$$p_A(y < \tilde{y}|\mathbf{e}) = 1 - p_A(\tilde{y} \leq y|\mathbf{e}) = \int_{\mathcal{A}} \bar{\delta}_y [f(\tau|\mathbf{a}, \mathbf{e}_M)] d_A(\mathbf{a}|\mathbf{e}_A) d\mathcal{A}, \quad (44.27)$$

respectively, where (i) \mathbf{a} is a vector defining one realization of aleatory uncertainty, (ii) $d_A(\mathbf{a}|\mathbf{e}_A)$ is the density function conditional on \mathbf{e}_A associated with the probability space that characterizes the aleatory uncertainty associated with \mathbf{a} , and (iii) $\underline{\delta}_y(\tilde{y})$ and $\bar{\delta}_y(\tilde{y})$ are defined the same as in Eq.(44.12). In turn, plots of the points $[y, p_A(\tilde{y} \leq y|\mathbf{e})]$ and $[y, p_A(y \leq \tilde{y}|\mathbf{e})]$ define the CDF and CCDF for $y = f(\tau|\mathbf{a}, \mathbf{e}_M)$, with these plots being conditional on the vector $\mathbf{e} = [\mathbf{e}_A, \mathbf{e}_M]$ from the sample space for epistemic uncertainty. Similarly,

$$E_A(y|\mathbf{e}) = \int_{\mathcal{A}} f(\tau|\mathbf{a}, \mathbf{e}_M) d_A(\mathbf{a}|\mathbf{e}_A) d\mathcal{A} \quad (44.28)$$

defines the expected value of $y = f(\tau|\mathbf{a}, \mathbf{e}_M)$ over aleatory uncertainty.

In most PAs, the integrals in Eqs. (44.26), (44.27) and (44.28) are too complex to estimate with formal quadrature procedures, with the result that these integrals are typically estimated with procedures based on some variant of random sampling or stratified sampling. In turn, the indicated sampling procedures result in estimates of the form

$$p_A(\tilde{y} \leq y|\mathbf{e}) \cong \begin{cases} \sum_{i=1}^m \underline{\delta}_y [f(\tau|\mathbf{a}_i, \mathbf{e}_M)] / m \\ \sum_{i=1}^{\tilde{m}} \underline{\delta}_y [f(\tau|\tilde{\mathbf{a}}_i, \mathbf{e}_M)] p_A(\mathcal{A}_i|\mathbf{e}_A), \end{cases} \quad (44.29)$$

$$p_A(y < \tilde{y}|\mathbf{e}) \cong \begin{cases} \sum_{i=1}^m \bar{\delta}_y [f(\tau|\mathbf{a}_i, \mathbf{e}_M)] / m \\ \sum_{i=1}^{\tilde{m}} \bar{\delta}_y [f(\tau|\tilde{\mathbf{a}}_i, \mathbf{e}_M)] p_A(\mathcal{A}_i|\mathbf{e}_A), \end{cases} \quad (44.30)$$

and

$$E_A(y|\mathbf{e}) \cong \begin{cases} \sum_{i=1}^m f(\tau|\mathbf{a}_i, \mathbf{e}_M) / m \\ \sum_{i=1}^{\tilde{m}} f(\tau|\tilde{\mathbf{a}}_i, \mathbf{e}_M) p_A(\mathcal{A}_i|\mathbf{e}_A), \end{cases} \quad (44.31)$$

where (i) $\mathbf{a}_i, i = 1, 2, \dots, m$, is a sample from \mathcal{A} generated in consistency with the density function $d_A(\mathbf{a}|\mathbf{e}_A)$ for aleatory uncertainty and (ii) the sets (i.e., strata) $\mathcal{A}_i, i = 1, 2, \dots, \tilde{m}$, satisfy $\cup_i \mathcal{A}_i = \mathcal{A}$ with $\mathcal{A}_i \cap \mathcal{A}_j = \emptyset$ for $i \neq j$, $\tilde{\mathbf{a}}_i$ is a representative element of \mathcal{A}_i , and $p_A(\mathcal{A}_i|\mathbf{e}_A)$ is the probability of \mathcal{A}_i . The summations with \mathbf{a}_i and $\tilde{\mathbf{a}}_i$ correspond to approximations with simple random or quasi-random sampling and stratified sampling, respectively.

Use of the approximations with the sets \mathcal{A}_i and associated values $\tilde{\mathbf{a}}_i$ in Eqs. (44.29), (44.30) and (44.31) corresponds to use of the ordered triple representation for risk in Eq.(44.1) with $\mathcal{S}_i = \mathcal{A}_i$, $p_{\mathcal{S}_i} = p_A(\mathcal{A}_i|\mathbf{e}_A)$, and $c_{\mathcal{S}_i} = f(\tau|\tilde{\mathbf{a}}_i, \mathbf{e}_M)$. In effect, representations of this form are being employed when an event tree is used to represent the effects of aleatory uncertainty, with each path

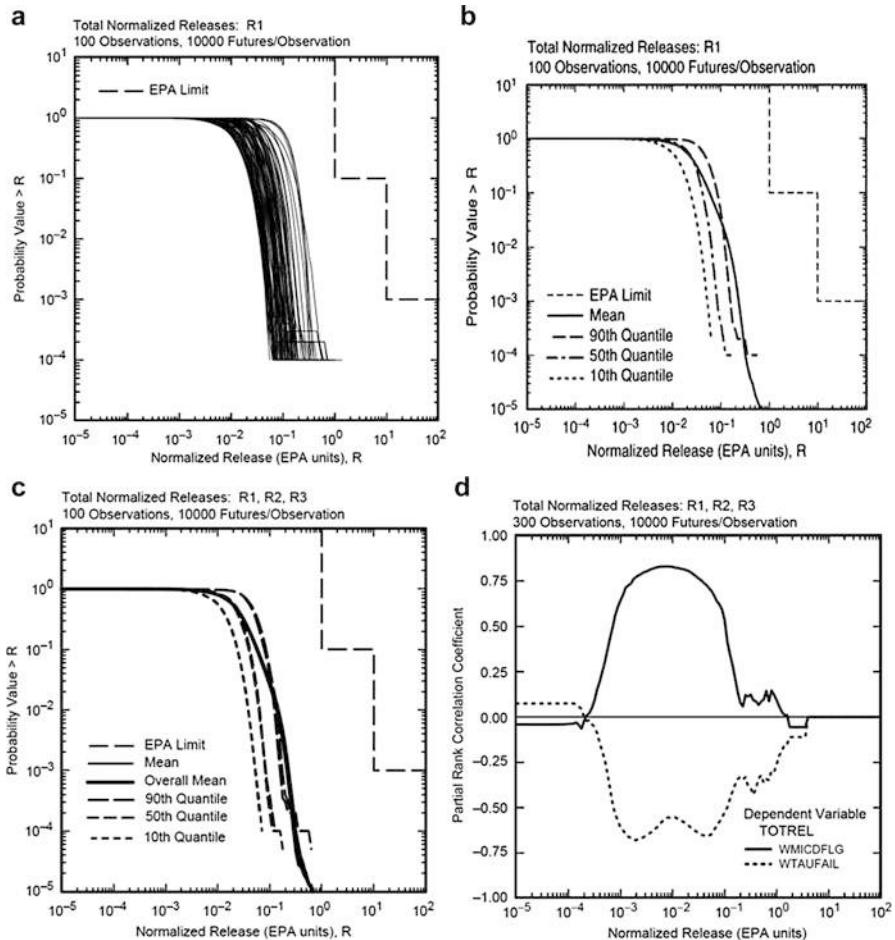

Fig. 44.5 Distribution of CCDFs for normalized release to the accessible environment over 10^4 yr obtained in the 1996 WIPP PA: (a) individual CCDFs for LHS of size 100 ([67], Fig. 1a), (b) mean and quantile curves for CCDFs in Frame a ([67], Fig. 1b), (c) replicated mean and quantile curves for CCDFs in Frame a for three independent LHSs (i.e., R1, R2, R3) of size 100 ([67], Fig. 2a), and (d) partial rank correlation coefficients (PRCCs) for all 300 CCDFs used to generate results in Frame c ([67], Fig. 5)

through the tree being used to both define one set \mathcal{A}_i and determine the probability of this set.

