they are likely to become more widely applied in epidemiology as their many advantages become more widely recognized.

8 Changes in Causes Make Future Effects Different From What They Otherwise Would Have Been: Potential-Outcome and Counterfactual Analyses

The insight that changes in causes produce changes in their effects, making the probability distributions for effect variables different from what they otherwise would have been, has contributed to a well-developed field of *counterfactual (potential-outcome) causal modeling* [51]. A common analytic technique in this field is to treat the unobserved outcomes that would have occurred had causes (e.g., exposures or treatments) been different as missing data and then to apply missing-data methods for regression models to estimate the average difference

in outcomes for individuals receiving different treatments or other causes. The estimated difference in responses for treated compared to untreated individuals, for example, can be defined as a measure of the impact caused by treatment at the population level.

To accomplish such counterfactual estimation in situations where randomized assignments of treatments or exposures to individuals is not possible, counterfactual models and methods such as *propensity score matching* (PSM) and *marginal structural models* (MSMs) [96] construct weighted samples that attempt to make the estimated distribution of measured confounders the same as it would have been in a randomized control trial. If this attempt is successful, and if the individuals receiving different treatments or exposures are otherwise statistically identical (more precisely, *exchangeable*), then any significant differences between the responses of subpopulations receiving different treatments or exposures (or other combinations of causes) might be attributed to the differences in these causes, rather than to differences in the distributions of measured confounders [18, 96]. However, this attribution is valid only if the individuals receiving different treatments or exposures are exchangeable – a crucial assumption that is typically neither tested nor easily testable. If treated and untreated individuals differ on unmeasured confounders, for example, then counterfactual methods such as PSM or MSM may produce mistaken estimates of causal impacts of treatment or exposure. Differing propensities to seek or avoid treatment or exposure based in part on unmeasured differences in individual health status could create biased estimates of the impacts of treatment or exposure on subsequent health risks. In general, counterfactual methods for estimating causal impacts of exposures or treatments on health risks make assumptions that imply that estimated differences in health risks between different exposure or treatment groups are caused by differences in the exposures or treatments. The validity of these assumptions is usually unproved. In effect, counterfactual methods assume (rather than establishing) the key conclusion that differences in health risks are caused by differences in treatments or exposures, rather than by differences in unmeasured confounders or by other violations of the counterfactual modeling assumptions.

In marginal structural models (MSMs), the most commonly used sample-weighting techniques (called inverse probability weighting (IPW), as well as refined versions that seek to stabilize the variance of the weights) can be applied at multiple time points to populations for which exposures or treatments, confounders, and individuals entering or leaving the populations are all time-varying. This flexibility, together with emphasis on counterfactuals and missing observations, make MSMs particularly well suited to the analysis of time-varying confounders and effects of treatments or interventions that involve feedback loops, such as when the treatment that a patient receives depends on his or her responses so far and also to analysis of data in which imperfect compliance, attrition from the sample, or other practical difficulties drive a wedge between what was intended and what actually occurred in the treatment and follow-up of patients [96]. For example, MSMs are often applied to *intent-to-treat* data, in which the intent or plan to treat patients in a certain way is taken as the controllable causal driver of outcomes, and what happens next may depend in part on real-world uncertainties.

Despite their advantages in being able in principle to quantify causal impacts in complex time-varying data sets, MSMs have some strong practical limitations. Their results are typically very sensitive to errors in the specification of the regression models used to estimate unobserved counterfactual values, and the correct model specification is usually unknown. Therefore, MSMs are increasingly being used in conjunction with *model ensemble* techniques to address model uncertainty. Model ensemble methods (including Bayesian model averaging, various forms of statistical boosting, k-fold cross-validation techniques, and super-learning, as described next) calculate results using many different models and then combine the results. The use of diverse plausible models avoids the false certainty and potential biases created by selecting a single model. For example, in *super-learning algorithms*, no single regression model is selected. Instead multiple different standard machine-learning algorithms (e.g., logistic regression, random forest, support vector machine, naïve Bayesian classifier, artificial neural network, etc.) are used to predict unobserved values [86] and to estimate IPW weights [37]. These diverse predictions are then combined via weighted averaging, where the weights reflect how well each algorithm predicts known values that have been deliberately excluded (held out for test purposes) from the data supplied to the algorithms – the computational statistical technique known as model cross validation. Applied to the practical problem of estimating the mortality hazard ratio for initiation versus no initiation of combined antiretroviral therapy among HIV-positive subjects, such ensemble learning algorithms produced clearer effects estimates (hazard ratios further below 1, indicating a beneficial effect of the therapy) and narrower confidence intervals than traditional single-model (logistic regression modeling) analysis (*ibid*).

Yet even these advances do not overcome the fact that MSMs requires strong, and often unverifiable, assumptions to yield valid estimates of causal impacts. Typical examples of such assumptions are that there are no unmeasured confounders, that the observed response of each individual (e.g., of each patient to treatment or nontreatment) is in fact caused by the observed risk factors, and that every value for the causal variables occurs for every combination of levels of the confounding variables (e.g., there is no time period before exposures began but confounders were present) [18]. Assuming that these conditions hold may lead to an unwarranted inference that a certain exposure causes an adverse health effect, e.g., that ozone air pollution causes increased asthma-related hospitalizations, even if analyses based only on realistic, empirically verifiable assumptions would reveal no such causal relation [82].

Counterfactual models are often used to assess the effects on health outcomes of medical treatments, environmental exposures, or preventable risk factors by comparing what happened to people who receive the treatments to what models predict would have happened without the treatments. However, a limitation of such counterfactual comparisons is that they are seldom explicit about *why* treatments would not have occurred in the counterfactual world envisioned. Yet, the answer can crucially affect the comparison being drawn [35, 46]. For example, if it is assumed that a patient would not have received a treatment because the physician is confident that it would not have worked and the patient would have died anyway,

then the estimated effect of the treatment on mortality rates might be very different from what it would be if it is assumed that the patient would not have received the treatment because the physician is confident that there is no need for it and that the patient would recover anyway. In practice, counterfactual comparisons usually do not specify in detail the causal mechanisms behind the counterfactual assumptions about treatments or exposures, and this can obscure the precise interpretation of any comparison between what did happen and what is supposed, counterfactually, would have happened had treatments (or exposure) been different. Standard approaches estimate effects under the assumption that those who are treated or exposed are exchangeable with those who are not within strata of adjustment factors that may affect (but are not affected by) the treatment or the outcome, but the validity of this assumption is usually difficult or impossible to prove.

An alternative, increasingly popular, approach to using untested assumptions to justify causal conclusions is the *instrumental variable* (IV) method, originally developed in econometrics [112]. In this approach, an *instrument* is defined as a variable that is associated with the treatment or exposure of interest – a condition that is usually easily verifiable – and that also affects outcomes (e.g., adverse health effects) only through the treatment or exposure variable, without sharing any causes with the outcome. (In DAG notation, such an instrument would be a variable with arrows directed only into Y and Z in the DAG model $X \rightarrow Y \rightarrow Z$, where Z is the outcome variable, Y the treatment or exposure variable, and X a variable that affects exposure, such as job category, residential location, or intent-to-treat.) These latter conditions are typically assumed in IV analyses, but not tested or verified. If they hold, then the effects of unmeasured confounders on the estimated association between Y and Z can be eliminated using observed values of the instrument, and this is the potential great advantage of IV analysis. However, in practice, IV methods applied in epidemiology are usually dangerously misleading, as even minor violations of their untested assumptions can lead to substantial errors and biases in estimates of the effects of different exposures or treatments on outcomes; thus, many methodologists consider it inadvisable to use IV methods to support causal conclusions in epidemiology, despite their wide and increasing popularity for this purpose [112]. Unfortunately, within important application domains in epidemiology, including air pollution health effects research, leading investigators sometimes draw strong but unwarranted causal conclusions using IV or counterfactual (PSM or MSM) methods and then present these dubious causal conclusions and effects estimates to policy-makers and the public as if they were known to be almost certainly correct, rather than depending crucially on untested assumptions of unknown validity (e.g., [104]). Such practices lead to important-seeming journal articles and policy recommendations that are untrustworthy, potentially reflecting the ideological biases or personal convictions of the investigator rather than true discoveries about real-world causal impacts of exposures [103]. Other scientists and policy makers are well advised to remain on guard against such enthusiastic claims about causal impacts and effects estimates promoted by practitioners of IV and counterfactual methods who do not appropriately caveat their conclusions by emphasizing their dependence on untested modeling assumptions.

When the required assumptions for counterfactual modeling cannot be confidently determined to hold, other options are needed for counterfactual analyses to proceed. The simplest and most compelling approach is to use genuine randomized control trials (RCTs), if circumstances permit it. They rarely do, but the exceptions can be very valuable. For example, the state of Oregon in 2008 used a lottery system to expand limited Medicaid coverage for the uninsured by randomly selecting names from a waiting list. Comparing subsequent emergency department use among the randomly selected new Medicaid recipients to subsequent use by those still on the waiting list who had not yet received Medicaid revealed a 40% increase in emergency department usage over the next 18 months among the new Medicaid recipients, including visits for conditions that might better have been treated in primary care physician settings. Because the selection of recipients was random, this increase in usage could be confidently attributed to a causal effect of the Medicaid coverage on increasing emergency department use [114]. The main limitation of such RCTs is not in establishing the existence and magnitude of genuine causal impacts of an intervention in the studied population but rather in determining to what extent the result can be generalized to other populations. While conclusions based on valid causal laws and mechanisms can be transported across contexts, as discussed later, this is not necessarily true of aggregate population-level causal impacts, which may depend on specific circumstances of the studied population.

In the more usual case where random assignment is not an option, use of non-randomized control groups can still be very informative for testing, and potentially refuting, assumptions about causation. Indeed, analyses that estimate the impacts of changes in exposures by comparing population responses before and after an intervention that changes exposure levels can easily be misled unless appropriate comparison groups are used. For example, a study that found a significant drop in mortality rates from the six years prior to a coal burning ban in Dublin county, Ireland, to the six years following the ban concluded that the ban had caused a prompt, significant fall in all-cause and cardiovascular mortality rates [42]. This finding eventually led officials to extend the bans to protect human health. However, such a pre-post comparison study design cannot support a logically valid inference of causality, since it pays no attention to what would have happened to mortality rates in the absence of an intervention, i.e., the coal-burning ban. When changes in all-cause and cardiovascular mortality rates outside the ban area were later compared to those in areas affected by the ban, it turned out that there was no detectable difference between them: contrary to the initial causal inference, the bans appeared to have had no detectable impact on reducing these rates [44]. Instead, the bans took place during a decades-long period over which mortality rates were decreasing, with or without bans, throughout much of Europe and other parts of the developed world, largely due to improvements in early detection, prevention, and treatment of cardiovascular risks. In short, what would have happened in the absence of an intervention can sometimes be revealed by studying what actually did happen in appropriate comparison or control groups – a key idea developed and applied in the field of quasi-experimental (QE) studies, discussed next. Counterfactual causal inferences drawn without such comparisons can easily be misled.

9 Valid Causal Relations Cannot Be Explained Away by Noncausal Explanations

An older, but still useful, approach to causal inference from observational data, developed largely in the 1960s and 1970s, consists of showing that there is an association between exposure and response that cannot plausibly be explained by confounding, biases (including model and data selection biases and specification errors), or coincidence (e.g., from historical trends in exposure and response that move together but that do not reflect causation). *Quasi-experiment* (QE) design and analysis approaches originally developed in social statistics [12] systematically enumerate potential alternative explanations for observed associations (e.g., coincident historical trends, regression to the mean, population selection, and response biases) and provide statistical tests for refuting them with data, if they can be refuted. The interrupted time series analysis studies discussed earlier are examples of quasi-experiments: they do not allow random assignment of individuals to exposed and unexposed populations but do allow comparisons of what happened in different populations before and after an intervention that affects some of the populations but not others (the comparison groups).

A substantial tradition of *refutationist approaches* in epidemiology follows the same general idea of providing evidence for causation by using data to explicitly test, and if possible refute, other explanations for exposure-response associations [77]. As stated by Samet and Bodurow [100], “Because a statistical association between exposure and disease does not prove causation, plausible alternative hypotheses must be eliminated by careful statistical adjustment and/or consideration of all relevant scientific knowledge. Epidemiologic studies that show an association after such adjustment, for example through multiple regression or instrumental variable estimation, and that are reasonably free of bias and further confounding, provide evidence but not proof of causation.” This is overly optimistic, insofar as associations that are reasonably free of bias and confounding do not necessarily provide evidence of causation. For example, strong, statistically significant associations (according to usual tests, e.g., t-tests) typically occur in regression models in which the explanatory and dependent variables undergo statistically independent random walks. The resulting associations do not arise from confounding or bias but from spurious regression, i.e., coincident historical trends created by random processes that are not well described by the assumptions of the regression models. Nonetheless, the recommendation that “plausible alternative hypotheses must be eliminated by careful statistical adjustment and/or consideration of all relevant scientific knowledge” well expresses the refutationist point of view.

10 Changes in Causes Produce Changes in Effects via Networks of Causal Mechanisms

Perhaps the most useful and compelling valid evidence of causation, with the possible exception of differences in effects between treatment and control groups in well-conducted randomized control trials, consists of showing that changes in

exposures propagate through a network of validated lawlike structural equations or mechanisms to produce predictable changes in responses. For example, showing that measured changes in occupational exposures to a workplace chemical consistently produce a sequence of corresponding changes in lung inflammation markers, recruitment rates of activated alveolar macrophages and activated neutrophils to the chronically inflamed lung, levels of tissue-degrading enzymes released by these cell populations, and resulting rates of lung tissue destruction and scarring, leading to onset of lung pathologies and clinically detectable lung diseases (such as emphysema, silicosis, fibrosis, or inflammation-mediated lung cancer), would provide compelling evidence of a causal relation between changes in exposures and changes in those disease rates. Observing the network of mechanisms by which changes in exposures are transduced to changes in disease risks provides knowledge-based evidence of causation that cannot be obtained from any purely statistical analysis of observational data on exposures and responses alone.

Several causal modeling techniques are available to describe the propagation of changes through networks of causal mechanisms. *Structural equation models (SEMs)*, in which changes in right-hand side variables cause adjustments of left-hand side variables to restore all equalities in a system of structural equations, as in Fig. 43.1, provide one way to describe causal mechanisms for situations where the precise time course of the adjustment process is not of interest. Differential equation models, in which flows among compartments change the values of variables representing compartment contents over time (which in turn may affect the rates of flows), eventually leading to new equilibrium levels following an exogenous intervention that changes the compartment content or flow rates, provide a complementary way to describe mechanisms when the time course of adjustment is of interest. Simulation models provide still another way to describe and model the propagation of changes through causal networks. Figure 43.6 illustrates the structure of a simulation model for cardiovascular disease (CVD) outcomes. At each time step, the value of each variable is updated based on the values of the variables that point into it. The time courses of all variables in the model can be simulated for any history of initial conditions and exogenous changes in the input variables (those with only outward-pointing arrows), given the computational models that determine the change in the value of each variable at each time step from the values of its parents in the DAG.

10.1 Structural Equation and Path Analysis Models Model Linear Effects Among Variables

For most of the past century, DAG models such as those in Figs. 43.1 and 43.6, in which arrows point from some variables into others and there are no directed cycles, have been used to explicate causal networks of mechanisms and to provide formal tests for their hypothesized causal structures. For example, *path analysis* methods showing the dependency relations among variables in SEMs have been used for many decades to show how some variables influence others when all relations are assumed to be linear. Figure 43.7 presents an example involving several

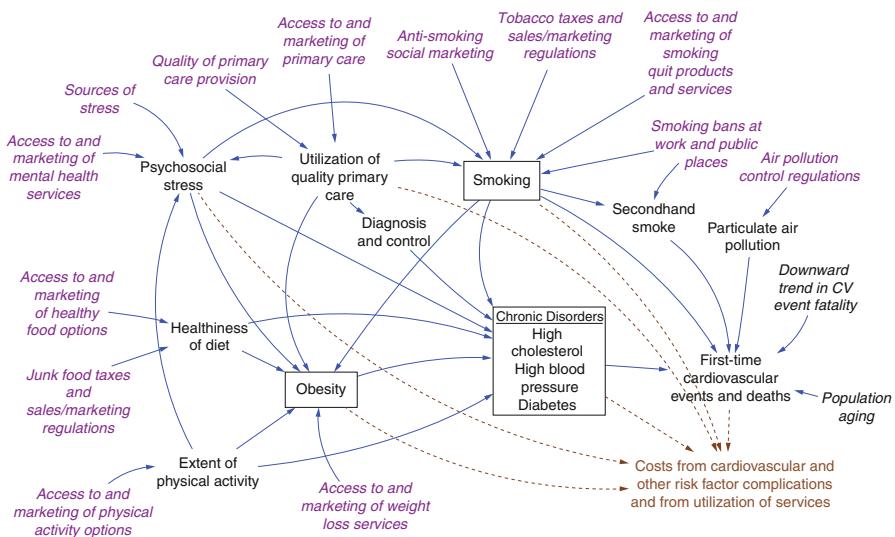

Fig. 43.6 Simulation model for major health conditions related to cardiovascular disease (CVD) and their causes. Boxes represent risk factor prevalence rates modeled as dynamic stocks. Population flows among these stocks – including people entering the adult population, entering the next age category, immigration, risk factor incidence, recovery, cardiovascular event survival, and death – are not shown (Source: [52])

Key: Blue solid arrows: causal linkages affecting risk factors and cardiovascular events and deaths. Brown dashed arrows: influences on costs.