As an example, the CCDFs for normalized radionuclide release to the accessible environment obtained in the 1996 WIPP PA are shown in Fig. 44.5a. In this example, the individual CCDFs are calculated as indicated in Eq. (44.30) with a random sample of size 10^4 from the sample space for aleatory uncertainty, and the distribution of CCDFs results from repeating this calculation for each element $\mathbf{e}_k = [\mathbf{e}_{Ak}, \mathbf{e}_{Mk}]$ of an LHS of size $n = 100$ from the sample space for epistemic

uncertainty (see Ref. [67] for computational details). As indicated immediately after Eq. (44.27), each CCDF in Fig. 44.5a is a plot of points of the form $[y, p_A(y \leq \tilde{y}|\mathbf{e}_k)]$ with y corresponding to normalized release R at 10,000 yr. Specifically, the indicated release is the integrated (i.e., total) release that takes place from repository closure (i.e., time 0 yr) out to 10,000 yr; thus, in the formal model representation $f(\tau|\mathbf{a}, \mathbf{e}_M)$ used in Eqs. (44.10–44.31), the time variable τ corresponds to 10,000 yr in Fig. 44.5a.

Displays of the form shown in Fig. 44.5a provide a visual impression of the effects of epistemic uncertainty in the determination of the presented results. A more quantitative presentation of the effects of epistemic uncertainty is provided by a plot of the expected value and selected quantile values (e.g., $q = 0.05, 0.5, 0.95$) for the exceedance probabilities associated with individual values on the abscissa (e.g., normalized release R as in Fig. 44.5a). In general and with the same notation as used in Eqs. (44.29), (44.30) and (44.31), the indicated expected value $E_E[p_A(y < \tilde{y}|\mathbf{e})]$ is given by

$$\begin{aligned} E_E[p_A(y < \tilde{y}|\mathbf{e})] &= \int_{\mathcal{E}} \left\{ \int_{\mathcal{A}} \bar{\delta}_y [f(\tau|\mathbf{a}, \mathbf{e}_M)] d_A(\mathbf{a}|\mathbf{e}) d\mathcal{A} \right\} d_E(\mathbf{e}) d\mathcal{E} \\ &\cong \begin{cases} \sum_{k=1}^n \left\{ \sum_{i=1}^m \bar{\delta}_y [f(\tau|\mathbf{a}_i, \mathbf{e}_{Mk})] / m \right\} / n \\ \sum_{k=1}^n \left\{ \sum_{i=1}^{\tilde{m}} \bar{\delta}_y [f(\tau|\tilde{\mathbf{a}}_i, \mathbf{e}_{Mk})] p_A(\mathcal{A}_i|\mathbf{e}_{Ak}) \right\} / n \end{cases} \quad (44.32) \end{aligned}$$

and the q quantile value $Q_{Eq}[p_A(y < \tilde{y}|\mathbf{e})]$ is the value of $p = p_A(y < \tilde{y}|\mathbf{e})$ such that

$$\begin{aligned} q &= \int_{\mathcal{E}} \underline{\delta}_p [p_A(y < \tilde{y}|\mathbf{e})] d_E(\mathbf{e}) d\mathcal{E} \\ &= \int_{\mathcal{E}} \underline{\delta}_p \left\{ \int_{\mathcal{A}} \bar{\delta}_y [f(\tau|\mathbf{a}, \mathbf{e}_M)] d_A(\mathbf{a}|\mathbf{e}_A) d\mathcal{A} \right\} d_E(\mathbf{e}) d\mathcal{E} \\ &\cong \begin{cases} \sum_{k=1}^n \underline{\delta}_p \left\{ \sum_{i=1}^m \bar{\delta}_y [f(\tau|\mathbf{a}_i, \mathbf{e}_{Mk})] / m \right\} / n \\ \sum_{k=1}^n \underline{\delta}_p \left\{ \sum_{i=1}^{\tilde{m}} \bar{\delta}_y [f(\tau|\tilde{\mathbf{a}}_i, \mathbf{e}_{Mk})] p_A(\mathcal{A}_i|\mathbf{e}_{Ak}) \right\} / n. \end{cases} \quad (44.33) \end{aligned}$$

As an example, mean and quantile (i.e., percentile) results for the CCDFs in Fig. 44.5a are presented in Fig. 44.5b.

Results analogous to those illustrated in Fig. 44.5a, b can also be obtained and presented for CDFs. However, CCDFs rather than CDFs usually provide the preferred presentation format for results obtained in PAs for two reasons. First, CCDFs provide an answer to questions of the form “How likely is it to be this bad

or worse?”, which is typically the type of question of most interest in a PA. Second, CCDFs facilitate the display of the probabilities associated with low probability but high consequence aleatory occurrences (especially when a \log_{10} scale is used on the ordinate); in contrast, such probabilities are difficult to obtain from a CDF owing to the lack of resolution in displayed probabilities as cumulative probability approaches 1.0.

As previously indicated, the 1996 WIPP PA used an LHS of size 100 in the propagation of epistemic uncertainty. To assess the adequacy of this sample size, the analysis was repeated with three replicated LHSs of size 100 denoted R1, R2, and R3. As shown in Fig. 44.5c, there is little variability in the results obtained with the individual replicated samples. The sensitivity analysis results with PRCCs in Fig. 44.5d are discussed in Sect. 7.

An interesting potential regulatory requirement is also illustrated in Fig. 44.5a, b. The two-step boundary labeled “EPA limit” in the upper right corner of Fig. 44.5a derives from a licensing regulation for the WIPP established by the US Environmental Agency (EPA) which requires for the time interval $[0, 10^4 \text{ yr}]$ after repository closure that (i) the probability of exceeding a normalized release of size $R = 1.0$ shall be less than 0.1 and (ii) the probability of exceeding a normalized release of size $R = 10.0$ shall be less than 0.001. As specified by the EPA, the indicated requirement is violated if the mean CCDF in Fig. 44.5b crosses the indicated boundary line (see Ref. [24] for additional details). A requirement of this type places stronger restrictions on system outcomes as the severity of these outcomes increases and is known as the Farmer limit line approach to the definition of acceptable risk [68–70].

An additional example of the representation of the effects of aleatory uncertainty conditional on a specific realization of epistemic uncertainty is provided by the treatment in the 2008 YM PA of expected dose $E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]$ over aleatory uncertainty to the RMEI conditional on a realization $\mathbf{e} = [\mathbf{e}_A, \mathbf{e}_M]$ of epistemic uncertainty. In the preceding, $D(\tau|\mathbf{a}, \mathbf{e}_M)$ represents dose (mrem/yr) to the RMEI at time τ (yr) conditional on the “future” defined by the vector \mathbf{a} of aleatory quantities (see Eq. (44.4)) and the vector \mathbf{e}_M of epistemically uncertain quantities (see Table 44.3) used in the calculation of dose to the RMEI; and $E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]$ is defined as indicated in Eq. (44.28). Specifically,

$$E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)] = \int_{\mathcal{A}} D(\tau|\mathbf{a}, \mathbf{e}_M) d_A(\mathbf{a}|\mathbf{e}_A) d\mathcal{A}. \quad (44.34)$$

The time-dependent expected values $E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]$ for $D(\tau|\mathbf{a}, \mathbf{e}_M)$ were estimated for the time intervals $[0, 20,000 \text{ yr}]$ and $[0, 10^6 \text{ yr}]$ for each of the LHS sample elements $\mathbf{e}_k = [\mathbf{e}_{Ak}, \mathbf{e}_{Mk}]$ indicated in Eq. (44.17).

The resultant expected dose curves $[\tau, E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]], k = 1, 2, \dots, n = 300$, the associated curves for the quantiles $Q_{Eq}\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}, q = 0.05, 0.5, 0.95$, and the expected value $E_E\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ for dose over aleatory and epistemic uncertainty are shown in Fig. 44.6a. The quantities $E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]$ and $E_E\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ are both expected doses but with