Purple italics: factors amenable to direct intervention.

Black italics (population aging, cardiovascular event fatality): other specified trends.

Black nonitalics: all other variables, affected by italicized variables and by each other

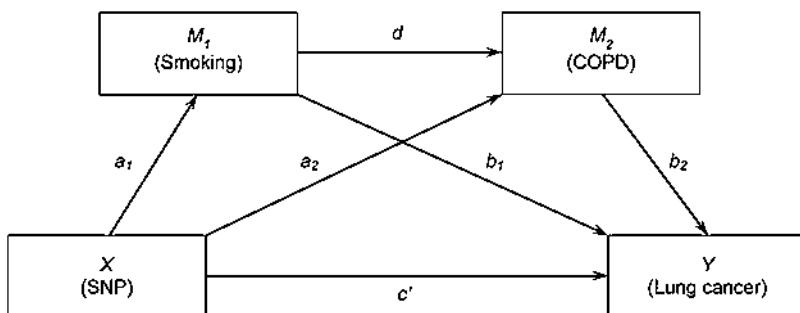

Fig. 43.7 A path diagram with standardized coefficients showing linear effects of some variables on others (Source: [120])

variables that are estimated to significantly predict lung cancer risk: the presence of a particular single nucleotide polymorphism (SNP) (the CHRNA5-A3 gene cluster, a genetic variant which is associated with increased risk of lung cancer), smoking, and presence of chronic obstructive pulmonary disease (COPD) [120].

The path coefficient on an arrow indicates by how much (specifically, by how many standard deviations) the expected value of the variable into which it points would change if the variable at the arrow's tail were increased by one standard deviation, holding all other variables fixed and assuming that all relations are well approximated by linear structural equation regression models, i.e., that changing the variable at the arrow's tail will cause a proportional change in the variable at its head. In this example, the path coefficients are denoted by a_1 , a_2 , b_1 , b_2 , c' , and d . These numbers must be estimated from data to complete the quantification of the path diagram model. Although such path analysis models are derived from correlations, the causal interpretation (i.e., that changing a variable at the tail of an arrow will change the variable at its head in proportion to the coefficient on the arrow between them) is an assumption. It is justified only if the regression equations used are indeed structural (causal) equations and if the assumptions required for multiple linear regression (e.g., additive effects, constant variance, normally distributed errors) hold. For the path diagram in Fig. 43.7, the authors found that the gene variant, X , affected lung cancer risk, Y , by increasing smoking behavior and, separately, by increasing COPD risk, as well as by increasing smoking-associated COPD risk: "The results showed that the genetic variant influences lung cancer risk indirectly through all three different pathways. The percent of genetic association mediated was 18.3% through smoking alone, 30.2% through COPD alone, and 20.6% through the path including both smoking and COPD, and the total genetic variant-lung cancer association explained by the two mediators was 69.1%."

Path diagrams reflect the fact that, if all effects of variables on each other are well approximated by linear regression SEMs, then correlations between variables should be stronger between variables that are closer to each other along a causal chain than between variables that are more remote, i.e., that have more intervening variables. Specifically, the effect of a change in the variable at the start of a path on a variable at the end of it that is transmitted along that path is given by the product of the path coefficients along the path. Thus, in Fig. 43.7, the presence of the SNP should be more strongly correlated with COPD than with COPD-associated lung cancer. Moreover, the effect of a change in an ancestor variable on the value of a remote descendent (several nodes away along one or more causal paths) can be decomposed into the effects of the change in the ancestor variable on any intermediate variables and the effects of those changes in intermediate variables, in turn, on the remote descendent variable. If one variable does *not* point into another, then the SEM/path analysis model implies that the first is not a direct cause of the second. For example, the DAG model $X \rightarrow Y \rightarrow Z$ implies that X is an ancestor (indirect cause) but not a parent (direct cause) of Z . An implication of the causal ordering in this simple DAG model can be tested, as previously noted, by checking whether Z is conditionally independent of X given Y .

In linear SEM/path analysis models, conditional independence tests specialize to testing whether partial correlation coefficients between two variables become zero after conditioning on the values of one or more other variables (e.g., the partial correlation between X and Z , holding Y fixed, would be zero for the path $X \rightarrow Y \rightarrow Z$). This makes information-theoretic methods unnecessary when the

assumptions of linear SEMs and jointly normally distributed error terms relating the value of each variable to the values of its parents hold; analyses based on correlations can then be used instead. Such consistency and coherence constraints can be expressed as systems of equations that can be solved, when identifiability conditions hold, to estimate the path coefficients (including confidence intervals) relating changes in parent variables to changes in their children. Summing these changes over all paths leading from exposure to response variables allows the total effect (via all paths) of a change in exposure on changes in expected responses to be estimated or predicted.

Path analysis and other SEM models are particularly valuable for detecting and quantifying the effects of unmeasured (“latent”) confounders based on the patterns of correlations that they induce among observed variables. SEM modeling methods have also been extended to include quadratic terms, categorical variables, and interaction terms [66]. Standard statistics packages and procedures, such as PROC CALIS in SAS, have made this technology available to modelers for the past four decades, and free modern implementations are readily available (e.g., in the R packages SEM or RAMpath).

10.2 Bayesian Networks Show How Multiple Interacting Factors Affect Outcome Probabilities

Path analysis, which is now nearly a century old, provided the main technology for causal modeling for much of the twentieth century. More recently, DAG models have been generalized so that causal mechanisms need not be described by linear equations for expected values, but may instead be described by arbitrary conditional probability relations. The nodes in such a graph typically represent random variables, stochastic processes, or time series variables in which a decision-maker may intervene from time to time by taking actions that cause changes in some of the time series [4, 23].

Bayesian networks (BNs) are a prominent type of DAG model in which nodes represent constants, random variables, or deterministic functions [3]. Figure 43.8 shows an example of a BN for cardiovascular disease (CVD). As usual, the absence of an arrow between two nodes, such as between *ethnic group* and *CVD* in Fig. 43.8, implies that neither has a probability distribution that depends directly on the value of the other. Thus, *ethnic group* is associated with CVD, but the association is explained by *smoking* as a mediating variable, and the structure of the DAG shows no further dependence of *CVD* on *ethnic group*. Statistically, the random variable indicating cardiovascular disease, *CVD*, is conditionally independent of *ethnic group*, given the value of *smoking*.

Some useful causal implications may be revealed by the structure of a DAG, even before the model is quantified to create a fully specified BN (or other DAG) model. For example, if the DAG structure in Fig. 43.8 correctly describes an individual or population, then elevated systolic BP (blood pressure) is associated with CVD risk, since both have age and ethnicity as ancestors in the DAG. However, changes in statin use, which could affect systolic BP via the intermediate variable

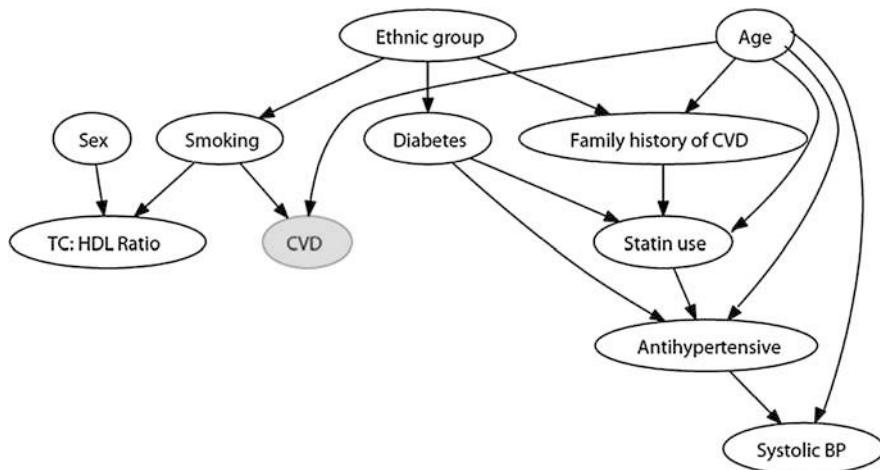

Fig. 43.8 Directed acyclic graph (DAG) structure of a Bayesian network (BN) model for cardiovascular disease (CVD) risk (Source: [115])

antihypertensive, would not be expected to have any effect on CVD risk. Learning the correct DAG structure of causal relations among variables from data – a key part of the difficult task of *causal discovery*, discussed later – can reveal important and unexpected findings about what works and what does not for changing the probabilities of different outcomes, such as CVD in Fig. 43.8. However, uncertainty about the correct causal structure can make sound inference about causal impacts (and hence recommendations about the best choice of actions to produce desired changes) difficult to determine. Such model uncertainty motivates the use of ensemble modeling methods, discussed later.

10.3 Quantifying Probabilistic Dependencies Among BN Variables

For quantitative modeling of probabilistic relations among variables, input nodes in a BN (i.e., nodes with only outward-pointing arrows, such as sex, age, and ethnic group in Fig. 43.8) are assigned marginal (unconditional) probability distributions for the values of the variables they represent. These marginal distributions can be thought of as being stored at the input nodes, e.g., in tables that list the probability or relative frequency of each possible input value (such as male or female for sex, age in years, etc.). They represent the prior probabilities that each input node will have each of its possible values for a randomly selected case or individual described by the BN model, before getting more information about a specific case or individual. For any specific individual to whom the BN model is applied, if the values of inputs such as sex, age, and ethnicity are known, then their values would be specified as inputs and conditioned on at subsequent nodes in applying the model to that individual. Figure 43.9 illustrates this concept.

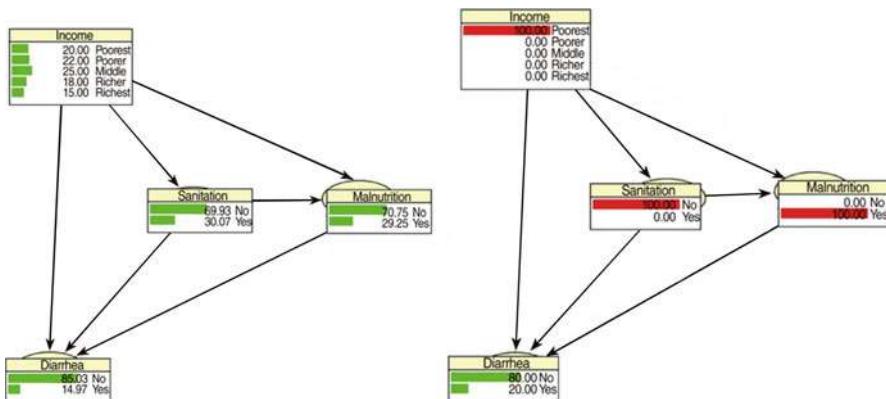

Fig. 43.9 BN model of risk of infectious diarrhea among children under 5 in Cameroon. The left panel shows the unconditional risk for a random child from the population (14.97%); the right panel shows the conditional risk for a malnourished child from a home in the lowest income quintile and with poor sanitation (20.00%) (Source: [87])

The left panel shows a BN model for risk of infectious diarrhea among young children in Cameroon. Each of three risk factors – income quintile, availability of toilets (“sanitation”), and stunted growth (“malnutrition”) – affects the probability that a child will ever have had diarrhea for at least two weeks (“diarrhea”). In addition, these risk factors affect each other, with an observation of low income making observations of poor sanitation and malnutrition more likely and observed poor sanitation also making observed malnutrition more likely at each level of income. The right panel shows an instance of the model for a particular case of a malnourished child from the poorest income quintile living with poor sanitation; these three risk factor values all have probabilities set to 100%, since their values are known. The result is that the risk of diarrhea, conditioned on this information, is increased from an average value of 14.97% in this population of children to 20% when all three risk factors are set to these values.

A BN model stores *conditional probability tables* (CPTs) at nodes with inward-pointing arrow. A CPT simply tabulates the conditional probabilities for the values of the node variable for each combination of values of the variables that point into it (its “parents” in the DAG). For example, the *malnutrition* node in Fig. 43.9 has a CPT with 10 rows, since its two parents, *Income* and *Sanitation*, have 5 and 2 possible levels, respectively, implying ten possible pairs of input values. For each of these ten combinations of input values, the CPT shows the conditional probability for each possible value of *Malnutrition* (here, just *Yes* and *No*, so that the CPT for *Malnutrition* has 2 columns); these conditional probabilities must sum to 1 for each row of the CPT. BN nodes can also represent deterministic functions by CPTs that assign 100% probability to a specific output value for each combination of input values. The conditional probability distribution for the value of a node (i.e., variable) thus depends on the values of the variables that point into it; it can be freely specified (or estimated from data, if adequate data are available) without making any

restrictive assumptions about linearity or normal errors. Such BN models greatly extend the flexibility of practical causal hypothesis testing and causal predictive modeling beyond traditional linear SEM and path analysis models.

In practice, CPTs can usually be condensed into relatively small tables by using classification trees or other algorithms (e.g., rough sets) to bin the potentially large number of combinations of values for a node's parents into just those that predict significantly different conditional probability distributions for the node's value. Instead of enumerating all the combinations of values for the parents, “don't care” conditions (represented by blanks in the CPT entries or by missing splits in a classification tree) can reduce the number of combinations that must be explicitly stored in the CPT. Alternatively, a logistic regression model or other statistical model can be used in place of a CPT at each node. For example, although the *Diarrhea* node in Fig. 43.9 could logically have a CPT with $5 \times 2 \times 2 = 20$ rows, it may be that a simple regression model with only three coefficients for the main effects of the parents, and few or no additional terms for interactions, would adequately approximate the full CPT.

10.4 Causal vs. Noncausal BNs

Any joint probability distribution of multiple random variables can be factored into a product of marginal and conditional probability distributions and displayed in DAG form, usually in several different ways. For example, the joint probability mass function $P(x, y)$ of two discrete random variables X and Y , specifying the probability of each pair of specific values (x, y) for random variables X and Y , can be factored as $P(x)P(y|x)$ or as $P(y)P(x|y)$ and can be displayed in a BN as $X \rightarrow Y$ or as $Y \rightarrow X$, respectively. Here, x and y denote possible values of random variables X and Y , respectively; $P(x, y)$ denotes the joint probability that $X = x$ and $Y = y$; $P(x)$ denotes the marginal probability that $X = x$; $P(y)$ denotes the marginal probability that $Y = y$, and $P(y|x)$ and $P(x|y)$ denote conditional probabilities that $Y = y$ given that $X = x$ and that $X = x$ given that $Y = y$, respectively. Thus, there is nothing inherently causal about a BN. Its nodes need not represent causal mechanisms that map values of inputs to probabilities for the values of outputs caused by those inputs. Even if they do represent such causal mechanisms, they may not explicate how or why the mechanisms work. For example, the direct link from *Income* to *Malnutrition* in Fig. 43.9 gives no insight into how or why changes in income affect changes in malnutrition – e.g., what specific decisions or behaviors are influenced by income that, in turn, results in better or worse nutrition. Thus, it is possible to build and use BNs for probabilistic inference without seeking any causal interpretation of the statistical dependencies among its variables.

However, BNs are often deliberately constructed and interpreted to mean that changes in the value of a variable at the tail of an arrow will cause a change in the probability distribution of the variable into which it points, as described by the CPT at that node. The effect of a change in a parent variable on the probability

distribution of a child variable into which it points may depend on the values of other parents of that node, thus allowing interactions among direct causes at that node to be modeled. For example, in Fig. 43.8, the effects of smoking on CVD risk may be different at different ages, and this would be indicated in the CPT for the CVD node by having different probabilities for the values of the CVD variable at different ages for the same value of the smoking variable. A *causal BN* is a BN in which the nodes represent stable causal mechanisms or laws that predict how changes in input values change the probability distribution of output values. The CPT at a node of a causal BN describes the conditional probability distribution for its value caused by each combination of values of its inputs, meaning that changes in one or more of its input values will be followed by corresponding changes in the probability distribution for the node's value, as specified by the CPT. This is similar to the concept of a causal mechanism in structural equation models, where a change in a right-hand side (explanatory or independent) variable in a structural equation is followed by a change in the left-hand side (dependent or response variable) to restore equality [119].

A causal BN allows changes at input nodes to be propagated throughout the rest of the network, yielding a posterior joint probability distribution for the values of all variables. (If the detailed time course of changes in probabilities is of interest, then differential equations or dynamic Bayesian networks (DBNs), discussed later, may be used to model how the node's probability distribution of values changes from period to period.) The order in which changes propagate through a network provides insight into the (total or partial) causal ordering of variables and can be used to help deduce network structures from time series data [119]. Similarly, in a set of simultaneous linear structural equations describing how equilibrium levels of variables in a system are related, the causal ordering of variables (called the *Simon causal ordering* in econometrics) is revealed by the order in which the equations must be solved to determine the values of all the variables, beginning with exogenous inputs (and assuming that the system of equations can be solved uniquely, i.e., that the values of all variables are uniquely identifiable from the data). Causality flows from exogenous to endogenous variables and among endogenous variables in such SEMs (*ibid*). Exactly how the changes in output probabilities (or in the expected values of left-side variables in an SEM) caused by changes in inputs are to be interpreted (e.g., as changes in the probability distribution of future observed values for a single individual or as changes in the frequency distribution of the variable values in a population of individuals described by the BN) depends on the situation being modeled.