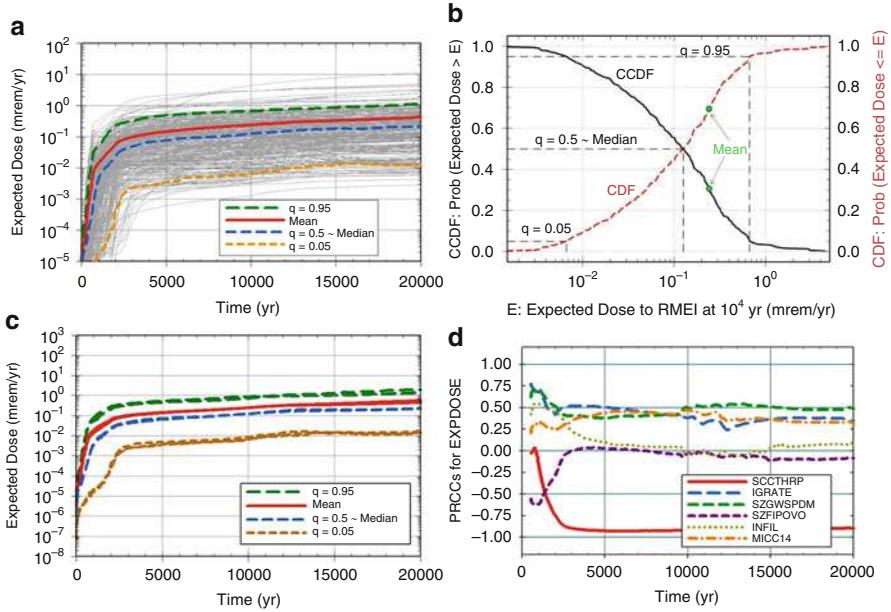

Fig. 44.6 Estimates obtained with an LHS of size $n = 300$ of expected dose $E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]$ to the RMEI in the 2008 YM PA for the time interval $[0, 20,000]$ yr: (a) expected dose $E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]$, $k = 1, 2, \dots, n = 300$, expected (mean) dose $E_E\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$, and quantiles $Q_{E_q}\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$, $q = 0.05, 0.5, 0.95$ ([61], Fig. 1a); (b) cumulate probabilities $p_E\{E_A[D(10^4|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A] \leq D\}$, exceedance probabilities $p_E\{D < E_A[D(10^4|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$, expected (mean) dose $E_E\{E_A[D(10^4|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$, and quantiles $Q_{E_q}\{E_A[D(10^4|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$, $q = 0.05, 0.5, 0.95$, for $\tau = 10^4$ yr ([61], Fig. 1b); (c) estimates of $E_E\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ and $Q_{E_q}\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$, $q = 0.05, 0.5, 0.95$, obtained with three replicated LHSs of size $n = 300$ as indicated in Eq. (44.24) ([61], Fig. 5); and (d) partial rank correlation coefficients (PRCCs) for $E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]$ ([61], Fig. 6)

expectations calculated with respect to different probability spaces. In consistency with regulatory requirements that place bounds on $E_E\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ for the YM repository, the 2008 YM PA refers to $E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]$ and $E_E\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ as “expected dose” and “expected (mean) dose,” respectively [26]. A more detailed summary of the distribution results for $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ at $\tau = 10^4$ yr is presented in Fig. 44.6b, and the stability of the results obtained with the three replicated LHSs of size 300 is illustrated in Fig. 44.6c by the similarity of the resultant plots for estimates of $Q_{Eq}\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$, $q = 0.05, 0.5, 0.95$, and $E_E\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$. The sensitivity analysis results in Fig. 44.6d are discussed in Sect. 7.

The numerics of determining the expected doses $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ in Fig. 44.6a are quite complicated and will be discussed briefly after this paragraph. Once the expected doses $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ are available, the estimation of $Q_{Eq}\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ and $E_E\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ is straightforward.

Specifically, $Q_{Eq}\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ corresponds to the value y defined and approximated by

$$\begin{aligned} q &= \int_{\mathcal{E}} \delta_y \{E_A [D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\} d_E(\mathbf{e}) d\mathcal{E} \\ &\cong \sum_{k=1}^n \delta_y \{E_A [D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]\} / n, \end{aligned} \quad (44.35)$$

and $E_E\{E_A[D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ is defined and approximated by

$$\begin{aligned} E_E \{E_A [D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\} &= \int_{\mathcal{E}} E_A [D(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A] d_E(\mathbf{e}) d\mathcal{E} \\ &\cong \sum_{k=1}^n E_A [D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}] / n. \end{aligned} \quad (44.36)$$

Similarly, $Q_{Eq}\{E_A[y(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ and $E_E\{E_A[y(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ for an arbitrary analysis result $y(\tau|\mathbf{a}, \mathbf{e}_M)$ are defined and approximated as indicated in Eqs. (44.35) and (44.36) with $y(\tau|\mathbf{a}, \mathbf{e}_M)$ and $y(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ replacing $D(\tau|\mathbf{a}, \mathbf{e}_M)$ and $D(\tau|\mathbf{a}, \mathbf{e}_{Mk})$.

The numerics of determining the expected doses $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ are now considered. In concept, $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ can be approximated by

$$E_A [D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_A] \cong \sum_{i=1}^m D(\tau|\mathbf{a}_i, \mathbf{e}_{Mk}) / m, \quad (44.37)$$

where $\mathbf{a}_i, i = 1, 2, \dots, m$, is a sample from the probability space \mathcal{A} for aleatory uncertainty (see Eq. (44.4)) generated in consistency with the density function $d_A(\mathbf{a}|\mathbf{e}_A)$. As is the case in many complex analyses, the overall structure of the 2008 YM PA was too complex (see Eq. (44.4) and Fig. 44.2) for this sampling-based approach for the estimation of $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ to be practicable. In such situations, it is necessary to (i) decompose the analysis into a number of intermediate calculations smaller than a complete calculation of the result of interest (e.g., $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ in Eq. (44.37) and Fig. 44.6) and then (ii) combine these intermediate results in a computationally efficient manner to obtain the final result of interest. The indicated combination of intermediate results involves taking advantage of computational efficiencies that derive from specific properties of the analysis and can include (i) division of the original integral over the sample space \mathcal{A} for aleatory uncertainty into a sum of integrals over subsets of \mathcal{A} ; (ii) use of additivity, linearity, and interpolations in conjunction with intermediate results to obtain additional results; and (iii) development of one or more metamodels that are approximations to the original model.

In the 2008 YM PA, the first step in the evaluation of $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ was to divide the defining integral for $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ in Eq. (44.34) into a sum of integrals over selected subsets of the sample space \mathcal{A} for aleatory uncertainty. These subsets are referred to as scenario classes (and sometimes as modeling cases) in the 2008 YM PA and are denoted and defined with the notation used in Eqs. (44.4–44.7) by (i) $\mathcal{A}_{EW} = \{\mathbf{a}|\mathbf{a} \in \mathcal{A} \text{ and } nEW \geq 1\}$ for the early WP failure scenario class, (ii) $\mathcal{A}_{ED} = \{\mathbf{a}|\mathbf{a} \in \mathcal{A} \text{ and } nED \geq 1\}$ for the early DS failure scenario class, (iii) $\mathcal{A}_{II} = \{\mathbf{a}|\mathbf{a} \in \mathcal{A} \text{ and } nII \geq 1\}$ for the igneous intrusion scenario class, (iv) $\mathcal{A}_{IE} = \{\mathbf{a}|\mathbf{a} \in \mathcal{A} \text{ and } nIE \geq 1\}$ for the igneous eruption scenario class, (v) $\mathcal{A}_{SG} = \{\mathbf{a}|\mathbf{a} \in \mathcal{A} \text{ and } nSG \geq 1\}$ for the seismic ground motion scenario class, (vi) $\mathcal{A}_{SF} = \{\mathbf{a}|\mathbf{a} \in \mathcal{A} \text{ and } nSF \geq 1\}$ for the seismic fault displacement scenario class, and (vii) $\mathcal{A}_N = \{\mathbf{a}|\mathbf{a} \in \mathcal{A} \text{ and } nEW = nED = nII = nIE = nSG = nSF = 0\} = \{\mathbf{a}_N\}$ for the nominal scenario class. In turn, the indicated sum of integrals is given by

$$\begin{aligned} & E_A [D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}] \\ &= \int_{\mathcal{A}} D(\tau|\mathbf{a}, \mathbf{e}_{Mk}) d_A(\mathbf{a}|\mathbf{e}_{Ak}) d\mathcal{A} \\ &\cong D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk}) + \sum_{C \in \mathcal{MC}} \int_{\mathcal{A}_C} D_C(\tau|\mathbf{a}, \mathbf{e}_{Mk}) d_A(\mathbf{a}|\mathbf{e}_{Ak}) d\mathcal{A} \quad (44.38) \\ &= D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk}) + \sum_{C \in \mathcal{MC}} \int_{\mathcal{A}_C} D_C(\tau|\mathbf{a}, \mathbf{e}_{Mk}) d_A(\mathbf{a}|\mathbf{e}_{Ak}) d\mathcal{A} \\ &= D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk}) + \sum_{C \in \mathcal{MC}} E_A [D_C(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}], \end{aligned}$$

with (i) $\mathcal{MC} = \{EW, ED, II, IE, SG, SF\}$ and (ii) the doses $D_C(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ for scenario class \mathcal{A}_C calculated with use of only the elements of \mathbf{a} and $\mathbf{e} = [\mathbf{e}_A, \mathbf{e}_M]$ that constitute part of the defining conditions for scenario class \mathcal{A}_C (i.e., early WP failure, early DS failure, igneous intrusion, igneous eruption, seismic ground motion, and seismic fault displacement). The preceding approximation to $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ was justified for use in the 2008 YM PA on the basis of trade-offs between the effects of high probability-low consequence scenario classes and low probability-high consequence scenario classes ([61], Sect. 5).