10.5 Causal Mechanisms Are Lawlike, Yielding the Same Output Probabilities for the Same Inputs

A true causal mechanism that has been explicated in enough detail to make reliable predictions can be modeled as a conditional probability table (CPT) that gives the same conditional probabilities of output values whenever the input values are the same. Such a stable, repeatable relation, which might be described as lawlike,

can be applied across multiple contexts as long as the inputs to the node are sufficient to determine (approximately) unique probabilities for its output values. For example, a dose-response relation between radiation exposure and excess age-specific probability (or, more accurately, hazard rate) for first diagnosis with a specific type of leukemia might be estimated from data for one population and then applied to another with similar exposures, provided that the change in risk caused by exposure does not depend on omitted factors. If it depends on age and ethnic group, for example, then these would have to be included, along with exposure, as inputs to the node representing leukemia status. By contrast, unexplained heterogeneity, in which the estimated CPT differs significantly when study designs are repeated by different investigators, signals that a lawlike causal mechanism has not yet been discovered. In that case, the models and the knowledge that the BN represents need to be further refined to discover and express predictively useful causal relations that can be applied to new conditions. The key idea is that, to be transferable across contexts (e.g., populations), the probabilistic relations encoded in CPTs must include all of the input conditions that suffice to make their conditional probabilities accurate, given accurately measured or estimated input values.

A proposed causal relation that turns out to be very heterogeneous, sometimes showing significant positive effects and other times no effects or significant negative effects under the same conditions, does not correspond to a lawlike causal relation and cannot be relied on to make valid causal predictions (e.g., by using mean values averaged over many heterogeneous studies). Thus, the estimated CPTs at nodes in Fig. 43.9 may be viewed as averages of many individual-specific CPTs, and the predictions that they make for any individual case may not be accurate. CPTs that simply summarize historical data on conditional frequency distributions, but that do not represent causal mechanisms, may be no more than mixtures of multiple CPTs for the (perhaps unknown) populations and conditions that contributed to the historical data. They cannot necessarily be generalized to new populations or conditions (sometimes described as being transported to new contexts) or used to predict how outputs will change in response to changes in inputs, unless the relevant mixtures are known. For example, suppose that the *Sanitation* node has a value of 1 for children from homes with toilets and a value of 0 otherwise. If homes may have toilets either because the owners bought them or because a government program supplied them as part of a program along with a child food and medicine program, then the effect of a finding that *Sanitation* = 1 on the conditional probability distribution of *Malnutrition* may depend very much on which of these reasons resulted in *Sanitation* = 1. But this is not revealed by the model in Fig. 43.9. In such a case, the estimated CPTs for the nodes in Fig. 43.9 should not be interpreted as describing causal mechanisms, and the effects on other variables of setting *Sanitation* = 1 by alternative methods cannot be predicted from the model in Fig. 43.9.

10.6 Posterior Inference in BN Models

Once a BN has been quantified by specifying its DAG structure and the probability tables at its nodes, it can be used to draw a variety of useful inferences by applying

any of several well-developed algorithms created and refined over the past three decades [3]. The most essential inference capability of a BN model is that if observations (or “findings”) about the values at some nodes are entered, then the conditional probability distributions of all other nodes can be computed, conditioned on the evidence provided by these observed values. This is called “posterior inference.” In other words, the BN provides computationally practicable algorithms for accomplishing the Bayesian operation of updating prior knowledge or beliefs, represented in the node probability tables, with observations to obtain posterior probabilities. For example, if known values of a patient’s age, sex, and systolic blood pressure were to be entered for the BN in Fig. 43.8, then the conditional probability distributions based on that information could be computed for all other variables, including diabetes status and CVD risk, by BN posterior inference algorithms. In Fig. 43.9, learning that a child is from a home with inadequate sanitation would allow updated (posterior) probabilities for the possible income and nutrition levels, as well as the probability of diarrhea, to be computed using exact probabilistic inference algorithms. The best-known exact algorithm (the junction tree algorithm) is summarized succinctly by [3]. For large BNs, approximate posterior probabilities can be computed efficiently using Monte Carlo sampling methods, such as Gibbs sampling, in which input values drawn from the marginal distributions at input nodes are propagated through the network by sampling from the conditional distributions given by the CPTs, thus building up a sample distribution for any output variable(s) of interest.

The BN in Fig. 43.10 illustrates that different types of data, from demographics (age and sex) to choices and behaviors (smoking) to comorbidities (diabetes) to clinical measurements (such as systolic and diastolic blood pressures (SP and DBP)) and biomarkers (cholesterol levels) can be integrated in a BN model, here built using

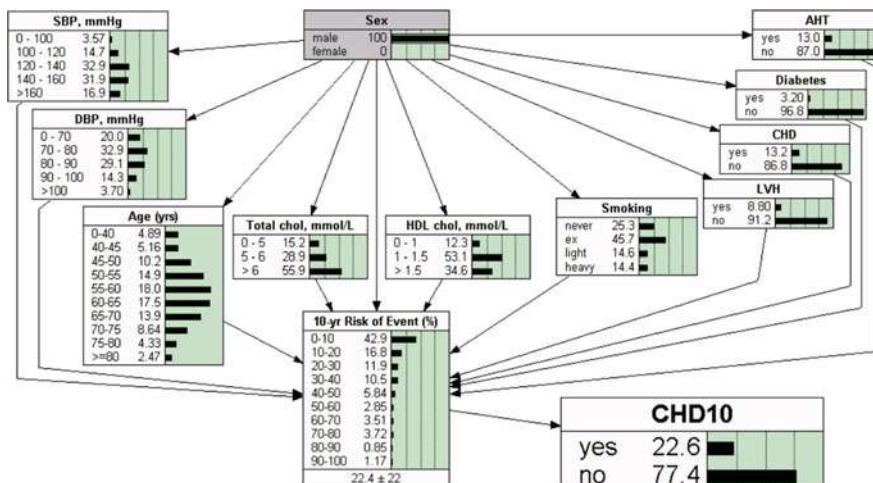

Fig. 43.10 BN model for predicting CHD risk from multiple types of data [117]

the popular *Netica* BN software product, to inform risk estimates for coronary heart disease (CHD) occurring in the next ten years. In addition to posterior inference of entire probability distributions for its variables, BNs can be used to compute the most likely explanations for observed or postulated outcomes (e.g., what are the most likely input values that lead to a specified set of output values) and to study the sensitivity of the probability of achieving (or avoiding) specified target sets of output values to changes in the probabilities of input values.

BN software products such as *Netica*, *Hugin*, or *BayesiaLab* not only provide algorithms to carry out these computations but also integrate them with graphic user interfaces for drawing BNs, populating their probability tables, and reporting results. For example, the DAG in Fig. 43.10, drawn in *Netica*, displays probability distributions for the values of each node. The probabilities are for a man, since the *Sex* node at the top of the diagram has its probability for the value “male” set to 100%. This node is shaded to show that observed or assumed values have been specified by the user, rather than being inferred by the BN model. If additional facts (“findings”) are entered, such as that the patient is a diabetic never-smoker, then the probability distributions at the *10-yr Risk of Event* node and the other nodes would all be automatically updated to reflect (condition upon) this information.

Free BN software packages for creating BNs and performing posterior inference are also available in both R and Python. In R, the *gRain* package allows BNs to be specified by entering the probability tables for their nodes. The resulting BN model can then be queried by entering the variables for which the posterior probability is desired, along with observed or assumed values for other variables. The package will return the posterior probabilities of the query variables, conditioned on the specified observations or assumptions. Both exact and approximate algorithms (such as the junction tree algorithm and Monte Carlo simulation-based algorithms, respectively) for such posterior inference in Bayesian networks are readily available if all variables are modeled as discrete with only a few possible values. For continuous variables, algorithms are available if each node can be modeled as having a normal distribution with a mean that is a weighted sum of the values of its parents, so that each node value depends on its parents’ values through a linear regression equation. Various algorithms based on Monte Carlo simulation are available for the case of mixed discrete and continuous BNs [13].

10.7 Causal Discovery of BNs from Data

A far more difficult problem than posterior inference is to infer or “learn” BNs or other causal graph models directly from data. This is often referred to as the problem of *causal discovery* (e.g., [54]). It includes the *structure discovery* problem of inferring the DAG graph of a BN from data, e.g., by making sure that it shows the conditional independence relations (treated as constraints), statistical dependencies, and order of propagation of changes [119] inferred from data. Structure learning algorithms are typically either constraint-based, seeking to find DAG structures that satisfy the conditional independence relations and other constraints inferred

from data or score-based, seeking to find the DAG structure that maximizes a criterion (e.g., likelihood or posterior probability penalized for complexity) [3,9,20], although hybrid algorithms have also been developed. Learning a BN from data also requires quantifying the probability tables (or other representations of the probabilistic input-output relation) at each node, but this is usually much easier than structure learning. Simply tabulating the frequencies of each output value for each combination of input values may suffice for large data sets if the nodes have been constructed to represent causal mechanisms. For smaller data sets, fitting classification trees or regression models to available data can generate an estimated CPT, giving the conditional probability of each output value for each set of values of the inputs. Alternatively, Bayesian methods can be used to condition priors (typically, Dirichlet priors for multinomial random variables) on available data to obtain posterior distributions for the CPTs [110].

Although many BN algorithms are now available to support learning BNs from data [105], a fundamental limitation and challenge remains that multiple different models often provide approximately equally good explanations of available data, as measured by any of the many scoring rules, information-theoretic measures, and other criteria that have been proposed, and yet they make different predictions for new cases or situations. In such cases, it is better to use an ensemble of BN models instead of any single one to make predictions and support decisions [3]. How best to use common-sense knowledge-based constraints (e.g., that death can be an effect but not a cause of exposure or that age can be a cause but not an effect of health effects) to extract unique causal models, or small sets of candidate models, from data is still an active area of research, but most BN packages allow users to specify both required and forbidden arrows between nodes when these knowledge-based constraints are available. Since it may be impossible to identify a unique BN model from available data, the BN-learning and causal discovery algorithms included in many BN software packages should be regarded as useful heuristics for suggesting possible causal models, rather than as necessarily reliable guides to the truth.

For practical applications, the *bnlearn* package in R [105] provides an assortment of algorithms for causal discovery, with the option of including knowledge-based constraints by specifying directed or undirected arcs that must always be included or that must never be included. For example, in Fig. 43.8, sex, age, and ethnic group cannot have arrows directed into them (they are not caused by other variables), and CVD deaths cannot be a cause of any other variable [115]. The DAG model for cardiovascular disease risk prediction in Fig. 43.8 was discovered using one of the *bnlearn* algorithms (the grow-shrink algorithm for structure learning), together with these knowledge-based constraints. On the other hand, the BN model in Fig. 43.10, which was developed manually based on an existing regression model, has a DAG structure that is highly questionable. Its logical structure is that of a regression model: for men, all other explanatory or independent variables point into the dependent variable *10-year Risk of Event*, and there are no arrows directed between explanatory variables, e.g., from smoking to risk of diabetes. Such additional structure would probably have been discovered had machine learning algorithms for causal discovery such as those in *bnlearn* been applied to the original data. If the

DAG structure of a BN model is incorrect, then the posterior inferences performed using it – e.g., inferences about risks (posterior probabilities) of disease outcomes, and how they would change if inputs such as smoking status were altered – will not be trustworthy. This raises a substantial practical challenge when the correct DAG structure of a BN is uncertain.

10.8 Handling Uncertainty in Bayesian Network Models

BNs and other causal graph model are increasingly used in epidemiology to model uncertain and multivariate exposure-response relations. They are particularly useful for characterizing uncertain causal relations, since they can represent both uncertainty about the appropriate causal structure (DAG model), via the use of multiple DAGs (“ensembles” of DAG models), and uncertainties about the marginal and conditional probabilities at the input and other nodes. As noted by Samet and Bodurow [100], “The uncertainty about the correct causal model involves uncertainty about whether exposure in fact causes disease at all, about the set of confounders that are associated with exposure and cause disease, about whether there is reverse causation, about what are the correct parametric forms of the relations of the exposure and confounders with outcome, and about whether there are other forms of bias affecting the evidence. One currently used method for making this uncertainty clear is to draw a set of causal graphs, each of which represents a particular causal hypothesis, and then consider evidence insofar as it favors one or more of these hypotheses and related graphs over the others.”

An important principle for characterizing and coping with uncertainty about causal models is not to select and use any single model when there is substantial uncertainty about which one is correct [3]. It is more effective, as measured by many performance criteria for evaluating predictive models, such as mean squared prediction error, to combine the predictions from multiple models that all fit the data adequately (e.g., that all have likelihoods at least 10% as large as that of the most likely model). Indeed, the use of multiple models is often essential for accurately depicting model uncertainty when quantifying uncertainty intervals or uncertainty sets for model-based predictions. For example, Table 43.3 presents a

Table 43.3 A machine learning challenge: What outcome should be predicted for case 7 based on the data in cases 1–6?

Case	Predictor 1	Predictor 2	Predictor 3	Predictor 4	Outcome
1	1	1	1	1	1
2	0	0	0	0	0
3	0	1	1	0	1
4	1	1	0	0	0
5	0	0	0	0	0
6	1	0	1	1	1
7	1	1	0	1	?

small hypothetical data set to illustrate that multiple models may provide equally good (in this example, perfect) descriptions of all available data and yet make very different predictions for new cases. For simplicity, all variables in this example are binary (0–1) variables.

Suppose that cases 1–6 constitute a “training set,” with 4 predictors and one outcome column (the right most) to be predicted from them. The challenge for predictive analytics or modeling in this example is to predict the outcome for case 7 (the value, either 0 or 1, in the “?” cell in the lower right of the table). For example, predictors 1–4 might represent various features (1 = present, 0 = absent) of a chemical, or perhaps results of various quick and inexpensive assays for the chemical (1 = positive, 0 = negative) and the outcome might indicate whether the chemical would be classified as a rodent carcinogen in relatively expensive two-year live-animal experiments. A variety of machine-learning algorithms are available for inducing predictive rules or models from training data, from logistic regression to classification trees (or random forest, an ensemble-modeling generalization of classification trees) to BN learning algorithms. Yet, no algorithm can provide trustworthy predictions for the outcome in case 7 based on the training data in cases 1–6, since many different models fit the training data equally well and yet make opposite predictions. For example, the following two models each describe the training data in rows 1–6 perfectly, yet they make opposite prediction for case 7:

Model 1: Outcome = 1 if the sum of predictors 2, 3, and 4 exceeds 1, else 0

Model 2: Outcome = value of Predictor 3.

Likewise, these two models would make opposite predictions for a chemical with predictor values of (0, 0, 1, 0). Model 1 can be represented by a BN DAG structure in which predictors 2, 3, and 4 are the parents of the outcome node (and the CPT is a deterministic function with probabilities of 1 or 0 that the outcome = 1, depending on the values of these predictors). Model 2 would be represented by a BN in which only node 3 is a parent of the outcome node. The following are additional models or prediction rules, e.g.:

Model 3: Outcome is the greater of the values of predictors 1 and 2 except when both equal 1, in which case the outcome is the greater of the values of predictors 3 and 4.

Model 4: Outcome is the greater of the values of predictors 1 and 2 except when both equal 1, in which case the outcome is the lesser of the values of predictors 3 and 4.

These models also provide equally good fits to, or descriptions of, the training data, but make opposite predictions for case 7 and imply yet another BN structure. Thus, it is impossible to confidently identify a single correct model structure from the training data (the data-generating process is *non-identifiable* from the training data), and no predictive analytics or machine learning algorithm can determine from these data a unique model (or set of prediction rules) for correctly predicting the outcome for new cases or situations.

This example illustrates that successful classification or description of reference cases in a training set is a different task from successful prediction of outcomes for new cases outside the training set. It is possible for a computational procedure to have up to 100% accuracy on the former task, while making predictions with no better than a random (50–50) probability of being correct for the latter task. Yet, it is the latter that should be the goal of chief interest to practitioners who want to make predictions or decisions for cases other than those used in building the model. Using ensembles of models can help to characterize the range or set of predicted outcomes for new cases that are consistent with the training data, in the sense of being predicted by models that describe the training data well. They can also provide a basis for procedures that adaptively improve predictions (or decisions) as new cases are observed.

One way to implement this model ensemble approach is via weighted averaging of model-specific predictions, with weights chosen to reflect each model's performance, e.g., how well it explains the data, as assessed by its relative likelihood [3, 78, 79]. Such *Bayesian model averaging* (BMA) of multiple causal graphs avoids the risk of betting predictions on a single model. It demonstrably leads to superior predictions and to reduced model-selection and over-fitting biases in many situations [79]. Similar ideas are included in *super-learning* algorithms, already discussed, which assess model performance and weights via cross validation rather than via likelihood and adaptive learning approaches that learn to optimize not just predictions, but decision rules for making sequences of interventions as outcomes are gradually observed over time (e.g., the *iqLearn* algorithm of Linn et al. [72]). An important application of such decision rule learning algorithms is in sequential multiple assignment randomized trial (SMART) designs for clinical trials. These designs allow treatments or interventions for individual patients to be modified over time as their individual response and covariate histories are observed, in order to increase the probabilities of favorable outcomes for each patient while learning what intervention sequences work best for each type of patient [71].