Use of the decomposition in Eq. (44.38) reduces the determination of $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ from the evaluation of a single very complex integral to the evaluations of (i) $D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk})$ and (ii) six individual integrals (i.e., one integral for each element of the set \mathcal{MC}). The six integrals for $D_C(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ over \mathcal{A}_C for $C \in \mathcal{MC}$ that need to be evaluated are still complex, but less complex than a single integral for $D(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ over \mathcal{A} . The advantage of the decomposition in Eq. (44.38) is that the integrals for $D_C(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ over \mathcal{A}_C for $C \in \mathcal{MC}$ can be implemented in ways that obtain computational efficiencies that take advantage of specific properties of the dose function $D_C(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ and the restriction of the density function to the set \mathcal{A}_C for scenario class C .

As a single example, a summary description of the evaluation of $D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ over the time interval [0, 20,000 yr] for the seismic ground motion scenario class will be used for illustration; a full description of the analysis for $D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ is given in Refs. [32, 71, 72]. In effect, the consideration of only seismic ground motion events reduces the sample space \mathcal{A} for aleatory uncertainty to the previously indicated set \mathcal{A}_{SG} with elements \mathbf{a} defined by

$$\mathbf{a} = [n_{SG}, t_1, v_1, A_1, t_2, v_2, A_2, \dots, t_{n_{SG}}, v_{n_{SG}}, A_{n_{SG}}], \quad (44.39)$$

where (i) n_{SG} = number of seismic ground motion events in 20,000 yr, (ii) t_i = time (yr) of event i , (iii) v_i = peak ground motion velocity (m/s) for event i , (iv) A_i = damaged area (m^2) on individual WPs for peak ground motion velocity v_i , (v) the occurrence of seismic ground motion events is characterized by a hazard curve for peak ground motion velocity, and (vi) damaged area is characterized by distributions conditional on peak ground motion velocity. In effect, \mathcal{A}_{SG} is the sample space for aleatory uncertainty when only seismic ground motion events are considered over the time interval [0, 20,000 yr].

To evaluate $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$, it is necessary to integrate the function $D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ over the set \mathcal{A}_{SG} with \mathbf{a} defined as indicated in Eq. (44.39). In full detail, $D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ is defined by the model system indicated in Fig. 44.2. Evaluation of this system is too computationally demanding to permit its evaluation 1000's of times for each element $\mathbf{e}_k = [\mathbf{e}_{Ak}, \mathbf{e}_{Mk}]$ of the LHS in Eq. (44.17). This is a common situation in analyses of complex systems, where very detailed physical models are developed which then turn out to be too computationally demanding to be naively used in the propagation of aleatory uncertainty. In such situations, it is necessary to find ways to efficiently use the results of a limited number of model evaluations to predict outcomes for a large number of different possible realizations of aleatory uncertainty.

For the seismic ground motion scenario class and the time interval [0, 20,000 yr], the needed computational efficiency was achieved by evaluating $D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ at a sequence of seismic event times (i.e., 100, 1000, 3000, 6000, 12,000, 18,000 yrs) and for a sequence of damaged areas (i.e., 10^{-8+s} (32.6 m^2) for $s = 1, 2, \dots, 5$ with 32.6 m^2 corresponding to the surface area of a WP) at each of the indicated times (Fig. 44.7a). This required $6 \times 5 = 30$ evaluations of the system indicated in Fig. 44.2 for each LHS element in Eq. (44.17). Once obtained, these evaluations can be used with appropriate interpolation and additive procedures to evaluate $D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ for different values of \mathbf{a} for each LHS element $\mathbf{e}_k = [\mathbf{e}_{Ak}, \mathbf{e}_{Mk}]$ (see Ref. [32], Sect. 4, for computational details).

The individual CCDFs in Fig. 44.7b are defined by probabilities of the form shown in Eq. (44.27) with (i) $D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})$ and \mathbf{e}_{Ak} replacing $y(\tau|\mathbf{a}, \mathbf{e}_M)$ and \mathbf{e}_A and (ii) $\tau = 10^4$ yr. Numerically, the integrals that define exceedance probabilities for the individual CCDFs are approximated with (i) random sampling from the possible values for \mathbf{a} as indicated in Eq. (44.30) and (ii) estimated values $\hat{D}_{SG}(10^4|\mathbf{a}_i, \mathbf{e}_{Mk})$ for $D_{SG}(10^4|\mathbf{a}, \mathbf{e}_{Mk})$ constructed from results of

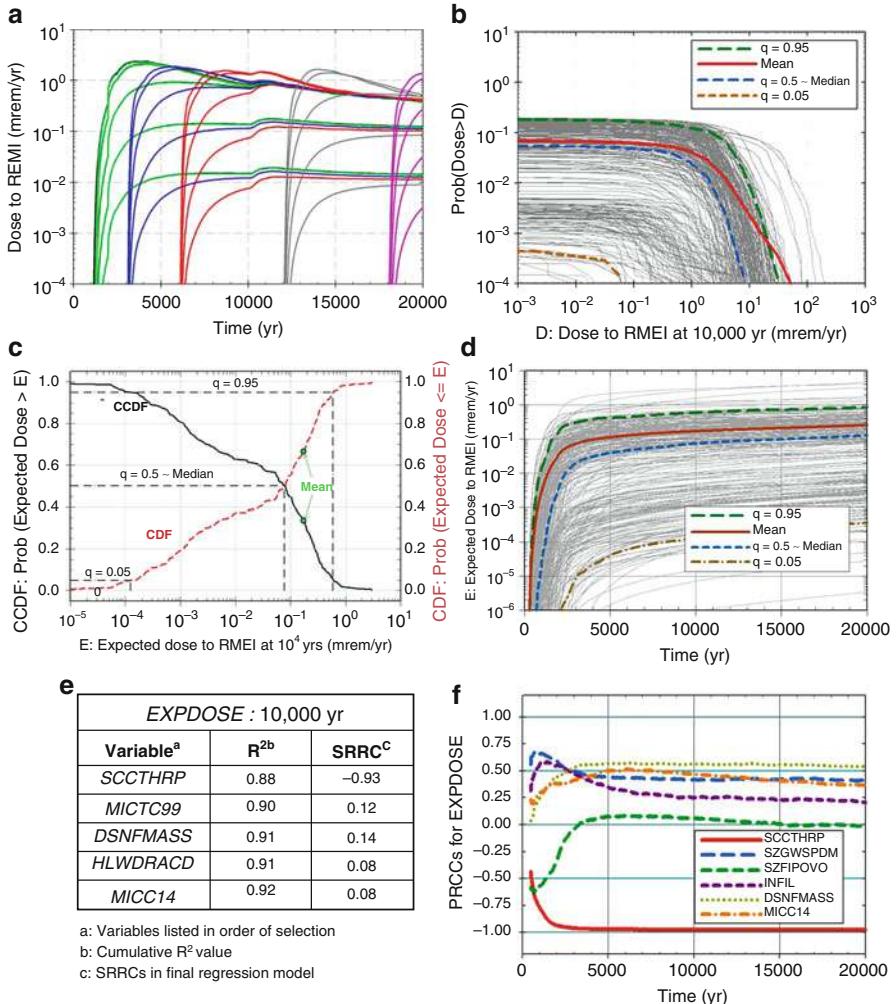

Fig. 44.7 Example results for dose (mrem/yr) to RMEI for seismic ground motion scenario class: (a) dose for seismic events occurring at different times and causing different damaged areas on WPs ([32], Fig. 4a), (b) CCDFs for dose at 10,000 yr ([32], Fig. 10), (c) CCDF and CDF for expected dose at 10,000 yr ([32], Fig. 6b), (d) time-dependent expected dose ([32], Fig. 6a), (e) stepwise rank regression for expected dose at 10,000 yr ([72], Table 4), and (f) time-dependent PRCCs for expected dose ([72], Fig. 4b)

the form shown in Fig. 44.7a (see Ref. [32], Sect. 4, for computational details). Specifically,

$$\hat{p}_A [y < D_{SG}(10^4 | \mathbf{a}, \mathbf{e}_{Mk}) | \mathbf{e}_{Ak}] = \sum_{i=1}^m \bar{\delta}_y [\hat{D}_{SG}(10^4 | \mathbf{a}_i, \mathbf{e}_{Mk})] / m, \quad (44.40)$$

with the \mathbf{a}_i , $i = 1, 2, \dots, m$, sampled in consistency with the density function $d_A(\mathbf{a}|\mathbf{e}_{Ak})$ for vectors of the form shown in Eq. (44.39). The mean and quantile curves in Fig. 44.7b are (i) defined and approximated as indicated in Eqs. (44.32) and (44.33) and (ii) provide a summary of the epistemic uncertainty present in the estimation of exceedance probabilities (i.e., $p_A[y < D_{SG}(10^4|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$) for $D_{SG}(10^4|\mathbf{a}, \mathbf{e}_{Mk})$.