When the probabilities to be entered into BN node probability tables are unknown, algorithms that propagate *imprecise probabilities* through BN models can be used (e.g., [29, 30]). Both the marginal probabilities at input nodes and the resulting probabilities of different outcomes (or the values at particular output nodes) will then be intervals, representing imprecise probabilities. More generally, instead of specifying marginal and conditional probability tables at the nodes of a BN, uncertainty about the probabilities can be modeled by providing a (usually convex) *set* of probability distributions at each node. BNs generalized in this way are called *credal networks*. Algorithms for propagating sets of probabilities through credal networks have been developed [15] and extended to support optimization of risk management decisions [20].

Alternatively, *second-order probability distributions* (“probabilities of probabilities”) for the uncertain probabilities at BN nodes can be specified. If these uncertainties about probabilities are well approximated by Dirichlet or beta probability distributions (as happens naturally when probabilities or proportions are estimated from small samples using Bayesian methods with uniform or Dirichlet

priors), then Monte Carlo uncertainty analysis can be used to propagate the uncertain probabilities efficiently through the BN model, leading to uncertainty distributions for the posterior probabilities of the values of the variables in the BN (Kleiter 1996). Imprecise Dirichlet models have also been used to learn credal sets from data, resulting in upper and lower bounds for the probability that each variable takes on a given value [15].

Rather than using sets or intervals for uncertain probabilities, it is sometimes possible to simply use best guesses (point estimates) and yet to have confidence that the results will be approximately correct. Henrion et al. (1996) note that, in many situations, the key inferences and insights from BN models are quite insensitive (or “robust”) to variations in the estimated values in the probability tables for the nodes. When this is the case, best guesses (e.g., MLE point estimates) of probability values may be adequate for inference and prediction, even if the data and expertise used to form those estimates are scarce and the resulting point estimates are quite uncertain.

10.9 Influence Diagrams Extend BNs to Support Optimal Risk Management Decision-Making

The BN techniques discussed so far are useful for predicting how output probabilities will change if input values are varied, provided that the DAG structure can be correctly interpreted as showing how changes in the inputs propagate through networks of causal mechanisms to cause changes in outputs. (As previously discussed, this requires that the network is constructed so that the CPTs at nodes represent not merely statistical descriptions of conditional probabilities in historical data but causal relations determining probabilities of output values for each combination of input values.) Once the probabilities of different outputs can be predicted for different inputs, it is natural to ask how the controllable inputs should be set to make the resulting probability distribution of outputs as desirable as possible. This is the central question of decision analysis, and mainstream decision analysis provides a standard answer: choose actions to maximize the expected utility of the resulting probability distribution of consequences.

To modify BN models to support optimal (i.e., expected utility-maximizing) risk management decision-making, the BNs must be augmented with two types of nodes that do not represent random variables or deterministic functions. There is a *utility node*, also sometimes called a *value node*, which is often depicted in DAG diagrams as a hexagon and given a name such as “Decision-maker’s utility.” There must also be one or more *choice nodes*, also called *decision nodes*, commonly represented by rectangles. The risk management decision problem is to make choices at the decision nodes to maximize the expected value of the utility node, taking into account the uncertainties and conditional probabilities described by the rest of the DAG model. Input decision nodes (i.e., decision nodes with only outward-directed arrows) represent inputs whose values are controlled by the decision-maker. Decision nodes with inputs represent *decision rules*, i.e., tables or functions specifying how the decision node’s value is to be chosen, for each

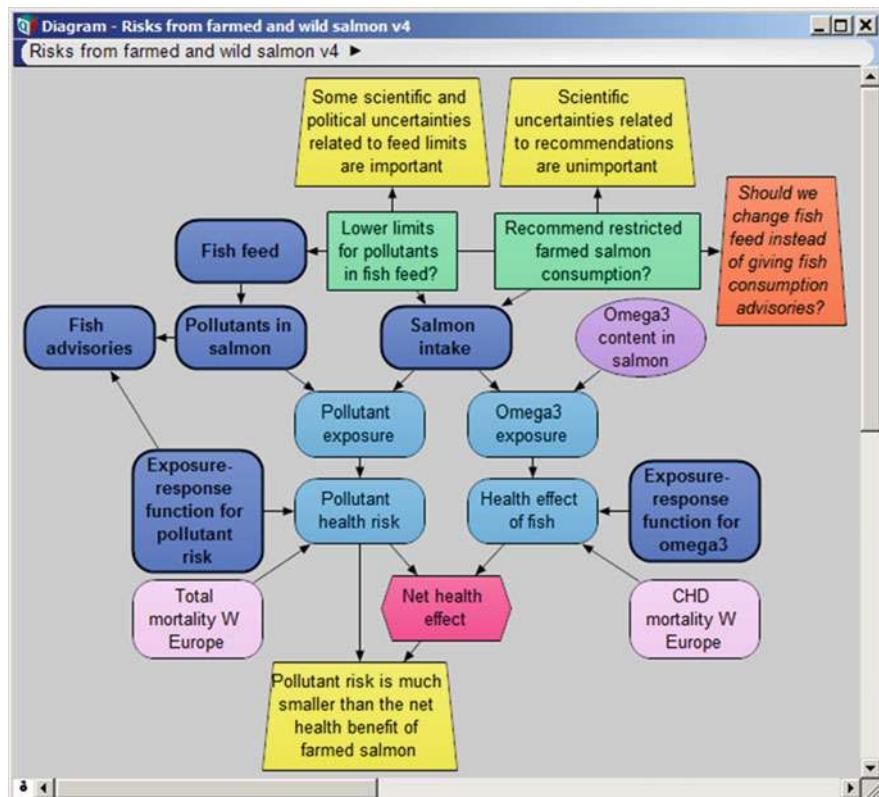

Fig. 43.11 An influence diagram (ID) model with two decision nodes (*green rectangles*) and with *Net health effect* as the value node. (Questions and comments in trapezoids on the periphery are not parts of the formal ID model, but help to interpret it for policy makers) (Source: www.lumina.com/case-studies/farmed-salmon/)

combination of values of its inputs. BNs with choice and value nodes are called *influence diagram* (ID) models. BN posterior inference algorithms can be adapted to solve for the best decisions in an ID, i.e., the choices to make at the choice nodes in order to maximize the expected value of the utility node [3, 123].

Figure 43.11 shows an example of an ID model developed and displayed using the commercial ID software package *Analytica*. Its two decision nodes represent choices about whether to lower the allowed limits for pollutants in fish feed and whether to recommend to consumers that they restrict consumption of farmed salmon, respectively [49]. The two decision nodes are shown as green rectangles, located toward the top of the ID. The value or utility node in Fig. 43.11, shown as a pink hexagon located toward the bottom of the diagram, is a measure of net health effect in a population. It can be quantified in units such as change in life expectancy (added person-year of life) or change in cancer mortality rates caused by different decisions and by the other factors shown in the model. Many of these

factors, such as (a) the estimated exposure-response relations for health harm caused by consuming pollutants in fish and (b) the health benefits caused by consuming omega three fatty acids in fish, are uncertain. The uncertainties are represented by random variables (the dark blue oval-shaped nodes throughout the diagram) and by modeling assumptions that allow other quantities (the light blue oval-shaped nodes) to be calculated from them.

An example of a modeling assumption is that pollutants increase mortality rates in proportion to exposure, with the size of this slope factor being uncertain. Different models (or expert opinions) for relevant toxicology, dietary habits, consumer responses to advisories and recommendations, nutritional benefits of fish consumption, and so forth can contribute to developing the CPTs for different parts of the ID model and characterizing uncertainties about them. IDs thus provide a constructive framework for coordinating and integrating multiple submodels and contributions from multiple domains of expertise and for applying them to help answer practical questions such as how different policies, regulations, warnings, or other actions will affect probable health effects, consumption patterns, and other outcomes of interest.

If multiple decision makers with different jurisdictions or spans of control attempt to control the same outcome, however, then coordinating their decisions effectively may require resolving game-theoretic issues in which each decision maker's best decision depends on what the others do. For example, in Fig. 43.11, if the regulators in charge of setting allowed limits for pollutant contamination levels in fish feed are different from the regulators or public health agencies issuing advisories about what to eat and what not to eat, then each might decide not to take additional action to protect public health if it mistakenly assumes that the other will do so. Problems of risk regulation or management with multiple decision-makers can be solved by generalizing IDs to *multi-agent influence diagrams* (MAIDs) [67, 89, 107]. MAID algorithms recommend what each decision-maker, each with its own utility function and decision variables, should do, taking into account any information it has about the actions of others, when their decisions propagate through a DAG model to jointly determine probabilities of consequences.

Although the idea of extending BNs to include decision and value nodes seems straightforward in principle, understanding which variables are controllable by whom over what time interval may require careful thought in practice. For example, consider a causal graph model (Fig. 43.12) showing factors affecting treatment of tooth defects (central node), such as patient's *age*, *genetics*, *smoking status*, *diabetes*, *use of antibacterials*, *pulpal status*, available surgical *devices*, and *operator skill* [1]. These variables have not been pre-labeled as chance or choice nodes. Even without expertise in dentistry, it is clear that some of the variables, such as *genetics* or *age*, should not ordinarily be modeled as decision variables. Others, such as *Use of antibacterials* and *Pulpal status* (reflecting oral hygiene) may result from a history of previous decisions by patients and perhaps other physicians or periodontists. Still others, such as available surgical *devices* and *operator skill*, are fixed in the short run, but might be considered decision variables over intervals long enough to include the operator's education, training, and experience or if the decisions to be

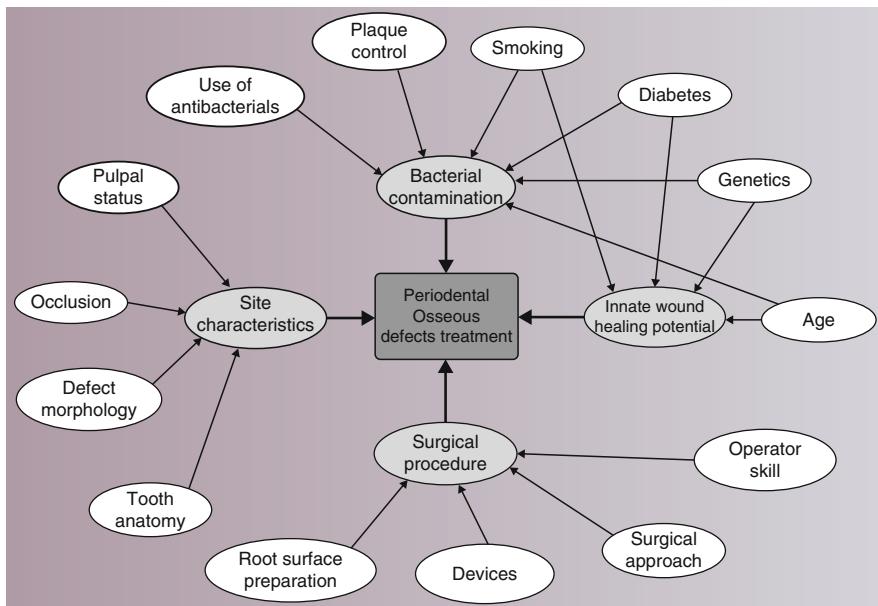

Fig. 43.12 Different variables can be treated as decision variables on different time scales (Source: [1])

made include hiring practices and device acquisition decisions of the clinic where the surgery is performed. *Smoking* and *diabetes* indicators might also be facts about a patient that cannot be varied in the short run, but that might be considered as at least in part determined by past health and lifestyle decisions. In short, even if a perfectly accurate causal graph model were available, the question of who acts upon the world how and over what time frame via the causal mechanisms in the model must still be resolved in formulating an ID or MAID model from a causal BN. In organizations or nations seeking to reduce various risks through policies or regulations, who should manage what, which variables should be taken as exogenously determined, and which should be subjected to control must likewise be resolved before ID or MAID models can be formulated and solved to obtain recommended risk management decisions.

10.10 Value of Information (VOI), Dynamic Bayesian Networks (DBNs), and Sequential Experiments for Reducing Uncertainties Over Time

Once a causal ID model has been fully quantified, it can be used to predict how the probability distributions for different outcomes of interest (such as net health effect in Fig. 43.11) and expected utility will change if different decisions are

made. This what-if capability, in turn, allows decision optimization algorithms to identify which specific decisions and decision rules maximize expected utility and to calculate how sensitive the recommended decisions are to other uncertainties and assumptions in the model. ID software products such as *Analytic* and *Netica* support construction of IDs and automatically solve them for the optimal decisions. For the example in Fig. 43.11, a robust optimal decision is to not recommend restrictions in fish consumption to consumers, as the estimated health benefits of greater fish consumption far outweigh the estimated health risks. This conclusion is unlikely to be reversed by further reductions in uncertainty, i.e., there is little doubt that it is true. By contrast, whether it is worth lowering allowed levels of pollutants in fish feed is much less clear, with the answer depending on modeling assumptions that are relatively uncertain. This implies a positive *value of information* (VOI) for reducing these uncertainties, meaning that doing so might change the best decision and increase expected utility. ID models can represent the option of collecting additional information before making a final decision about what actions to take, such as lowering or not lowering allowed pollutant levels, by including one or more additional decision nodes to represent information acquisition, followed by chance nodes showing what the additional information might reveal.

In an ID with options for collecting more information before taking a final action, the optimal next step based on presently available information might turn out to be to collect additional information before committing to final regulations or other costly actions. This will be the case if and only if the costs of collecting further information next, including any costs of delay that this entails, are less than the benefits from better-informed subsequent decisions, in the sense that collecting more information before acting (e.g., implementing a regulation or issuing a warning in Fig. 43.11) has greater expected utility than taking the best action now with the information at hand. Optimal delay and information acquisition strategies based on explicit VOI calculations often conflict with more intuitive or political criteria. Both individuals and groups are prone to conclude prematurely that there is already sufficient information on which to act and that further delay and information collection are therefore not warranted, due to narrow framing, overconfidence and confirmation biases, groupthink, and other psychological aspects of decision-making [61]. Politicians and leaders may respond to pressure to exhibit the appearance of strong leadership by taking prompt action without first learning enough about their probable consequences. VOI calculations can help to overcome such well-documented limitations of informal decision-making by putting appropriate weight on the value of reducing uncertainty before acting.

To explicitly model the sequencing of information collection, action selection, and resulting changes in outcomes over time, consecutive period-specific BNs or IDs can be linked by information flows, meaning that the nodes in each period's network (or "slice" of the full multi-period model) are allowed to depend on information received in previous periods. The resulting *dynamic Bayesian networks* (DBNs) or dynamic IDs provide a very convenient framework for predicting and optimizing decisions and consequences over time as initial uncertainties are gradually reduced or resolved. They have proved valuable in medical decision-

making for forecasting in detail the probabilities of different time courses of diseases and related quantities, such as probability of first diagnosis with a disease or adverse condition within a specified number of months or years [121], survival times and probabilities for patients with different conditions and treatments, and remaining days of hospitalization or remaining years of life for individual patients being monitored and treated for complex diseases, from cancers to multiple surgeries to sequential organ failures [5, 101].

DBN estimation software is freely available in R packages [69, 94]. It has been developed and used largely by the systems biology community for interpreting time series of gene expressions in systems biology. Biological and medical researchers, electrical engineers, computer scientists, artificial intelligence researchers, and statisticians have recognized that DBNs generalize important earlier methods of dynamic estimation and inference, such as Hidden Markov Models and Kalman filtering for estimation and signal processing [34]. DBNs are also potentially extremely valuable in a wide range of other engineering, regulatory, policy, and decision analysis settings where decisions and their consequences are distributed over time, where feedback loops or other cycles make any static BN inapplicable, or where detailed monitoring of changing probabilities of events is desired so that midcourse changes in actions can be made in order to improve final outcomes.

Development and application of DBN algorithms and various generalizations are fruitful areas of ongoing applied research. Key concepts of DBNs and multi-agent IDs have been successfully combined to model *multi-agent control* of dynamic random processes (modeled as multi-agent partially observable Markov decision processes, POMDPs) [93]. More recently, DBN methods have been combined with ideas from change-point analysis for situations where arcs in the DAG model are gained or lost at certain times as new influences or mechanisms start to operate or former ones cease [97]. These advances further extend the flexibility and realism of DBN models (and dynamic IDs based on them) to apply to description and control of nonstationary time series.

As already discussed, value of information (VOI) calculations, familiar from decision analysis, can be carried out straightforwardly in ID models. Less familiar, but still highly useful, are methods for optimizing the sequential collection of information to better ascertain correct causal models. The best available methods involve design of experiments [116] and of time series of observations [90]. When the correct ID model describing the relation between decisions and consequence probabilities is initially uncertain, then collecting additional information may have value not only for improving specific decisions (i.e., changing decisions or decision rules to increase expected utility) within the context of a specified ID model but also for discriminating among alternative ID models to better ascertain which ones best describe reality. New information can help in learning IDs from data by revealing how the effects of manipulations develop in affected variables over time [119]. For example, Tong and Koller [116] present a Bayesian approach to sequential experimentation in which a distribution of BN DAG structures and CPTs is updated by experiments that set certain variables to new values and monitor the changes in

values of other variables. At each step, the next experiment to perform is selected to most reduce expected loss from incorrect inferences about the presence and directions of arcs in the DAG model. Even in BNs without decision or utility nodes, designing experiments and time series of observations to facilitate accurate learning of BN descriptions can be very valuable in creating and validating models with high predictive accuracy [90].

11 Causal Analytics

The preceding sections have discussed how causal Bayesian networks and other DAG and time series algorithms provide constructive methods for carrying out many risk assessment and risk management tasks, even when there is substantial initial uncertainty about relevant cause-and-effect relations and about the best (expected utility-maximizing) courses of action. Other graphical formalisms for risk analysis and decision-making, such as decision trees, game trees, fault trees, and event trees, which have long been used to model the propagation of probabilistic events in complex systems, can all be converted to equivalent IDs or BNs, often with substantial reductions in computational complexity and with savings in the number of nodes and combinations of variable values that must be explicitly represented [107]. Thus, BNs and IDs provide an attractive unifying framework for characterizing, quantifying, and reducing uncertainties and for deciding what to do under the uncertainties that remain. They, together with time series techniques and machine learning techniques, provide a toolkit for using data to inform inference, prediction, and decision-making with realistic uncertainties. These methods empower the following important and widely used types of analytics for using data to inform decisions:

- *Descriptive analytics:* BNs and IDs describe how the part of the world being modeled probably works, showing which factors influence or determine the probability distributions for which other variables and quantifying the probabilistic relations among variables. If a BN or ID has CPTs that represent the operation of lawlike causal mechanisms – i.e., if it is a causal BN or ID – then it can be used to describe how changes in some variables affect the probability distributions of others and hence how probabilistic causal influences propagate to change the probabilities of outcomes.
- *Predictive analytics:* A BN can be used to predict how the probabilities of future observations change when new evidence is acquired (or assumed). A causal BN or ID predicts how changes made at input nodes will affect the future probabilities of outputs. Dynamic Bayesian networks (DBNs) are used to forecast the probable sequences of future changes that will occur after observed changes in inputs, culminating in a new posterior joint probability distribution for all other variables over time (calculated via posterior inference algorithms). BNs and DBNs are also used to predict and compare the probable consequences (changes in probability distributions of outputs and other variables) caused by alternative hypothetical (counterfactual) scenarios for changes in inputs,

including alternative decisions. Conversely, BNs can predict the most likely explanation for observed data, such as the most likely diagnosis explaining observed symptoms or the most likely sequence of component failures leading to a real or hypothesized failure of a complex system. By predicting the probable consequences of alternative policies or decisions and the most likely causes for undesired outcomes, BNs can inform risk management decision-making and help to identify where to allocate resources to repair or forestall likely failure paths.

- *Uncertainty analytics.* Both BNs and IDs are designed to quantify uncertainties about their predictions by using probability distributions for all uncertain quantities. When model uncertainty is important, model ensemble methods allow the predictions or recommendations from multiple plausible models to be combined to obtain more accurate forecasts and better-performing decision recommendations [3]. DBNs provide the ability to track event probabilities in detail as they change over time, and dynamic versions of MAIDs allow uncertainties about the actions of other decision-makers to be modeled.
- *Prescriptive analytics.* If a net benefit, loss, or utility function for different outcomes is defined, and if the causal DAG relating choices to probabilities of consequences is known, then ID algorithms can be used to solve for the best combination of decision variables to minimize expected loss or maximize expected utility. If more than one decision-maker or policy maker makes choices that affect the outcome, then MAIDS or dynamic versions of MAIDs can be used to recommend what each should do.
- *Evaluation and learning analytics.* Ensembles of BNs, IDs, and dynamic versions and extensions of these can be learned from data and experimentation. Value of information (VOI) calculations determine when a single decision-maker in a situation modeled by a known ID should stop collecting information and take action. Dynamic causal BNs and IDs can be learned from time series data in many settings (including observed responses to manipulations or designed experiments) and current decision rules or policies can be evaluated and improved during the learning process, via methods such as low-regret learning with model ensembles, until no further improvements can be found [107]. Learning about causal mechanisms from the observed time series of responses to past interventions, manipulations, decisions, or policies provides a promising technical approach to using past experience to deliberately improve future decisions and outcomes.

Table 43.4 shows how these various components, which might collectively be called *causal analytics*, provide constructive methods for answering the fundamental questions raised in the introduction. For event detection and consequence prediction, DBNs (especially, nonstationary DBNs) and change-point analysis (CPA) algorithms are well suited for detecting changes in time series of observations and occurrences of unobserved events based on their observable effects. DBNs and causal simulation models, as well as time series models that accurately describe how impacts of changes are distributed over time, are also useful for predicting the probable future consequences of recent changes or “shocks” in the inputs to a system.

Table 43.4 Causal analytics algorithms address fundamental risk management questions under realistic uncertainties

Fundamental questions	Causal analytics algorithms and methods for answering the questions
<i>Event detection: What has changed recently in disease patterns or other adverse outcomes, by how much, when?</i>	<ul style="list-style-type: none"> • Change-point analysis (CPA) algorithms • Dynamic Bayesian networks (DBNs)
<i>Consequence prediction: What are the implications for what will probably happen next if different actions (or no new actions) are taken?</i>	<ul style="list-style-type: none"> • Dynamic Bayesian networks (DBNs) • Simulation modeling • Time series forecasting
<i>Risk attribution: What is causing current undesirable outcomes? Does a specific exposure harm human health, and, if so, who is at greatest risk and under what conditions?</i>	<ul style="list-style-type: none"> • Causal DAG models (e.g., BNs, IDs) • Ensembles of DAG models • Granger causality and transfer entropy (TE) for time series
<i>Response modeling: What combinations of factors affect health outcomes, and how strongly? How would risks change if one or more of these factors were changed?</i>	<ul style="list-style-type: none"> • Causal DAG models, e.g., BN models
<i>Decision making: What actions or interventions will most effectively reduce uncertain health risks?</i>	<ul style="list-style-type: none"> • Influence diagram (ID) algorithms • MAIDs for multiple decision makers • Adaptive learning methods, e.g., iqLearn, if the ID model is uncertain
<i>Retrospective evaluation and accountability: How much difference have exposure reductions or other policies actually made in reducing adverse health outcomes?</i>	<ul style="list-style-type: none"> • Quasi-experimental (QE) studies • Intervention analysis for time series • Ensemble learning algorithms such as iqLearn for continuous improvement

For risk attribution, causal graph models (such as BNs, IDs, and dynamic versions of these) or ensembles of such models can be learned from data and used to quantify the evidence that suspected hazards indeed cause the adverse effects attributed to them (i.e., that there is, with high confidence, a directed arc pointing from a node representing exposure to a hazard into a node representing the effect). If so, the CPT for the effect node quantifies how changes in the exposure node change probabilities of effects, given the levels of other causes with which exposure may interact. Multivariate response modeling, in which the joint distributions of one or more responses vary with the levels of one or more factors that probabilistically cause them, can readily be modeled by DAGs that include the different causal factors and effects. For risk management or regulation under uncertainty, if utility nodes and decision nodes are incorporated into the causal graph models to create known causal ID or MAID models, then the best decisions for risk management (i.e., for inducing the greatest achievable expected utilities) can be identified by well-developed ID solution algorithms, and VOI calculations can be used to optimize costly information collection and the timing of final decisions.

Finally, for retrospective evaluation and accountability, quasi-experiments and intervention analysis of interrupted time series provide traditional methods of analysis, although they require using data (or assumptions) to refute noncausal explanations for changes in time series. More recently developed ensemble-learning methods [3, 107] and adaptive learning algorithms (such as iqLearn for learning to optimize treatment sequences) can be used to continually evaluate and improve the success of current decision rules, policies, or regulations for managing uncertain risks, based on their performance to date and on relative expected costs of switching among them and of failing to do so. Such adaptive evaluation and improvement is possible provided that the consequences of past actions (probably) are monitored and the data are made available and used to update causal IDs, MAIDs, or dynamic versions of such models to allow ongoing learning and optimization. Thus, causal graph methods (including ensemble methods, when appropriate models are uncertain, and time series methods that uncover DAG structures relating time series variables) provide a rich set of tools for addressing fundamental challenges of uncertainty quantification and decision-making under uncertainty.

12 Summary and Conclusions: Applying Causal Graph Models to Better Manage Risks and Uncertainties

The power and maturity of the technical methods in Table 43.4 have spurred their rapid uptake and application in fields such as neurobiology, systems biology, econometrics, artificial intelligence, control engineering, game theory, signal processing, and physics. However, they have so far had relatively limited impact on the practice of uncertainty quantification and risk management in epidemiology, public health, and regulatory science, perhaps because these fields give great deference to the use of subjective judgments informed by weight-of-evidence considerations – an approach widely used and taught since the 1960s, but of unproved and doubtful probative value [83]. Previous sections have illustrated some of the potential of more modern methods of causal analytics, but the vast majority of applied work in epidemiology, public health, and regulatory risk assessment unfortunately still uses older association-based methods and subjective opinions about the extent to which statistically significant differences between risk model coefficients for differently exposed populations might have causal interpretations.

To help close the gap between these poor current practices and the potentially much more objective, reliable, accurate, and sensitive methods of causal analytics in Table 43.4, the following checklist may prove useful in judging the adequacy of policy analyses or quantitative risk assessments (QRAs) that claims to have identified useful predictive causal relations between exposures to risk factors or hazards and resulting risks of adverse effects (responses), i.e., causal exposure-response (E-R) relations.

1. *Does the QRA show that changes in exposures precede the changes in health effects that they are said to cause?* Are results of appropriate technical analyses (e.g., change-point analyses, intervention analyses and other quasi-experimental comparisons, and Granger causality tests or transfer entropy results) presented, along with supporting data? If effects turn out to precede their presumed causes, then unmeasured confounders or residual confounding by confounders that the investigators claim were statistically “controlled for” may be at work.
2. *Does the QRA demonstrate that health effects cannot be made conditionally independent of exposure* by conditioning on other variables, especially potential confounders? Does it present the details, data, and results of appropriate statistical tests (e.g., conditional independence tests and DAGs) showing that health effects and exposures share mutual information that cannot be explained away by any combination of confounders?
3. *Does the QRA present and test explicit causal graph models*, showing the results of formal statistical tests of the causal hypotheses implied by the structure of the model (i.e., which variables point into which others)? Does it identify which alternative causal graph models are most consistent with available data (e.g., using the Occam’s Window method of [78])? Most importantly, does it present clear evidence that changes in exposure propagate through the causal graph, causing successive measurable changes in the intermediate variables along hypothesized causal paths? Such coherence, consistency, and biological plausibility demonstrated in explicit causal graph models showing how hypothesized causal mechanisms dovetail with each other to transduce changes in exposures to changes in health risks can provide compelling objective evidence of a causal relation between them, thus accomplishing what older and more problematic WoE frameworks have long sought to provide [95].
4. *Have noncausal explanations for statistical relations among observed variables (including exposures, health effects, and any intermediate variables, modifying factors, and confounders) been explicitly identified and convincingly refuted* using well-conducted and reported statistical tests? Especially, have model diagnostics (e.g., plots of residuals and discussions of any patterns) and formal tests of modeling assumptions been presented that show that the models used appropriately describe the data to which the QRA applies them and that claimed associations are not caused by model selection biases or specification errors, failures to model errors in exposure estimates and other explanatory variables, omitted confounders or other latent variables, uncorrected multiple testing bias, or coincident historical trends (e.g., spurious regression, if the exposure and health effects time series in longitudinal studies are not stationary)?
5. *Have all causal mechanisms postulated in the QRA modeling been demonstrated to exhibit stable, uniform, lawlike behavior*, so that there is no substantial unexplained heterogeneity in estimated input-output (e.g., E-R or C-R) relations? If the answer is no, then missing factors may need to be identified and their effects modeled before valid predictions can be made based on the assumption that changes in causes will yield future changes in effects that can be well described and predicted based on estimates of cause-effect relations from past data.

If the answers to these five diagnostic questions are all yes, then the QRA has met the burden of proof of showing that the available data are consistent with a causal relation and that other (noncausal) explanations are not plausible. It can then proceed to quantify the estimated changes in probability distributions of outputs, such as future health effects, that would be caused by changes in controllable inputs (e.g., future exposure levels) using the causal models developed to show that exposure causes adverse effects. The effort needed to establish valid evidence of a causal relation between historical levels of inputs and outputs by being able to answer yes to questions 1–5 pays off at this stage. Causal graph models (e.g., Bayesian networks with validated causal interpretations for their CPTs), simulation models based on composition of validated causal mechanisms, and valid path diagrams and SEM causal models can all be used to predict quantitative changes in outputs that would be caused by changes in inputs, e.g., changes in future health risks caused by changes in future exposure levels, given any scenario for the future values of other inputs.

Conversely, if the answer to any of the preceding five diagnostic questions is no, then it is premature to make causal predictions based on the work done so far. Either the additional work needed to make the answers yes should be done or results should be stated as contingent on the as-yet unproved assumption that this can eventually be done.

Conceptual Structure of Performance Assessments for Geologic Disposal of Radioactive Waste

44

Jon C. Helton, Clifford W. Hansen, and Cédric J. Salaberry

Abstract

A conceptual structure for performance assessments (PAs) for radioactive waste disposal facilities and other complex engineered facilities based on the following three basic conceptual entities is described: EN1, a probability space that characterizes aleatory uncertainty; EN2, a function that predicts consequences for individual elements of the sample space for aleatory uncertainty; and EN3, a probability space that characterizes epistemic uncertainty. This structure provides a basis for (i) a separation of the effects and implications of aleatory and epistemic uncertainty; (ii) the design, computational implementation, and documentation of a PA for a complex system; and (iii) informative uncertainty and sensitivity analyses. The implementation of this structure is illustrated with results from PAs for the Waste Isolation Pilot Plant for transuranic radioactive waste and the proposed Yucca Mountain repository for spent nuclear fuel and high-level radioactive waste.

Keywords

Aleatory uncertainty • Epistemic uncertainty • Performance assessment • Radioactive waste • Sensitivity analysis • Uncertainty analysis

1 Introduction

A conceptual structure for performance assessments (PAs) for the geologic disposal of radioactive waste is described. Illustrations of this structure are provided by past PAs for (i) a repository for transuranic radioactive waste near Carlsbad, New Mexico, known as the Waste Isolation Pilot Plant (WIPP) [1] and (ii) a proposed repository for spent nuclear fuel and high-level radioactive waste at Yucca Mountain (YM), Nevada [2]. Probabilistic risk assessments (PRAs) for nuclear power plants and other complex engineered facilities also have a similar conceptual structure [3–5].

The following topics are addressed: (i) characterization of uncertainty (Sect. 2), (ii) representation of aleatory uncertainty (Sect. 3), (iii) estimation of consequences (Sect. 4), (iv) representation of epistemic uncertainty (Sect. 5), (v) propagation and display of uncertainty (Sect. 6), and (vi) sensitivity analysis (Sect. 7). The presentation then ends with a brief summary (Sect. 8).

This presentation is an edited and updated adaption of two prior conference presentations [6, 7] and also draws on additional material in two special journal issues devoted to the indicated WIPP and YM PAs [1, 2].

2 Characterization of Uncertainty

A PA for a geologic repository for radioactive waste or any other complex facility is an analysis intended to answer three questions about the facility and one additional question about the analysis itself. The initial three questions are Q1, “What could happen?”; Q2, “How likely is it to happen?”; and Q3, “What are the consequences if it does happen?”. Formally, the answers to the preceding three questions can be represented by a set of ordered triples of the form

$$(\mathcal{S}_i, p\mathcal{S}_i, \mathbf{cS}_i), i = 1, 2, \dots, n_S, \quad (44.1)$$

where (i) \mathcal{S}_i is a set of similar occurrences, (ii) the sets \mathcal{S}_i are disjoint (i.e., $\mathcal{S}_i \cap \mathcal{S}_j = \emptyset$ for $i \neq j$) and $\cup_i \mathcal{S}_i$ contains everything that could potentially occur at the particular facility under consideration, (iii) $p\mathcal{S}_i$ is the probability for \mathcal{S}_i , and (iv) \mathbf{cS}_i is a vector of consequences associated with \mathcal{S}_i [8]. The fourth question is Q4,

“What is the uncertainty in the answers to the first three questions?” or, equivalently, “What is the level of confidence in the answers to the first three questions?”.

The set of ordered triples in Eq. (44.1) is often referred to as the Kaplan-Gärrick ordered triple representation for risk and, in essence, is an intuitive representation for a function f (i.e., a random variable) defined in association with a probability space $(\mathcal{A}, \mathbb{A}, p_A)$, where (i) \mathcal{A} is the set of everything that could occur in the particular universe under consideration, (ii) \mathbb{A} is the collection of subsets of \mathcal{A} for which probability is defined, and (iii) p_A is the function that defines probability for the elements of \mathbb{A} ([9], Sect. IV.3). Specifically, the sets \mathcal{S}_i are elements of \mathbb{A} with $\cup_i \mathcal{S}_i = \mathcal{A}$; $p_A(\mathcal{S}_i)$ is the probability $p_{\mathcal{S}_i}$ of \mathcal{S}_i ; and $f(\mathbf{a}_i)$ for a representative element \mathbf{a}_i of \mathcal{S}_i defines \mathbf{cS}_i . Another less commonly used possibility is that \mathbf{cS}_i is the expected value of f conditional on \mathcal{S}_i .