As indicated in Eqs. (44.28) and (44.31), the expected value $E_A[D_{SG}(10^4|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ of $D_{SG}(10^4|\mathbf{a}, \mathbf{e}_{Mk})$ over aleatory uncertainty can also be defined and estimated, with the estimates $\hat{E}_A[D_{SG}(10^4|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ obtained with the random samples used to construct the CCDFs in Fig. 44.7b. The expected values $E_A[D_{SG}(10^4|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ and their corresponding estimates are the result of reducing each CCDF in Fig. 44.7b to a single number. As illustrated in Fig. 44.7c, the epistemic uncertainty associated $E_A[D_{SG}(10^4|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]$ can be summarized by (i) an expected (mean) value $E_E\{E_A[D_{SG}(10^4|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ over epistemic uncertainty, (ii) a CDF defined by the cumulative probabilities for $E_A[D_{SG}(10^4|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]$, or (iii) a CCDF defined by the complementary cumulative probabilities for $E_A[D_{SG}(10^4|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]$. The indicated expected value, CDF and CCDF are defined and approximated in a manner analogous to that used to obtain the results in Fig. 44.3a with $\hat{E}_A[D_{SG}(10^4|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ replacing $D_N(600,000|\mathbf{a}_N, \mathbf{e}_M)$. The expected (mean) value $E_E\{E_A[D_{SG}(10^4|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ illustrated in Fig. 44.7c is the outcome of reducing all the information in Fig. 44.7b to a single number.

Expected doses $E_A[D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ for individual LHS elements correspond to the lighter lines in Fig. 44.7d, and quantile values $Q_{Eq}\{E_A[D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]\}$ and expected (mean) values $E_E\{E_A[D_{SG}(\tau|\mathbf{a}, \mathbf{e}_M)|\mathbf{e}_A]\}$ for $E_A[D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ that summarize the effects of epistemic uncertainty correspond to the darker dashed and solid lines. The results in Fig. 44.7d at 10,000 years correspond to the results shown in more detail in Fig. 44.7c. For reasons of computational efficiency, the individual expected dose curves $E_A[D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ for $0 \leq \tau \leq 20,000$ yr in Fig. 44.7d were estimated with a quadrature procedure that used the results in Fig. 44.7a rather than with a sampling-based procedure as illustrated in Fig. 44.7b; details of this procedure are given in Ref. [32]. The sensitivity analysis results in Fig. 44.7e and f are discussed in Sect. 7.

The expected doses $E_A[D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ in Fig. 44.7d constitute one of the six expected doses appearing in the approximation to $E_A[D_{SG}(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ in Eq. (44.38) for $0 \leq \tau \leq 20,000$ yr. The other five expected doses $E_A[D_C(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$, $C = EW, ED, II, IE, SF$, were determined in a generally similar manner in which a representative set of calculations analogous to those indicated in Fig. 44.7a were performed for each LHS element and then used to estimate $E_A[D_C(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$; details of these calculations are given in Refs. [30–32]. The resultant values for all six expected doses $E_A[D_C(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ for the LHS in Eq. (44.17) are shown in Fig. 44.8. As indicated in Eq. (44.38), the doses $E_A[D_C(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ in Fig. 44.8 are added to obtain the approximations to $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ for $0 \leq \tau \leq 20,000$ yr in Fig. 44.6a. Associated analyses

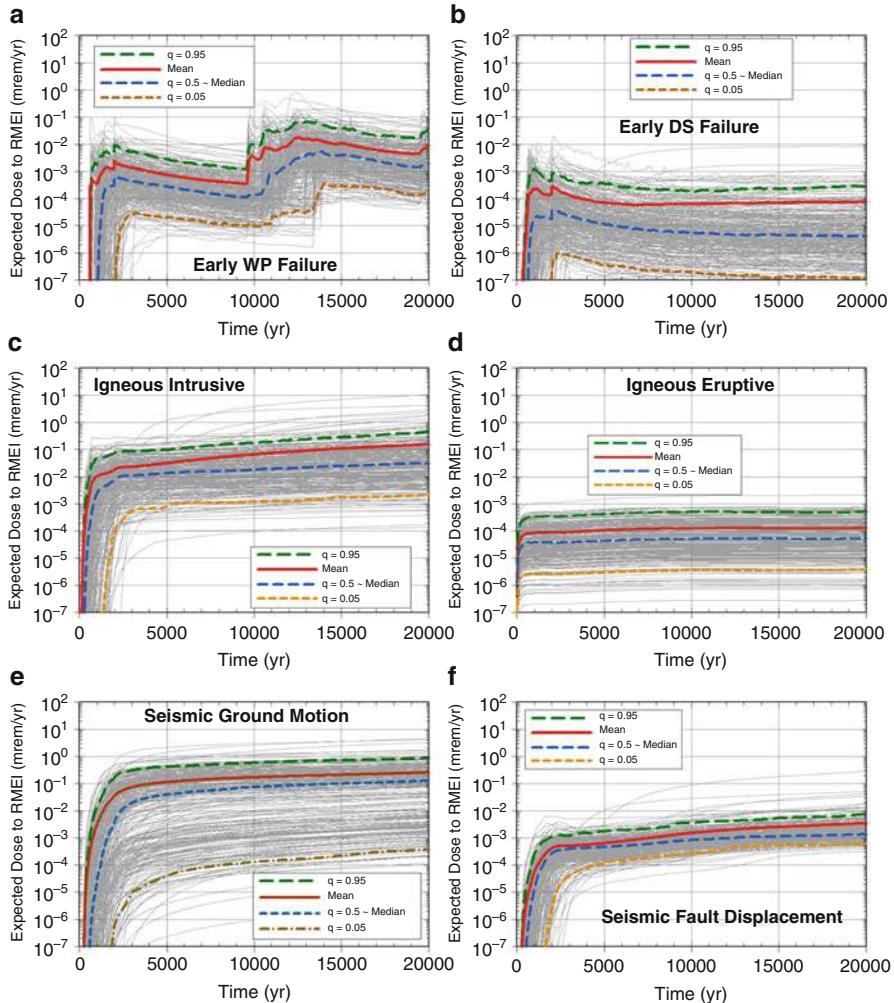

Fig. 44.8 Expected dose $E_A[D_C(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ to RMEI for $0 \leq \tau \leq 20,000$ yr for $C \in \{EW, ED, II, IE, SG, SF\}$: (a) early WP failure, (b) early DS failure, (c) igneous intrusion, (d) igneous eruption, (e) seismic ground motion, and (f) seismic fault displacement ([61], Fig. 2)

Showed that $D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk}) = 0$ mrem/yr for $0 \leq \tau \leq 20,000$ yr (see Fig. 44.3a); thus, $D_N(\tau|\mathbf{a}_N, \mathbf{e}_{Mk})$ made no contribution to $E_A[D(\tau|\mathbf{a}, \mathbf{e}_{Mk})|\mathbf{e}_{Ak}]$ for $0 \leq \tau \leq 20,000$ yr.

7 Sensitivity Analysis

Sensitivity analysis is an important part of a PA and, indeed, any analysis. Specifically, while uncertainty analysis is intended to determine the total uncertainty

in analysis outcomes, sensitivity analysis is intended to determine the contributions of individual uncertain analysis inputs to the total uncertainty in analysis results of interest. The descriptor sensitivity analysis is usually used in reference to the determination of the effects of epistemic uncertainty on analysis outcomes of interest. As a result, sensitivity analysis is typically closely tied to the previously indicated propagation of epistemic uncertainty. In particular, a sampling-based propagation of epistemic uncertainty generates a mapping between uncertain analysis inputs and uncertain analysis results that can then be explored with a variety of sensitivity analysis procedures, including examination of scatterplots, correlation analysis, regression analysis, partial correlation analysis, rank transformations, statistical tests for patterns based on gridding, entropy tests for patterns based on gridding, non-parametric regression analysis, squared rank differences/rank correlation test, two-dimensional Kolmogorov-Smirnov test, tests for patterns based on distance measures, top-down coefficient of concordance, and variance decomposition [73, 74].