The uncertainty characterized by the sets \mathcal{S}_i and associated probabilities $p_{\mathcal{S}_i}$ in Eq. (44.1) introduced as answers to questions Q1 and Q2 is often referred to as aleatory uncertainty and results from a perceived randomness in future occurrences that could take place at the facility under consideration. The descriptor aleatory derives from the Latin *āleae*, which refers to games of dice, and is the reason for the notational use of “A” in the definition of the probability space $(\mathcal{A}, \mathbb{A}, p_A)$. Alternative designators for aleatory uncertainty include stochastic, type A, and irreducible. Question Q4 relates to uncertainty that results from a lack of knowledge with respect to the appropriateness of assumptions and/or parameter values used in an analysis. The basic idea is that an analysis has been developed to the point that it has a well-defined overall structure with fixed values for models and parameters, but uncertainty remains with respect to appropriate parameter values and possibly submodel structure or choice for use in this overall structure. This form of uncertainty is usually indicated by the descriptor epistemic, which derives from the Greek *epistēmē* for knowledge. Alternative descriptors for epistemic uncertainty include subjective, state of knowledge, type B, and reducible. Most analyses use probability to characterize epistemic uncertainty, which in turn means that in some way a probability space $(\mathcal{E}, \mathbb{E}, p_E)$ characterizing epistemic uncertainty must be defined and incorporated into the analysis. The representation of aleatory and epistemic uncertainty is an important, and sometimes contentious, part of the analysis of a complex system. As a result, an extensive literature exists on the incorporation of aleatory and epistemic uncertainty into analyses of complex systems (e.g., [10–23]).

A PA for a geologic repository for radioactive waste or any other complex facility is a very involved analysis. The understanding of such an analysis is greatly facilitated if it can be seen “in the large” before having to work through all the details of the implementation of the analysis. Fortunately, such an analysis is typically underlain by three basic entities or components: EN1, a probability space $(\mathcal{A}, \mathbb{A}, p_A)$ that characterizes aleatory uncertainty; EN2, a function f that estimates consequences for individual elements \mathbf{a} of the sample space \mathcal{A} for aleatory uncertainty; and EN3, a probability space $(\mathcal{E}, \mathbb{E}, p_E)$ that characterizes epistemic uncertainty [7, 24–26]. A recognition and understanding of these three basic entities makes it possible to understand the conceptual and computational structure of a

large PA without having basic concepts obscured by fine details of the analysis and leads to an analysis that results in informative uncertainty and sensitivity analyses. The nature and role of these three basic entities in PA and associated uncertainty and sensitivity analyses are elaborated on and illustrated in following sections.

3 EN1, Representation of Aleatory Uncertainty

As indicated in Sect. 2, aleatory uncertainty is formally characterized by a probability space $(\mathcal{A}, \mathbb{A}, p_A)$. The elements \mathbf{a} of \mathcal{A} are vectors

$$\mathbf{a} = [a_1, a_2, \dots, a_{nA}] \quad (44.2)$$

characterizing individual futures that potentially could occur at the facility under consideration. The set \mathcal{A} and the individual futures \mathbf{a} contained in \mathcal{A} are typically defined for some specified time interval. For example, the time interval $[0, 10^4 \text{ yr}]$ is specified in the regulations for WIPP [24, 27], and time intervals of $[0, 10^4 \text{ yr}]$ and $[0, 10^6 \text{ yr}]$ are specified in different parts of the regulations for the proposed YM repository ([26], Sect. 6). In contrast, futures are, in effect, defined for 1 year time intervals in PAs for nuclear power plants [3–5]. In practice, the probability space $(\mathcal{A}, \mathbb{A}, p_A)$ is usually defined by specifying distributions for the individual elements of \mathbf{a} . For notational purposes, it is often convenient to represent the distribution associated with the elements \mathbf{a} of \mathcal{A} with a density function $d_A(\mathbf{a})$.

For the 1996 PA supporting the Compliance Certification Application (CCA) for the WIPP, the only disruptions with sufficient potential for occurrence over the 10^4 yr regulatory period to merit inclusion in the analysis were drilling for petroleum resources and mining of potash above the excavated waste disposal drifts [27, 28]. As a consequence, the individual futures underlying the 1996 WIPP PA have the form

$$\mathbf{a} = \underbrace{[t_1, l_1, e_1, b_1, p_1, \mathbf{a}_1]}_{\text{1st intrusion}}, \underbrace{[t_2, l_2, e_2, b_2, p_2, \mathbf{a}_2], \dots, [t_n, l_n, e_n, b_n, p_n, \mathbf{a}_n]}_{\text{2nd intrusion}}, \dots, \underbrace{[t_n, l_n, e_n, b_n, p_n, \mathbf{a}_n]}_{\text{nth intrusion}}, t_{\min}, \quad (44.3)$$

where (i) n is the number of drilling intrusions, (ii) t_i is the time (yr) of the i th intrusion, (iii) l_i designates the location of the i th intrusion, (iv) e_i designates the penetration of an excavated or nonexcavated area by the i th intrusion, (v) b_i designates whether or not the i th intrusion penetrates pressurized brine in the Castile Formation, (vi) p_i designates the borehole plugging procedure used with the i th intrusion, (vii) \mathbf{a}_i designates the type of waste penetrated by the i th intrusion, and (viii) t_{\min} is the time (yr) at which potash mining occurs within the land withdrawal boundary. The distributions for times t_i for drilling intrusions and t_{\min} for potash mining are defined by Poisson processes; the distributions for the remaining elements of \mathbf{a} are defined on the basis of the properties of the waste disposal drifts associated with the WIPP and the geologic environment that surrounds these drifts.

Additional information on the elements of \mathbf{a} and their probabilistic characterization is available in Table III of Ref. [29] and in Ref. [27].

For the 2008 PA supporting the license application for the proposed YM repository,

$$\mathbf{a} = [nEW, nED, nII, nIE, nSG, nSF, \mathbf{a}_{EW}, \mathbf{a}_{ED}, \mathbf{a}_{II}, \mathbf{a}_{IE}, \mathbf{a}_{SG}, \mathbf{a}_{SF}], \quad (44.4)$$

where (i) nEW = number of early waste package (WP) failures, (ii) nED = number of early drip shield (DS) failures, (iii) nII = number of igneous intrusive events, (iv) nIE = number of igneous eruptive events, (v) nSG = number of seismic ground motion events, (vi) nSF = number of seismic fault displacement events, (vii) \mathbf{a}_{EW} = vector defining the nEW early WP failures, (viii) \mathbf{a}_{ED} = vector defining the nED early DS failures, (ix) \mathbf{a}_{II} = vector defining the nII igneous intrusive events, (x) \mathbf{a}_{IE} = vector defining the nIE igneous eruptive events, (xi) \mathbf{a}_{SG} = vector defining the nSG seismic ground motion events, and (xii) \mathbf{a}_{SF} = vector defining the nSF fault displacement events. In turn, the vectors \mathbf{a}_{EW} , \mathbf{a}_{ED} , \mathbf{a}_{II} , \mathbf{a}_{IE} , \mathbf{a}_{SG} , and \mathbf{a}_{SF} are of the form

$$\mathbf{a}_{EW} = [\mathbf{a}_{EW,1}, \mathbf{a}_{EW,2}, \dots, \mathbf{a}_{EW,nEW}], \mathbf{a}_{ED} = [\mathbf{a}_{ED,1}, \mathbf{a}_{ED,2}, \dots, \mathbf{a}_{ED,nED}], \quad (44.5)$$

$$\mathbf{a}_{II} = [\mathbf{a}_{II,1}, \mathbf{a}_{II,2}, \dots, \mathbf{a}_{II,nII}], \mathbf{a}_{IE} = [\mathbf{a}_{IE,1}, \mathbf{a}_{IE,2}, \dots, \mathbf{a}_{IE,nIE}], \quad (44.6)$$

and

$$\mathbf{a}_{SG} = [\mathbf{a}_{SG,1}, \mathbf{a}_{SG,2}, \dots, \mathbf{a}_{SG,nSG}], \mathbf{a}_{SF} = [\mathbf{a}_{SF,1}, \mathbf{a}_{SF,2}, \dots, \mathbf{a}_{SF,nSF}], \quad (44.7)$$

where (i) $\mathbf{a}_{EW,j}$ = vector defining early WP failure j for $j = 1, 2, \dots, nEW$, (ii) $\mathbf{a}_{ED,j}$ = vector defining early DS failure j for $j = 1, 2, \dots, nED$, (iii) $\mathbf{a}_{II,j}$ = vector defining igneous intrusive event j for $j = 1, 2, \dots, nII$, (iv) $\mathbf{a}_{IE,j}$ = vector defining igneous eruptive event j for $j = 1, 2, \dots, nIE$, (v) $\mathbf{a}_{SG,j}$ = vector defining seismic ground motion event j for $j = 1, 2, \dots, nSG$, and (vi) $\mathbf{a}_{SF,j}$ = vector defining seismic fault displacement event j for $j = 1, 2, \dots, nSF$. Definitions of the vectors $\mathbf{a}_{EW,j}$, $\mathbf{a}_{ED,j}$, $\mathbf{a}_{II,j}$, $\mathbf{a}_{IE,j}$, $\mathbf{a}_{SG,j}$, and $\mathbf{a}_{SF,j}$ and their associated probabilistic characterizations are given in Refs. [30–32].

As an example, the individual vectors $\mathbf{a}_{EW,j}$, $j = 1, 2, \dots, nEW$, appearing in the definition of \mathbf{a}_{EW} in Eq. (44.5) are defined by

$$\mathbf{a}_{EW,j} = [t_j, b_j, d_j] \quad (44.8)$$

and characterize the properties of failed WP j , where (i) t_j designates WP type (i.e., $t_j = 1 \sim$ commercial spent nuclear fuel (CSNF) WP, $t_j = 2 \sim$ codisposed (CDSF) WP), (ii) b_j designates percolation bin in which failed WP is located (i.e., $b_j = k \sim$ location of failed WP in percolation bin k for $k = 1, 2, 3, 4, 5$; see Fig. 44.2, Ref. [33]), and (iii) d_j designates whether the failed WP experiences nondripping or dripping conditions (i.e., $d_j = 0 \sim$ nondripping conditions and $d_j = 1 \sim$ dripping

conditions). In turn, the associated probabilities are based on the assumption that the number of early failed WPs follows a binomial distribution with the failed WPs distributed randomly over WP types, percolation bins, and nondripping/dripping conditions.

Although potentially complex, representations of aleatory uncertainty of the form illustrated for the WIPP CCA PA and the YM license application PA permit a complete and unambiguous description of what constitutes aleatory uncertainty and the probabilistic characterization of this uncertainty.

4 EN2, Model That Estimates Consequences

As indicated in Sect. 2, the second entity that underlines a PA for a complex system is a function f that estimates a vector $f(\mathbf{a})$ of consequences for individual elements \mathbf{a} of the sample space \mathcal{A} for aleatory uncertainty. In most analyses, the function f corresponds to a sequence of models for multiple physical processes that must be implemented and numerically evaluated in one or more computer programs. However, for notational and conceptual purposes, it is useful to represent this sequence of models as a function of elements of the sample space \mathcal{A} for aleatory uncertainty. In most analyses associated with radioactive waste disposal, the analysis results of interest are functions of time. In this situation, the model used to predict system behavior can be represented by $f(\tau|\mathbf{a})$, where τ corresponds to time and the indication of conditionality (i.e., “ $|\mathbf{a}$ ”) emphasizes that the results at time τ depend on the particular element of \mathcal{A} under consideration. In most analyses, $f(\tau|\mathbf{a})$ corresponds to a large number of results. In general, τ could also correspond to designators other than time such as spatial coordinates; however, it is possible that spatial coordinates and associated location-dependent results would simply be viewed as part of a very large number of results corresponding to $f(\tau|\mathbf{a})$.

As an example, the sequence of linked models that corresponds to f in the 1996 WIPP PA is indicated in Fig. 44.1. As summarized in Table 44.1, the models indicated in Fig. 44.1 represent a variety of physical processes and also involve a variety of mathematical structures (see Refs. [1, 28] for additional information on the models used in the 1996 WIPP PA).

As another example, a subset of the models that correspond to f in the 2008 PA for the proposed YM repository is indicated in Fig. 44.2. The particular configuration of models shown in Fig. 44.2 was used in the YM PA to calculate consequences associated with elements of the sample space \mathcal{A} for aleatory uncertainty that involved seismic disruptions. Similar model configurations were used to calculate consequences for early WP failures, early DS failures, and igneous intrusive events; a very different suite of models was used to calculate consequences for igneous eruptive events. The number of individual models used in the 2008 YM PA is too great to permit their individual description here. However, descriptions of these models are available in Refs. [35, 36] and in the more detailed model-specific technical reports cited in Refs. [35, 36].

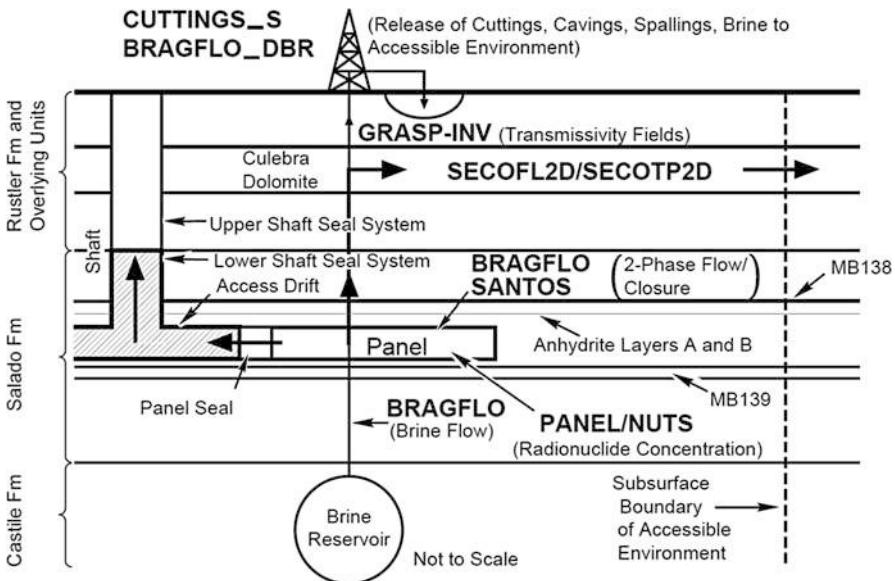

Fig. 44.1 Models used in the 1996 WIPP PA ([34], Fig. 44.4); see Table 44.1 for a description of individual models

As is evident from Fig. 44.1, Fig. 44.2, and Table 44.1, the function f that constitutes the second of the three entities that underlie a PA for radioactive waste repository can be quite complex.

5 EN3, Representation of Epistemic Uncertainty

As indicated in Sect. 2, epistemic uncertainty is formally characterized by a probability space $(\mathcal{E}, \mathbb{E}, p_E)$. The elements \mathbf{e} of \mathcal{E} are vectors of the form

$$\mathbf{e} = [\mathbf{e}_A, \mathbf{e}_M] = [e_1, e_2, \dots, e_{nE}], \quad (44.9)$$

where \mathbf{e}_A is a vector of epistemically uncertain quantities involved in the definition of the probability space $(\mathcal{A}, \mathbb{A}, p_A)$ for aleatory uncertainty that constitutes the first of the three entities that underlies a PA and \mathbf{e}_M is a vector of epistemically uncertain quantities involved in the definition of the function f that constitutes the second of the three entities that underlies a PA. The probability space $(\mathcal{E}, \mathbb{E}, p_E)$ for epistemic uncertainty and its associated density function $d_E(\mathbf{e})$ are usually developed through an expert review process that involves assigning a distribution to each element e_j of \mathbf{e} [37–44]. With the introduction of the epistemically uncertain quantities that constitute the elements of $\mathbf{e} = [\mathbf{e}_A, \mathbf{e}_M]$, the notation for the density function $d_A(\mathbf{a})$ associated with the probability space $(\mathcal{A}, \mathbb{A}, p_A)$ for aleatory uncertainty becomes $d_A(\mathbf{a}|\mathbf{e}_A)$ to indicate the dependence on \mathbf{e}_A ; similarly, the notation for the time-dependent values for the function f becomes $f(\tau|\mathbf{a}, \mathbf{e}_M)$.