Example sensitivity analyses based on partial rank correlation coefficients (PRCCs) are presented in Figs. 44.3d, 44.5d, 44.6d, and 44.7f. In these examples, the PRCCs are determined by analyzing the uncertainty associated with the analysis results above individual values on the abscissas in the indicated figures and then connecting these results to form curves of sensitivity analysis results for individual analysis inputs ([73], Sects. 6.4 and 6.5; [75]). As a result of the use of a rank transformation ([73], Sect. 6.5; [76]), a PRCC provides a measure of the strength of the monotonic effect of an uncertain analysis input on an analysis result after the removal of the monotonic effects of all other uncertain analysis inputs. In the presence of nonlinear but monotonic relationships between a dependent variable and multiple independent (i.e., sampled) variables, use of the rank transformation can substantially improve the resolution of sensitivity analysis results. Specifically, a sensitivity analysis based on rank-transformed data operates in the following manner: (i) the smallest value for each variable is assigned a rank of 1, (ii) next largest value is assigned a rank of 2, (iii) tied values are assigned their average rank, and (iv) so on up to the largest value, which is assigned a rank equal to the sample size in use; then, the analysis is performed with these rank-transformed values. The rank transformation is a very useful procedure in many sensitivity analyses as it converts nonlinear but monotonic relationships into linear relationships.

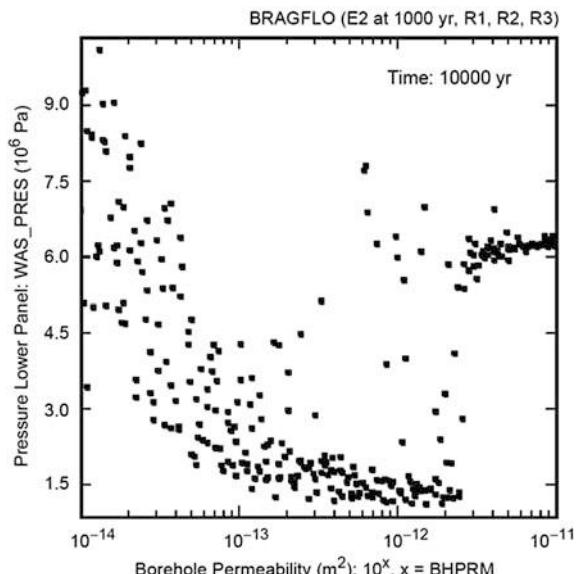

The results in Figs. 44.3d, 44.5d, 44.6d, and 44.7f illustrate a spectrum of the possibilities in which sensitivity analyses can be performed in a PA, including: (i) results conditional on a specific realization of aleatory uncertainty (Fig. 44.3d), (ii) exceedance probabilities that define CCDFs that summarize the effects of aleatory uncertainty (Fig. 44.5d), (iii) expected values over aleatory uncertainty (Fig. 44.6d), and (iv) intermediate results that are part of a very complex calculation (Fig. 44.7f).

As another example, stepwise rank regressions are presented in Figs. 44.3c and 44.7e for results at specific points in time. In stepwise regression, a regression model is first constructed with the most influential variable (i.e., x_1 as determined based on R^2 values for regression models containing only single variables). Then, a regression model is constructed with x_1 and the next most influential variable (i.e., x_2 as determined based on R^2 values for regression models containing x_1 and

each of the remaining variables). The process then repeats to determine x_3 in a similar manner and continues until no more variables with an identifiable effect on the dependent variable can be found. Variable importance (i.e., sensitivity) is then indicated by (i) the order in which variables are selected in the stepwise process, (ii) the changes in cumulative R^2 values as additional variables are added to the regression model, and (iii) the standardized regression coefficients for the variables in the final regression model ([73], Sect. 6.3). In a rank regression, the variables are rank-transformed before the regression analysis is performed.

When relationships between individual independent variables and a dependent variable are both nonlinear and nonmonotonic, sensitivity analyses with partial correlation coefficients and stepwise regression procedures will perform poorly with both untransformed data and rank-transformed data. In such situations, examination of scatterplots may be sufficient to reveal the effects of nonlinear relationships between individual independent variables and a dependent variable ([73], Sect. 6.6; [77]). Specifically, for a sample $\mathbf{x}_k = [x_{k1}, x_{k2}, \dots, x_{k1,nV}]$, $k = 1, 2, \dots, n$, from nV uncertain analysis inputs (e.g., as in Eq. (44.17)) and a corresponding analysis result $y_k = y(\mathbf{x}_k)$, the scatterplot for variable x_l is a plot of the points (x_{kl}, y_k) for $k = 1, 2, \dots, n$. As an example, the well-defined relationship between BHPRM and pressure is clearly shown by the scatterplot in Fig. 44.9 but missed by partial correlation and regression analyses with untransformed and rank-transformed data. More formal procedures to identify nonlinear relationships in sampling-based analyses are provided by grid-based procedures ([73], Sect. 6.6; [78]), nonparametric regression procedures ([73], Sect. 6.8; [79–82]), and the squared rank differences/rank correlation test ([73], Sect. 6.9; [83]).

Fig. 44.9 Example of a scatterplot obtained in the sampling-based uncertainty/sensitivity analysis for the WIPP ([92], Fig. 28; see [92], Sect. 4, for additional discussion of this example)

Many additional examples of sampling-based sensitivity analysis results are available in Ref. [1] for the 1996 WIPP PA and in Ref. [2] for the 2006 YM PA. Additional information on both sampling-based approaches to uncertainty and sensitivity analysis and additional approaches to uncertainty and sensitivity analysis (e.g., differential analysis and variance decomposition) is available in a number of reviews [73, 74, 84–91].

8 Summary

As described and illustrated in this presentation, a conceptual structure and an associated computational structure for PAs for radioactive waste disposal facilities and other complex engineered facilities can be based on the following three conceptual entities : EN1, a probability space ($\mathcal{A}, \mathbb{A}, p_A$) that characterizes aleatory uncertainty; EN2, a function f that estimates consequences for individual elements **a** of the sample space \mathcal{A} for aleatory uncertainty; and EN3, a probability space ($\mathcal{E}, \mathbb{E}, p_E$) that characterizes epistemic uncertainty [7, 8, 24–26]. A recognition and understanding of these three basic entities makes it possible to understand the conceptual and computational structure of a large PA without having basic concepts obscured by fine details of the analysis and leads to an analysis that results in insightful uncertainty and sensitivity analyses. For example, calculations that are basically integrations of very complex functions can be recognized and described as such before the introduction of the often highly-complex numerical procedures needed to perform such integrations.

The indicated conceptual structure also provides a basis and organizational structure for the production of quality documentation for a PA. Everyone will not agree with the results of a complex PA that supports an important societal decision. However, everyone should be able to know what was done and obtained in such a PA. Such knowledge is (i) essential to an informed discussion of a PA and its results and (ii) dependent on quality documentation. A poorly documented PA is likely to be extensively criticized as result of (i) frustrations over trying to determine what was done and (ii) resultant misassumptions about what was done.

Use of the described uncertainty and sensitivity analysis procedures provide important insights into a PA and the factors that affect its outcomes. Uncertainty analysis results enhance the quality of decisions that can be made on the basis of a PA and also enhance the credibility of a PA by showing the resolution (i.e., uncertainty) in its results. Sensitivity analysis provides guidance on both (i) the dominant contributors to the uncertainty in results obtained in a PA and (ii), if necessary, where resources can be best invested to reduce the uncertainty in the results of a PA.

In addition, sampling-based uncertainty and sensitivity analysis procedures are important analysis verification tools. The extensive exercising of the models used in a PA in a sampling-based uncertainty and sensitivity analysis provides a very effective test of the operation of these models. Further, the associated sensitivity results are effective in revealing inappropriate relationships between variables that

are indicative of errors in the formulation or implementation of the PA and its underlying models.

Owing to both the insights that can be gained and the potential for the identification of analysis errors, the examination of uncertainty and sensitivity results should never be limited to only the final outcomes of greatest interest in a PA. Rather, uncertainty and sensitivity results should be examined at multiple points in the chain of computations that lead to the final result or results of greatest interest (e.g., regulatory requirements). Examples of the analysis of intermediate results in a PA are provided by Refs. [92–97] for the WIPP PA and Refs. [33, 72, 98, 99] for the YM PA. Extensive experience with complex PAs has shown that an initial sampling-based uncertainty and sensitivity analysis will almost always reveal errors that need to be corrected before the results of the PA are ready for presentation.

Redundancy of Structures and Fatigue of Bridges and Ships Under Uncertainty

45

Dan M. Frangopol, Benjin Zhu, and Mohamed Soliman

Abstract

Bridges and ships are key components of civil and marine infrastructure systems, respectively. Due to the nature of their in-service role, failure of such structures may lead to very high consequences. Preventing such failures requires rigorous design and life-cycle management techniques. In order to maintain satisfactory performance for these structures throughout their service life, various uncertainties associated with the design and management processes should be properly accounted for. Among the important design considerations for bridges and ships that highly depend on the proper identification of these uncertainties are the structural redundancy quantification and fatigue life assessment. In this chapter, quantification of redundancy and its integration into the design process of structural components are discussed. Additionally, the probabilistic fatigue assessment problem and the sources of uncertainties associated with the fatigue life prediction models are presented.

1 Introduction

Structures are expected to maintain desired levels of serviceability and safety during their service life. Due to the unavoidable uncertainties in structural design and performance assessment, probabilistic performance indicators, such as reliability and redundancy, were introduced. Redundancy, in general, indicates the ability of a structural system to redistribute the load after the failure of one component or subsystem. Adequate redundancy should be considered in structural design. System redundancy has attracted a lot of research interest in recent decades [19, 21, 22, 26, 44].

Even though redundancy is a highly desired attribute for a structure, quantitative guidance is not commonly available in the structural design specifications. Load and resistance factor design (LRFD) replaced allowable stress design within the last decades with better understanding of structural performance and system reliability theory [2]. Since LRFD approach considers the uncertainties associated with the resistances and load effects using separate factors, it provides better means of incorporating system reliability and redundancy concepts in the structural design.

Several measures for quantifying structural redundancy are available in the literature. Frangopol and Curley [19] defined the system redundancy as the ratio of the reliability index of the intact system to the difference between the reliability indices of the intact and the damaged systems. Rabi et al. [44] defined the redundancy by comparing the probability of system collapse to the probability of first member failure. Ghosn and Moses [22] proposed three redundancy measures that are defined in terms of relative reliability indices. Since redundancy is regarded as an important performance indicator, research on the evaluation of system redundancy in real structures has been conducted. Tsopelas and Husain [52] studied the system redundancy of reinforced concrete buildings. Wen and Song [53] investigated the redundancy of special moment resisting frames and dual systems under seismic excitations. Kim [27] evaluated the redundancy of steel box-girder bridge by using a nonlinear finite element model.

Fatigue is another critical mechanism which can adversely affect the safety of metallic structures. Fatigue is the process of crack initiation and propagation resulting from repetitive loads on the structure [17]. These cracks, if not effectively detected and repaired, may cause sudden failure of the damaged component. If the structure does not have an adequate redundancy level, a catastrophic structural

failure may occur due to the failure of the cracked component. Although methodologies for fatigue assessment and design are already established in literature and design specifications, fatigue cracks exist in various types of structures such as bridges, offshore structures, and naval vessels. This can be attributed to the fact that a large number of factors contribute to the fatigue crack initiation and propagation including the structural configuration of the detail, presence of initial defects, environmental conditions, and loading conditions, among others. Additionally, several sources of uncertainty affect the fatigue crack initiation and propagation. Such uncertainties must be well-understood and should be accounted for in order to correctly assess the performance of a structure with respect to fatigue. Accordingly, several researchers address the fatigue life estimation and performance assessment on probabilistic basis [28, 41, 54].

This chapter presents a brief review of several proposed redundancy measures. A methodology to assess the life-cycle redundancy of a structure is described in details in context of system reliability. Next, several quantifications of the redundancy factor used for structural component design are discussed. The chapter also discusses the probabilistic aspects of the fatigue life estimation problem.

2 Quantitative Redundancy Measures

Redundancy is a performance indicator that measures the reserve capacity of structures after the failure of a component or subsystem and provides an indication on the presence of alternative load paths within the structure. For a redundant system, the failure of a single member will not result in the collapse of the entire structure if it is a redundant system. Several redundancy measures were proposed in the literature, including deterministic and probabilistic performance indicators. Frangopol and Klisinski [20] defined a reserve strength factor as the ratio of the load-carrying capacity of the intact structure or member, C , to the nominal applied load on the structure or the effect of this load on the member, Q ,

$$R_1 = \frac{C}{Q} \quad (45.1)$$

The reserve strength factor varies from a value of infinity, when the intact structure has no load, to a value of 1.0, when the nominal load on the intact structure equals its capacity.

The residual strength factor provides a measure for the strength of the system in a damaged condition compared to the intact system. It is defined as the ratio of the capacity of the damaged structure or member, C_d , to the capacity of the intact structure or member, C , and can be expressed as [20]

$$R_2 = \frac{C_d}{C} \quad (45.2)$$

This factor takes values between 0, when damaged structure has zero capacity, and 1.0, when damaged structure does not have any reduction in its load-carrying

capacity. Frangopol and Klisinski [20] also proposed the following deterministic measure of redundancy:

$$R_3 = \frac{1}{1 - R_2} \quad (45.3)$$

where R_2 is the residual strength factor.

Ghosn and Moses [22] defined redundancy as the capability of a structure to continue to carry loads after the damage or failure of one or more members. In order to provide objective measures of system redundancy, they investigated the load multipliers LF_u , LF_f , LF_d , and LF_1 . It is assumed that the live load applied has a certain configuration (e.g., AASTHO HS-20 truck), and then the first main member will fail when the reference load is multiplied by a factor LF_1 . Similarly, LF_u is the load multiplier when the ultimate capacity of the intact structure is reached. LF_f is the load multiplier when large vertical deformations rendering the structure unfit for use are reached, in other words when the functionality is lost. LF_d is the load multiplier when the ultimate capacity of the damaged structure is reached. Ghosn and Moses [22] defined three deterministic measures of the system's capacity as compared to the most critical member's capacity as:

$$R_u = \frac{LF_u}{LF_1} \quad (45.4)$$

$$R_f = \frac{LF_f}{LF_1} \quad (45.5)$$

$$R_d = \frac{LF_d}{LF_1} \quad (45.6)$$

where R_u is the system reserve ratio for the ultimate limit state, R_f is the system reserve ratio for the functionality limit state, and R_d is the system reserve ratio for the damage condition.

In order to account for the uncertainties in system and member capacities, as well as the applied loads, Frangopol and Curley [19] proposed a probabilistic measure for redundancy as

$$RI = \frac{P_{f(dmg)} - P_{f(sys)}}{P_{f(sys)}} \quad (45.7)$$

where RI is the system redundancy index, $P_{f(dmg)}$ is the probability of damage occurrence to the system, and $P_{f(sys)}$ is the probability of system failure. In addition, they defined redundancy index in terms of reliability index as

$$I_R = \frac{\beta_{intact}}{\beta_{intact} - \beta_{damaged}} \quad (45.8)$$

where I_R is redundancy index, β_{intact} is the reliability index of the intact system, and $\beta_{damaged}$ represents the reliability index of the damaged system.

Ghosn and Moses [22] also proposed probabilistic measures of redundancy. They examined the differences between the reliability indices of the systems expressed in terms of the reliability index associated with the ultimate capacity of the intact structure, $\beta_{ultimate}$; the reliability index associated with the functionality loss, $\beta_{functionality}$; the reliability index associated with the ultimate capacity of the damaged structure, $\beta_{damaged}$; and the reliability index of the most critical member of the structure, β_{member} . As measures of redundancy levels, they investigated the relative reliability indices for the ultimate $\Delta\beta_u$, functionality $\Delta\beta_f$, and damaged $\Delta\beta_d$ limit states and are defined as:

$$\Delta\beta_u = \beta_{ultimate} - \beta_{member} \quad (45.9)$$

$$\Delta\beta_f = \beta_{functionality} - \beta_{member} \quad (45.10)$$

$$\Delta\beta_d = \beta_{damaged} - \beta_{member} \quad (45.11)$$

2.1 Time-Variant Redundancy

The majority of studies on system redundancy assume that both the loads and resistances are time independent. In other words, the probability density functions (PDF) of the random variables are kept constant during the lifetime of a structure due to the complexity involved in dealing with time-dependent systems. Nevertheless, accounting for the effects of time on structures may have significant impact on the redundancy measures and is necessary for accurate performance assessment of structural systems.

Prediction of both the time-variant loads and resistances is required to include the time factor in the performance prediction model. The resistances of structural components and systems are subjected to deterioration in time. Deterioration can be caused by various mechanisms, such as corrosion and fatigue. Furthermore, the applied loading may increase over time (e.g., traffic loads on bridges). The combined effect of the decrease in resistance and increase in load will lead to significant drop of structural reliability and redundancy.

In this section, a procedure for evaluating the time-variant redundancy for structural systems under uncertainty and deterioration, based on the redundancy measure given in Eq. (45.8), is presented. As indicated in this equation, the reliabilities (or failure probabilities) associated with the intact and damaged structures must be determined to evaluate redundancy. A common approach for assessing the time-variant reliability is the point-in-time method in which the reliability index is computed at discrete time points to establish a lifetime reliability profile. Alternatively, the reliability and redundancy can be assessed in continuous time periods using survivor functions [40]. In the point-in-time method, the limit state functions are required to be updated at every time point according to the predictive models for deteriorated resistance and increased traffic loads.