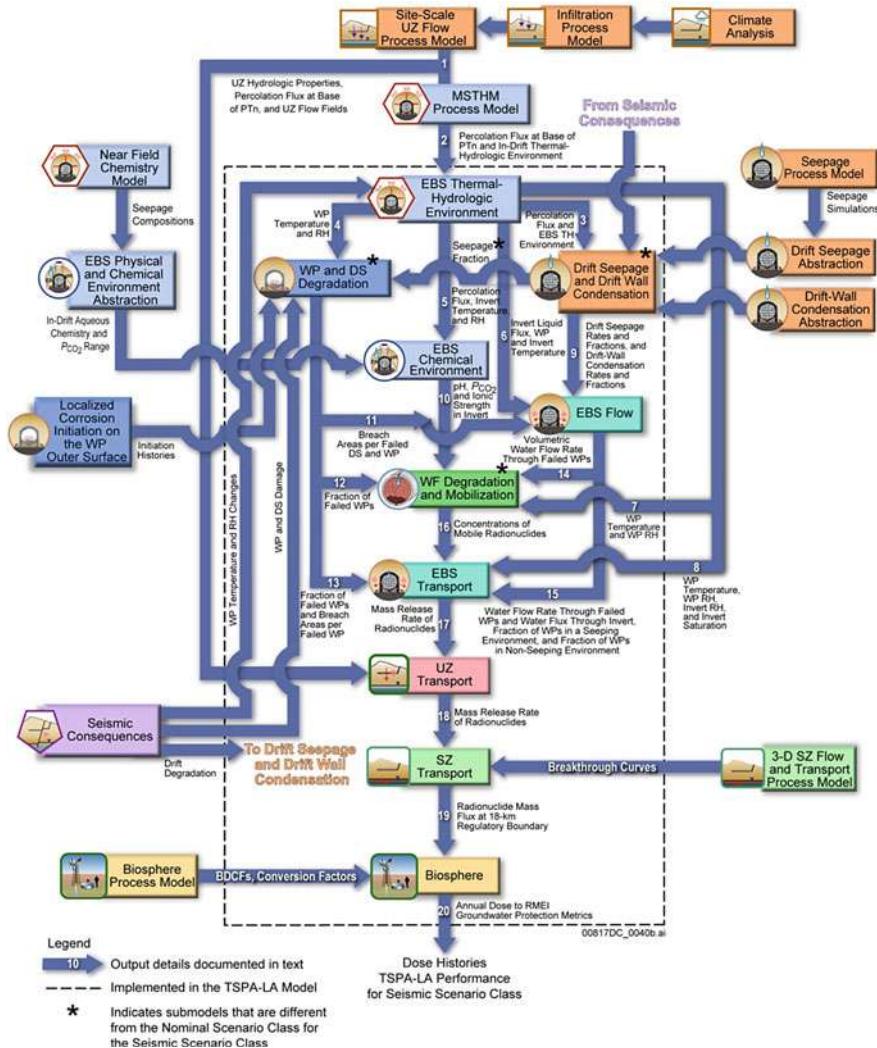

Fig. 44.2 Models used in the 2008 YM PA for seismic disruptions ([35], Fig. 6.1.4–6)

As examples, the probability spaces for epistemic uncertainty in the 1996 WIPP PA and the 2008 YM PA involved $nE = 57$ and $nE = 392$ epistemically uncertain quantities, respectively. Example elements of the vector \mathbf{e} for the WIPP and YM PAs are described in Tables 44.2 and 44.3. The example variables in Tables 44.2 and 44.3 were selected to include all variables that appear in the example sensitivity analyses discussed in Sect. 7.

As done in the WIPP and YM PAs, probability is the most widely used mathematical structure for the representation of epistemic uncertainty. However, a number of additional structures for the representation of epistemic uncertainty in

Table 44.1 Summary of individual models used in the 1996 WIPP PA ([34], Table 1)

BRAGFLO: Calculates multiphase flow of gas and brine through a porous heterogeneous reservoir. Uses finite difference procedures to solve system of nonlinear partial differential equations (PDEs) that describes the conservation of gas and brine along with appropriate constraint equations, initial conditions, and boundary conditions.
BRAGFLO-DBR: Special configuration of BRAGFLO model used to calculate dissolved radionuclide releases to the surface at the time of a drilling intrusion. Uses initial value conditions obtained from calculations performed with BRAGFLO and CUTTINGS_S.
CUTTINGS_S: Calculates quantity of radioactive material brought to the surface in cuttings, cavings, and spallings generated by a drilling intrusion. Spalling calculation uses initial value conditions obtained from calculations performed with BRAGFLO.
GRASP-INV: Generates transmissivity fields conditioned on measured transmissivity values and calibrated to steady-state and transient pressure data at well locations using an adjoint sensitivity and pilot-point technique.
NUTS: Solves system of PDEs for dissolved radionuclide transport in the vicinity of the repository. Uses brine volumes and flows calculated by BRAGFLO as input.
PANEL: Calculates rate of discharge and cumulative discharge of radionuclides from a waste panel through an intruding borehole. Uses brine volumes and flows calculated by BRAGFLO as input.
SANTOS: Determines quasistatic, large deformation, inelastic response of two-dimensional solids with finite element techniques. Used to determine porosity of waste as a function of time and cumulative gas generation, which is an input to calculations performed with BRAGFLO.
SECOFL2D: Calculates single-phase Darcy flow for groundwater flow in two dimensions based on a PDE for hydraulic head. Uses transmissivity fields generated by GRASP-INV.
SECOTP2D: Simulates transport of radionuclides in a fractured porous medium. Solves two PDEs: one provides a two-dimensional representation for convective and diffusive radionuclide transport in fractures and the other provides a one-dimensional representation for diffusion of radionuclides into the rock matrix surrounding the fractures. Uses flow fields calculated by SECOFL2D.

Table 44.2 Examples of the $nE = 57$ elements of the vector \mathbf{e} of epistemically uncertain variables in the 1996 WIPP PA (see [45], Table 1, for a complete listing of the indicated 57 epistemically uncertain variables and sources of detailed information on the individual variables)

<i>ANHPRM</i> – Logarithm of anhydrite permeability (m^2). <i>Distribution</i> : Student's with 5 degrees of freedom. <i>Range</i> : -21.0 to -17.1 . <i>Correlation</i> : -0.99 rank correlation with <i>ANHCOMP</i> (anhydrite compressibility).
<i>BHPRM</i> – Logarithm of borehole permeability (m^2). <i>Distribution</i> : Uniform. <i>Range</i> : -14.0 to -11.0 .
<i>HALPOR</i> – Halite porosity (dimensionless). <i>Distribution</i> : Piecewise uniform. <i>Range</i> : 0.001 to 0.03 .
<i>SHBCEXP</i> – Brooks-Corey pore distribution parameter for shaft (dimensionless). <i>Distribution</i> : Piecewise uniform. <i>Range</i> : 0.11 to 8.10 .
<i>WRGSSAT</i> – Residual gas saturation in waste (dimensionless). <i>Distribution</i> : Uniform. <i>Range</i> : 0 to 0.15 .
<i>WMICDFLG</i> – Pointer variable for microbial degradation of cellulose (dimensionless). <i>Distribution</i> : Discrete. $WMICDFLG = 1, 2, 3$ implies no microbial degradation of cellulose, microbial degradation of only cellulose, microbial degradation of cellulose, plastic and rubber.
<i>WTAUFAIL</i> – Shear strength of waste (Pa). <i>Distribution</i> : Uniform. <i>Range</i> : 0.05 to 10 .

Table 44.3 Examples of the $nE = 392$ elements of the vector **e** of epistemically uncertain variables in the 2008 YM PA (see [26], App. B, for a complete listing of the indicated 392 epistemically uncertain variables and sources of detailed information on the individual variables)

<i>CORRATSS.</i> Stainless steel corrosion rate ($\mu\text{m}/\text{yr}$). <i>Distribution:</i> Truncated log normal. <i>Range:</i> 0.01 to 0.51. <i>Mean/Median/Mode:</i> 0.267. <i>Standard Deviation:</i> 0.209.
<i>CSNFMASS.</i> Scale factor used to characterize uncertainty in radionuclide content of commercial spent nuclear fuel (CSNF) (dimensionless). <i>Distribution:</i> Uniform. <i>Range:</i> 0.85 to 1.4.
<i>DSNFMASS.</i> Scale factor used to characterize uncertainty in radionuclide content of defense spent nuclear fuel (DSNF) (dimensionless). <i>Distribution:</i> Triangular. <i>Range:</i> 0.45 to 2.9. <i>Mode:</i> 0.62.
<i>DTDRHUNC.</i> Selector variable used to determine the collapsed drift rubble thermal conductivity (dimensionless). <i>Distribution:</i> Discrete. <i>Range:</i> 1 to 2.
<i>HLWDRACD.</i> Effective rate coefficient (affinity term) for the dissolution of high-level waste (HLW) glass in codisposed spent nuclear fuel (CDSP) waste packages (WPs) under low pH conditions ($\text{g}/(\text{m}^2\text{d})$). <i>Distribution:</i> Triangular. <i>Range:</i> 8.41E 03 to 1.15E 07. <i>Mode:</i> 8.41E 03.
<i>IGRATE.</i> Frequency of intersection of the repository footprint by a volcanic event (yr^{-1}). <i>Distribution:</i> Piecewise uniform. <i>Range:</i> 0 to 7.76E-07.
<i>INFIL.</i> Pointer variable for determining infiltration conditions: 10th, 30th, 50th, or 90th percentile infiltration scenario (dimensionless). <i>Distribution:</i> Discrete. <i>Range:</i> 1 to 4.
<i>INRFRCTC.</i> The initial release fraction of ^{99}Tc in a CSNF waste package (dimensionless). <i>Distribution:</i> Triangular. <i>Range:</i> 0.0001 to 0.0026. <i>Mode:</i> 0.001.
<i>MICC14.</i> Groundwater Biosphere Dose Conversion Factor (BDCF) for ^{14}C in modern interglacial climate ($(\text{Sv}/\text{year})/(\text{Bq}/\text{m}^3)$). <i>Distribution:</i> Discrete. <i>Range:</i> 7.18E-10 to 2.56E-08. <i>Mean:</i> 1.93E-09. <i>Standard Deviation:</i> 1.85E-09.
<i>MICTC99.</i> Groundwater BDCF for ^{99}Tc in modern interglacial climate ($(\text{Sv}/\text{year})/(\text{Bq}/\text{m}^3)$). <i>Distribution:</i> Discrete. <i>Range:</i> 5.28E-10 to 2.85E-08. <i>Mean:</i> 1.12E-09. <i>Standard Deviation:</i> 1.26E-09.
<i>SCCTHR.</i> Residual stress threshold for stress corrosion cracking (MPa). <i>Distribution:</i> Uniform. <i>Range:</i> 315.9 to 368.55.
<i>SCCTHRP.</i> Residual stress threshold for stress corrosion crack (SCC) nucleation of Alloy 22 (as a percentage of yield strength in MPa) (dimensionless). <i>Distribution:</i> Uniform. <i>Range:</i> 90 to 105.
<i>SZFIPOVO.</i> Logarithm of flowing interval porosity in volcanic units (dimensionless). <i>Distribution:</i> Piecewise uniform. <i>Range:</i> -5 to -1. <i>Mean/Median/Mode:</i> -3.
<i>SZGWSPDPM.</i> Logarithm of the scale factor used to characterize uncertainty in groundwater-specific discharge (dimensionless). <i>Distribution:</i> Piecewise uniform. <i>Range:</i> -0.951 to 0.951.
<i>THERMCON.</i> Selector variable for one of three host-rock thermal conductivity scenarios (low, mean, and high) (dimensionless). <i>Distribution:</i> Discrete. <i>Range:</i> 1 to 3.
<i>WDGCA22.</i> Temperature-dependent slope term of Alloy 22 general corrosion rate (K). <i>Distribution:</i> Truncated normal. <i>Range:</i> 666 to 7731. <i>Mean:</i> 4905. <i>Standard Deviation:</i> 1413.
<i>WDGCUA22.</i> Variable for selecting distribution for general corrosion rate (low, medium, or high) (dimensionless). <i>Distribution:</i> Discrete. <i>Range:</i> 1 to 3.
<i>WDNSCC.</i> Stress corrosion cracking growth rate exponent (repassivation slope) (dimensionless). <i>Distribution:</i> Truncated normal. <i>Range:</i> 0.935 to 1.395. <i>Mean:</i> 1.165. <i>Standard Deviation:</i> 0.115.
<i>WDZOLID.</i> Deviation from median yield strength range for outer lid (dimensionless). <i>Distribution:</i> Truncated normal. <i>Range:</i> -3 to 3. <i>Mean:</i> 0. <i>Standard Deviation:</i> 1.

the presence of limited information have also been developed, including interval analysis, evidence theory, and possibility theory (e.g., [46–55]). As yet, these uncertainty structures have not been used in large-scale PAs.

6 Propagation and Display of Uncertainty

Two possibilities exist when the propagation and display of uncertainty are considered in a PA that involves a separation of aleatory uncertainty and epistemic uncertainty: (i) presentation of the effects of epistemic uncertainty conditional on a specific realization of aleatory uncertainty and (ii) presentation of the effects of aleatory uncertainty conditional on a specific realization of epistemic uncertainty. The presentation of the effects of epistemic uncertainty conditional on a specific realization of aleatory uncertainty is considered first.

Effects of epistemic uncertainty conditional on a specific realization of aleatory uncertainty. Epistemic uncertainty in an outcome of a PA conditional on a specific realization \mathbf{a} of aleatory uncertainty can be formally summarized with a cumulative distribution function (CDF) or a complementary cumulative distribution function (CCDF). For a real-valued analysis outcome $y = f(\tau|\mathbf{a}, \mathbf{e}_M)$, the CDF and CCDF for y resulting from epistemic uncertainty in \mathbf{e}_M are defined by

$$p_E(\tilde{y} \leq y|\mathbf{a}) = \int_{\mathcal{E}} \underline{\delta}_y[f(\tau|\mathbf{a}, \mathbf{e}_M)] d_E(\mathbf{e}_M) d\mathcal{E} \quad (44.10)$$

and

$$p_E(y < \tilde{y}|\mathbf{a}) = 1 - p_E(\tilde{y} \leq y|\mathbf{a}) = \int_{\mathcal{E}} \bar{\delta}_y[f(\tau|\mathbf{a}, \mathbf{e}_M)] d_E(\mathbf{e}_M) d\mathcal{E}, \quad (44.11)$$

respectively, where (i) \mathbf{e}_M is a vector of epistemically uncertain quantities affecting the function f as indicated in conjunction with Eq. (44.9), (ii) $d_E(\mathbf{e}_M)$ is the density function associated with the probability space that characterizes the epistemic uncertainty associated with \mathbf{e}_M , (iii) \mathcal{E} and $d_E(\mathbf{e}_M)$ are restricted to possible values for \mathbf{e}_M , and (iv)

$$\underline{\delta}_y(\tilde{y}) = \begin{cases} 1 & \text{for } \tilde{y} \leq y \\ 0 & \text{otherwise} \end{cases} \quad \bar{\delta}_y(\tilde{y}) = 1 - \underline{\delta}_y(\tilde{y}) = \begin{cases} 1 & \text{for } y \leq \tilde{y} \\ 0 & \text{otherwise.} \end{cases} \quad (44.12)$$

Specifically, plots of the points $[y, p_E(\tilde{y} \leq y|\mathbf{a})]$ and $[y, p_E(y \leq \tilde{y}|\mathbf{a})]$ define the CDF and CCDF for $y = f(\tau|\mathbf{a}, \mathbf{e}_M)$, with these plots being conditional on the vector \mathbf{a} from the sample space for aleatory uncertainty. In addition,

$$E_E(y|\mathbf{a}) = \int_{\mathcal{E}} f(\tau|\mathbf{a}, \mathbf{e}_M) d_E(\mathbf{e}_M) d\mathcal{E} \quad (44.13)$$

defines the expected value of $y = f(\tau|\mathbf{a}, \mathbf{e}_M)$ over epistemic uncertainty.

In most PAs, the integrals in Eqs. (44.10), (44.11) and (44.13) are too complex to estimate with formal quadrature procedures, with the result that these integrals are typically estimated with procedures based on simple random sampling or Latin hypercube sampling. In turn, the indicated sampling procedures result in estimates of the form

$$p_E(\tilde{y} \leq y|\mathbf{a}) \cong \sum_{k=1}^n \underline{\delta}_y[f(\tau|\mathbf{a}, \mathbf{e}_{Mk})]/n, \quad (44.14)$$

$$p_E(y < \tilde{y}|\mathbf{a}) \cong \sum_{k=1}^n \bar{\delta}_y[f(\tau|\mathbf{a}, \mathbf{e}_{Mk})]/n, \quad (44.15)$$

and

$$E_E(y|\mathbf{a}) \cong \sum_{k=1}^n f(\tau|\mathbf{a}, \mathbf{e}_{Mk})/n, \quad (44.16)$$

where \mathbf{e}_{Mk} , $k = 1, 2, \dots, n$, is a sample from \mathcal{E} obtained in consistency with the density function $d_E(\mathbf{e}_M)$ for epistemic uncertainty.

Dose (mrem/yr) to the reasonably maximally exposed individual (RMEI) determined in the 2008 YM PA under the assumption of nominal (i.e., undisturbed) conditions provides an illustration of the results formally defined in Eqs. (44.10–44.16). In the 2008 YM PA, nominal conditions correspond to the occurrence of the aleatory future \mathbf{a}_N defined in Eq. (44.4) for which no disruptions of any type occur (i.e., the future in which $nEW = nED = nII = nIE = nSG = nSF = 0$). The 2008 YM PA used a Latin hypercube sample (LHS)

$$\mathbf{e}_k = [\mathbf{e}_{Ak}, \mathbf{e}_{Mk}], k = 1, 2, \dots, n = 300, \quad (44.17)$$

of size 300 in the propagation of epistemic uncertainty [26, 56, 57]. Latin hypercube sampling operates in the following manner to generate a sample of size n from the distributions D_1, D_2, \dots, D_{nE} associated with the elements of $\mathbf{e} = [e_1, e_2, \dots, e_{nE}]$. The range of each variable e_l is divided into n disjoint intervals of equal probability, and one value e_{kl} is randomly selected from each interval. The n values for e_1 are randomly paired without replacement with the n values for e_2 to produce n pairs. These pairs are then randomly combined without replacement with the n values for e_3 to produce n triples. This process is continued until a set of $n nE$ -tuples $\mathbf{e}_k = [e_{k1}, e_{k2}, \dots, e_{knE}], k = 1, 2, \dots, n$, is obtained, with this set constituting the LHS. Owing to its efficient stratification properties, Latin hypercube sampling has also been used for the propagation of epistemic uncertainty in the 1996 WIPP PA [45], the NUREG-1150 probabilistic risk assessments for five nuclear power stations [3, 4], and many other analyses.

As indicated in Sect. 5, only elements of the vector \mathbf{e}_M in Eq. (44.17) are involved in this example for dose to the RMEI as the elements of the vector \mathbf{e}_A are involved in the definition of probability distributions related to the characterization of aleatory uncertainty. In consistency with the notation used in the 2008 YM PA, $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ is used to represent dose to the RMEI at time τ conditional on (i) the future corresponding to \mathbf{a}_N and (ii) the values for epistemically uncertain quantities contained in the vector \mathbf{e}_M . A complex sequence of calculations similar to those indicated in Fig. 44.2 is used to determine

$$D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk}) \text{ for } 0 \leq \tau \leq 10^6 \text{ yr and } k = 1, 2, \dots, n = 300. \quad (44.18)$$

In turn, approximations to the CDF, CCDF, and expected value for $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ as defined in Eqs. (44.14), (44.15) and (44.16) are given by

$$p_E[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M) \leq D] \cong \sum_{k=1}^{n=300} \underline{\delta}_D[D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk})]/n, \quad (44.19)$$

$$p_E[D < D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)] \cong \sum_{k=1}^{n=300} \bar{\delta}_D[D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk})]/n, \quad (44.20)$$

$$E_E[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)] \cong \sum_{k=1}^{n=300} D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk})/n, \quad (44.21)$$

and illustrated in Fig. 44.3a for $\tau = 600,000$ yr.

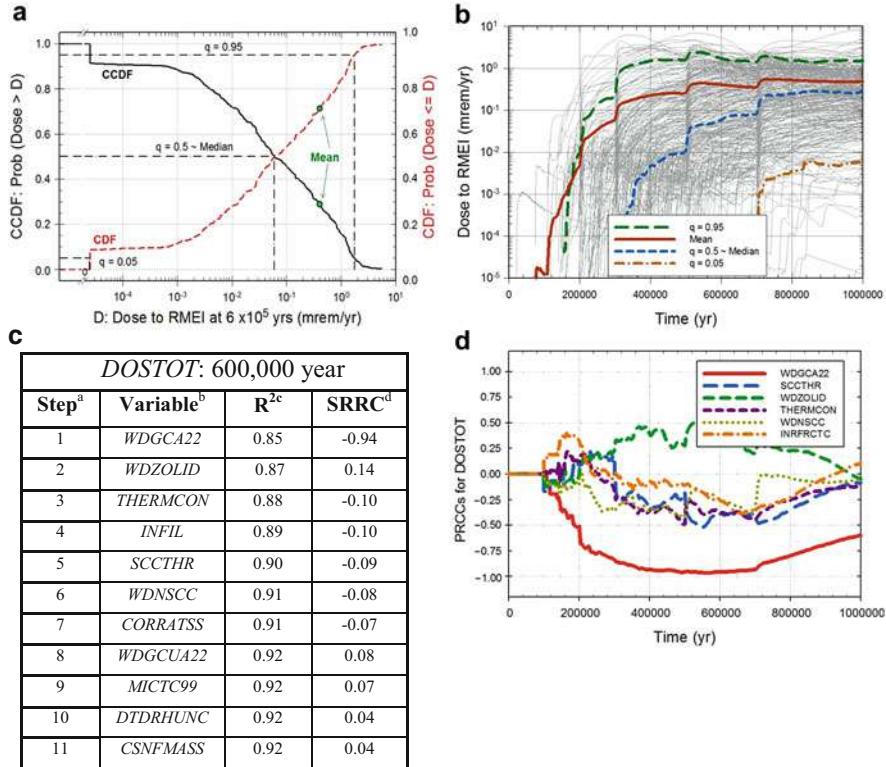

Also identified in Fig. 44.3a are selected quantile values for $q = 0.05, 0.5$, and 0.95 . Once a CDF is available, quantile values are easily determined as indicated in Fig. 44.3a by (i) starting at a desired quantile value q on the ordinate of the CDF plot, (ii) drawing a horizontal line to the CDF, and (iii) then dropping a vertical line to the abscissa to obtain the q -quantile of the variable under consideration. More formally and with the same notation as used in Eqs. (44.10–44.16), the q quantile value $Q_{Eq}[f(\tau|\mathbf{a}, \mathbf{e}_M)]$ for $y = f(\tau|\mathbf{a}, \mathbf{e}_M)$ conditional on \mathbf{a} and arising from the epistemic uncertainty associated with \mathbf{e}_M is the value of y such that

$$\begin{aligned} q &= \int_{\mathcal{E}} \underline{\delta}_y[f(\tau|\mathbf{a}, \mathbf{e}_M)] d_E(\mathbf{e}_M) d\mathcal{E} \\ &\cong \sum_{k=1}^n \underline{\delta}_y[f(\tau|\mathbf{a}, \mathbf{e}_{Mk})]/n. \end{aligned} \quad (44.22)$$

Specifically, the quantiles $Q_{Eq}[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)]$ for $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ at $\tau = 600,000$ yr indicated in Fig. 44.3a are defined by the values of D such that

$$q \cong \sum_{k=1}^{n=300} \underline{\delta}_D[D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk})]/n \quad (44.23)$$

for $q = 0.05, 0.5$, and 0.95 .

Fig. 44.3 Estimates obtained with an LHS of size $n = 300$ of the epistemic uncertainty in dose $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ to RMEI conditional on the realization \mathbf{a}_N of aleatory uncertainty corresponding to nominal conditions: (a) CDF and CCDF for $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ with $\tau = 600,000$ yr ([58], Fig. 1b); (b) individual results $D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk})$, $k = 1, 2, \dots, n$, and associated expected (mean) values $E_E[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)]$ and quantile values $Q_{E_q}[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)]$, $q = 0.05, 0.5, 0.95$, for $0 \leq \tau \leq 10^6$ yr ([58], Fig. 1a); (c) stepwise rank regressions for $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ at $\tau = 600,000$ yr ([33], Table 10); and (d) partial rank correlation coefficients (PRCCs) for $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ for $0 \leq \tau \leq 10^6$ yr ([33], Fig. 23b)

As is the case for many PA results, $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ is a function of time. Specifically, $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ is determined for $0 \leq \tau \leq 10^6$ yr in the 2008 YM PA. Although plots of the form shown in Fig. 44.3a provide a complete display of the effects of epistemic uncertainty at the time under consideration (e.g., $\tau = 600,000$ yr in Fig. 44.3a), they are not practical for displaying the effects of epistemic uncertainty at a large number of times. In such situations, an effective presentation format is to use a single plot to present both (i) the

individual results $f(\tau|\mathbf{a}, \mathbf{e}_M), k = 1, 2, \dots, n$, calculated for the time interval $t_{mn} \leq \tau \leq t_{mx}$ under consideration and (ii) the expected value $E_E[f(\tau|\mathbf{a}, \mathbf{e}_M)]$ and selected quantile values $Q_{Eq}[f(\tau|\mathbf{a}, \mathbf{e}_M)]$ for $f(\tau|\mathbf{a}, \mathbf{e}_M)$ also calculated for the time interval $t_{mn} \leq \tau \leq t_{mx}$. As an example, this presentation format is illustrated in Fig. 44.3b for $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ and $0 \leq \tau \leq 10^6$ yr, where (i) the lighter lines correspond to the results $D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk}), k = 1, 2, \dots, n = 300$, calculated as indicated in conjunction with Eq. (44.18) and (ii) the heavier lines correspond to the expected value $E_E[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)]$ calculated as indicated in Eq. (44.21) and the quantiles $Q_{Eq}[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)], q = 0.05, 0.5, 0.95$, calculated as indicated in Eq. (44.23). The presentation format illustrated in Fig. 44.3b provides an effective way to present a large amount of information in a small amount of space. The sensitivity analysis results in Fig. 44.3c and d are discussed in Sect. 7.

Latin hypercube sampling and the propagation of epistemic uncertainty. Latin hypercube sampling was developed for use in the analysis of computationally demanding analysis structures for which computational demands severely limit the number of system simulations that can be performed ([56]; [59], App. A). As a result, the LHS size in use in such analyses is often perceived as being small relative to the number of epistemically uncertain variables being sampled (e.g., an LHS of size 100 from 57 variables in the 1996 WIPP PA and an LHS of size 300 from 392 variables in the 2008 YM PA). In response to this concern, a replicated sampling procedure has been developed to provide a way to assess the adequacy of the LHS size used in the analysis of a complex and computationally demanding analysis structure ([60]; [45], Sect. 7). Specifically, the goal of the procedure is to determine how much variability exists in estimated analysis outcomes when different LHSs of size n are used.

The procedure is based on independently generating LHSs of size n with different random seeds nR times. At an intuitive level, the adequacy of the sample size can be assessed by simply comparing the results obtained with the individual samples. At a more formal level, the t -distribution can be used to place confidence intervals around summary results (e.g., expected values over epistemic uncertainty) obtained from individual samples. Specifically, assume that the LHS has been replicated nR times to produce $r = 1, 2, \dots, nR$ independently generated LHSs

$$\mathbf{e}_{rk} = [\mathbf{e}_{A_{rk}}, \mathbf{e}_{M_{rk}}], k = 1, 2, \dots, n, \quad (44.24)$$

of size n and that C_r is an analysis result of interest obtained for replicated sample r . For example, C might be the expected value $E_E[f(\tau|\mathbf{a}, \mathbf{e}_M)]$ at time τ that is estimated with the use of Latin hypercube sampling, and $C_r = E_{Er}[f(\tau|\mathbf{a}, \mathbf{e}_M)]$ would be the estimate for $C = E_E[f(\tau|\mathbf{a}, \mathbf{e}_M)]$ obtained with replicated sample r . Then,

$$\bar{C} = \sum_{r=1}^{nR} C_r / nR \text{ and } SE(\bar{C}) = \left\{ \sum_{r=1}^{nR} [C_r - \bar{C}]^2 / nR(nR - 1) \right\}^{1/2} \quad (44.25)$$

provide an additional estimate of C and an estimate of the standard error associated with this additional estimate. The t -distribution with $nR - 1$ degrees of freedom can now be used to place confidence intervals around the estimate \bar{C} for C in Eq. (44.25). Specifically, the $1 - \alpha$ confidence interval for C is given by $\bar{C} \pm t_{1-\alpha/2}SE(\bar{C})$, where $t_{1-\alpha/2}$ is the $1 - \alpha/2$ quantile of the t -distribution with $nR - 1$ degrees of freedom. For example, $t_{1-\alpha/2} = 4.303$ for $\alpha = 0.05$ and $nR = 3$.

The 2008 YM PA used $nR = 3$ replicated LHSs of size 300 to assess the adequacy of an LHS of size 300 from the 392 epistemically uncertain variables under consideration. As an example, the results obtained for $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ are shown in Fig. 44.4. Specifically, the results for the individual replicates (i.e., $E_{Er}[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)]$ and $Q_{Eqr}[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)]$ for $q = 0.05, 0.5, 0.95$) are shown in Fig. 44.4a, and the time-dependent 95% confidence intervals for $E_E[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)]$ are shown in Fig. 44.4b. As indicated by the results in Fig. 44.4, an LHS of size 300 is adequate for assessing the epistemic uncertainty present in estimates for $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$. There is a substantial amount of variability in the LHS results prior to about 300,000 yr; however, this is due to the presence of results that are either 0 or so small as to be below the resolution of the calculation (see Fig. 44.3b).

As part of the 2008 YM PA, the effects of sample size for a large number of different analysis outcomes were assessed with the three indicated replicated LHSs (e.g., see [30], Fig. 10; [31], Figs. 10 and 19; [32], Figs. 11 and 23; [61], Figs. 5 and 10; [62]). In each case, an LHS of size 300 is adequate for assessing the epistemic uncertainty present in the analysis outcome under consideration.

Another approach to assess sample size adequacy is to observe the results obtained with a sequence of LHSs of increasing size. An adequate sample size then corresponds to the sample size at which estimates of the analysis results of primary interest stabilize with respect to increasing sample size (e.g., [63], Figs. 13 and 14). Unlike simple random sampling, the size of an LHS cannot be extended by sampling additional sample elements without consideration of the sample elements already present in the sample. However, a technique does exist to extend an LHS of a given size to an LHS of a larger size [64].

Another concern that arises from the small sample sizes used with Latin hypercube sampling is that these small sample sizes could result in spurious correlations between variables within a sample. However, this problem can be controlled with a restricted pairing technique developed by Iman and Conover to control rank correlations between variables within random samples and LHSs [65, 66]. Specifically, this technique can be used to insure that a sample has (i) rank correlations close to zero for uncorrelated variables and (ii) desired rank correlations between correlated variables.

Effects of aleatory uncertainty conditional on a specific realization of epistemic uncertainty. The formal representation of the effects of aleatory uncertainty conditional on a specific realization of epistemic uncertainty is similar to the formal

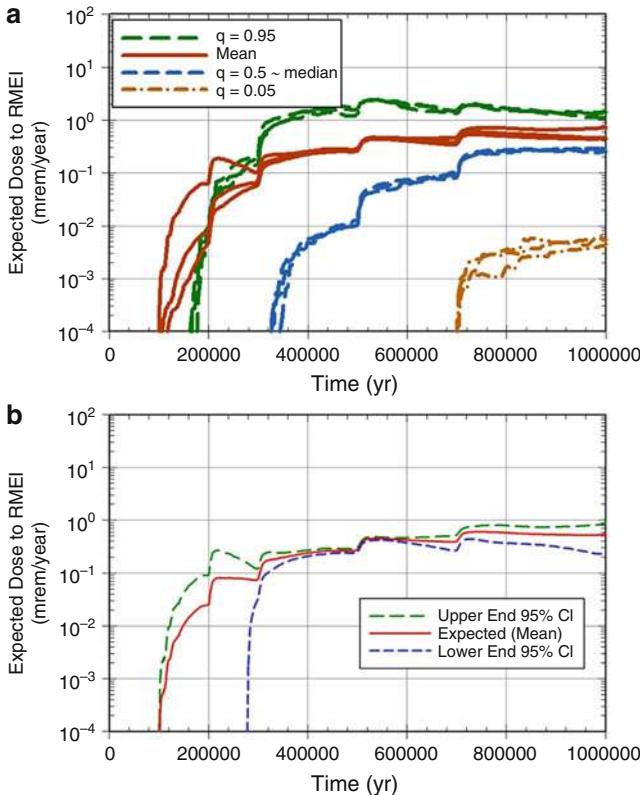

Fig. 44.4 Illustration of replicated sampling to determine the adequacy of an LHS of size 300 for the assessment of the epistemic uncertainty present in estimates for the dose $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ to the RMEI conditional on undisturbed (i.e., nominal) repository conditions as indicated by the vector \mathbf{a}_N ([58], Fig. 4): (a) expected values $E_{E_T}[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)]$ and quantiles $Q_{Eqr}[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)], q = 0.05, 0.5, 0.95$, for $D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)$ obtained for each of the three replicated samples indicated in Eq. (44.24) and (b) time-dependent 95% confidence intervals (i.e., for $\alpha = 0.05$) for $E_E[D_N(\tau|\mathbf{a}_N, \mathbf{e}_M)]$ obtained as indicated in conjunction with Eq. (44.25)

representation of the effects of epistemic uncertainty conditional on a specific realization of aleatory uncertainty but with the roles of the probability spaces for epistemic uncertainty and aleatory uncertainty reversed. Specifically, aleatory uncertainty in an outcome of a PA conditional on a specific realization $\mathbf{e} = [\mathbf{e}_A, \mathbf{e}_M]$ of epistemic uncertainty can be formally summarized with a CDF or a CCDF. For a real-valued analysis outcome $y = f(\tau|\mathbf{a}, \mathbf{e}_M)$, the CDF and CCDF for y resulting from aleatory uncertainty are defined by

$$p_A(\tilde{y} \leq y|\mathbf{e}) = \int_{\mathcal{A}} \delta_y [f(\tau|\mathbf{a}, \mathbf{e}_M)] d_A(\mathbf{a}|\mathbf{e}_A) d\mathcal{A} \quad (44.26)$$

and