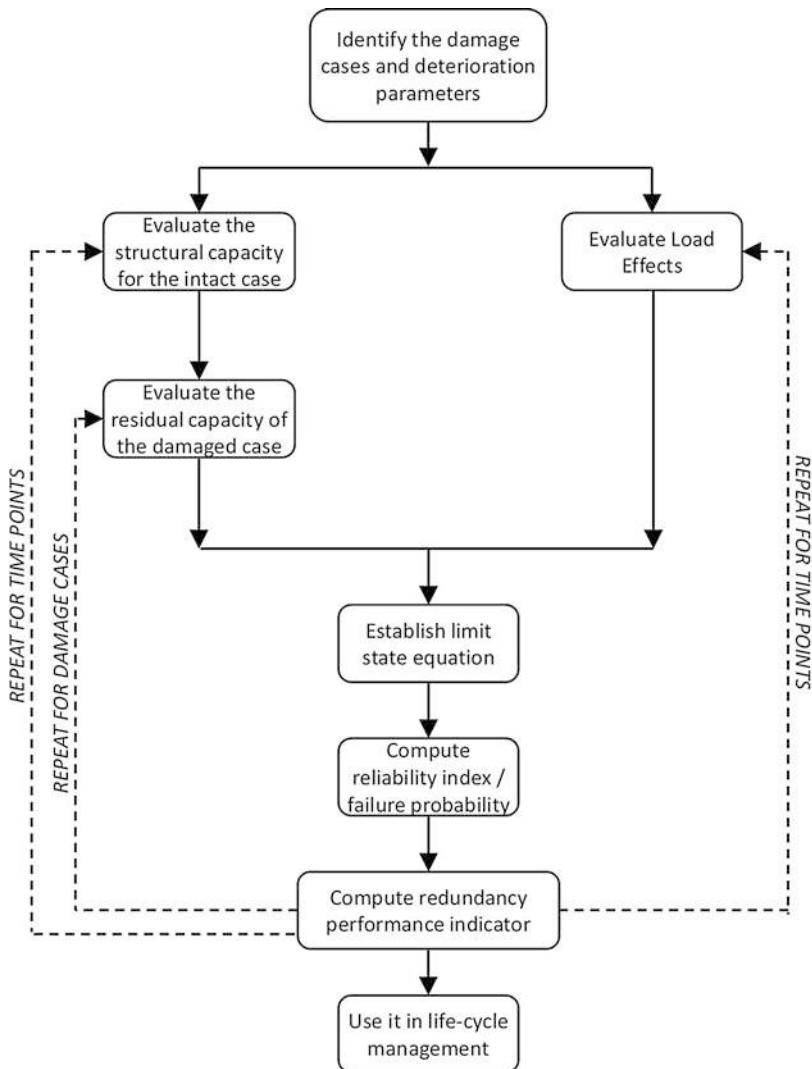

Fig. 45.1 Methodology for assessing time-variant redundancy

The methodology for assessing the time-variant redundancy of deteriorating structures is illustrated in Fig. 45.1. In this methodology, the term redundancy is associated with a certain damage case (e.g., failure of a critical member). The first step of the methodology is identifying the damage cases and deterioration parameters to be considered in the life-cycle performance evaluation. The next steps are the computations for the resistance and the load effects. The random variables associated with the resistance must be identified. The load capacity of the structure associated with the considered damage case should be computed accounting for

uncertainties. The variation of the live load over time is required in order to perform time-dependent reliability analysis. Then, the limit state equation consisting of the resistance and the load effects needs to be established. The instantaneous probability of failure and/or reliability index associated with a damage case can be obtained by first-order reliability method (FORM), second-order reliability method (SORM), or Monte Carlo simulation. Once the reliability index or probability of failure is obtained for a time point, the redundancy index can be calculated based on the adopted formulation (e.g., Eq. (45.8)). This procedure should be repeated at different time steps with time-variant values of resistance and load effects in order to obtain the lifetime redundancy profile. In addition, redundancy associated with different damage cases must be evaluated to identify the importance of components within the system.

The procedure for system reliability assessment with emphasis on bridges is further illustrated herein. The system reliability of bridges can be assessed based on appropriate assumptions associated with the interaction of individual components. In general, a bridge system can be modeled as a series, parallel, or series-parallel system. The reliability of a bridge structural system is often evaluated by considering the system failure as series-parallel combination of the components' failures. After determining the random variables and their statistical parameters for component reliability analysis, the limit states of components can be included in the system model. A bridge component may have several failure modes. For example, a girder can fail in bending or shear. The flexural or shear capacity for girders and the slab can be calculated based on the strength limit state relations given in AASHTO LRFD Bridge Design Specifications [1].

Another approach for redundancy assessment of bridges makes use of finite element (FE) method. An appropriate statistical distribution for the desired output of FE analysis (e.g., stress, displacement, bending moment) can be obtained by repeating the analysis for a large number of samples of the random variables associated with the structure. However, for complex structures, it may be computationally expensive to repeat the FE analysis several times. In such cases, the response surface method (RSM) can be used to approximate the relation between the desired output of FE analysis and random variables by performing analyses for a significantly less number of samples [40]. In this method, the response surface function is generated by fitting a mathematical model to the simulation outcomes in terms of input variables of the simulation model. Support points for each design variable are selected to estimate the parameters of the response surface function. This task can be performed by using experimental design concepts.

2.2 Redundancy Factor for Structural Component Design

Structures are purposefully designed much stronger than what is usually needed to accommodate intended loading. The main objective is to create a margin of safety under extreme events with high consequences, unexpected loadings, and structural deterioration. The extent by which the structural capacity of a system exceeds the

expected loads or actual loads is described as factor of safety. Safety factor is applied to the material strength of structural component in the conventional allowable stress design (ASD) to obtain the allowable strength. Although this ASD has been the primary approach used for structural component design since the early 1900s, it is not a rational and economical design method as the uncertainties involved in the structural design process are not properly considered.

With the increased understanding of structural behavior and loading process, the design philosophy evolved to the load factor design (LFD) around the 1970s. Compared to the ASD, LFD recognizes that the live load was more variable than dead load, and, therefore, uncertainties in load prediction were considered by introducing the load factors. However, deterministic approaches were still used when calibrating these factors. Due to the development and application of probability-based reliability theory in structural engineering, a design philosophy referred to as load and resistance factor design (LRFD) was introduced in the 1980s. Compared with the previous design methods, LRFD is more rational because the uncertainties associated with resistances and loads are quantitatively incorporated in the design process [51].

Structural components in a system do not behave independently; instead, they interact with other components under external loads to form a structural system. However, the previous design methods ignore this system effect in the component design. The aforementioned definitions of redundancy indicate that it is connected to system behavior. Therefore, consideration of system redundancy is essential for component design. Structures with sufficient redundancy can be rewarded by allowing their components to have less conservative designs, while structures that are nonredundant would be required to have higher component capacities. The existence of uncertainties in resistances and loads requires quantifying the system redundancy in a probabilistic manner. Since the LRFD approach was developed based on the probability theory, it provides a basis to incorporate system reliability and redundancy concepts in structural component design.

In the current LRFD design specifications, load and resistances factors are developed using statistical knowledge of the variability of loads and structural performance. In the AASHTO LRFD bridge design specifications, three system factors relating to ductility, redundancy, and operation classification, respectively, are applied on the load side of the strength limit state. The factor relating to redundancy, denoted as η_R , is included to account for the effect of system redundancy on the component design. Its value is determined based on three redundancy levels [1], as follows:

$$\eta_R \begin{cases} \geq 1.05 & \text{for nonredundant member} \\ = 1.00 & \text{for conventional level of redundancy} \\ \geq 0.95 & \text{for exceptional levels of redundancy} \end{cases} \quad (45.12)$$

This classification of the redundancy levels is very general, and the evaluation of the factor relating to redundancy is very subjective. In fact, this factor is affected by several parameters, such as system type, number of components in

a structure, and correlations among the resistances of members, among others (Hendawi and Frangopol 1994; [22]). Therefore, although the LRFD code has been continuously refined and revised since its initial publication in 1994, there is room for further improvement in the classification of the redundancy level and quantification of the associated values [51], as indicated in section 1.3.2.1 in AASHTO [1]: “improved quantification of ductility, redundancy, and operational classification may be attained with time, and possibly leading to a rearranging of Eq. 1.3.2.1-1, in which these effects may appear on either side of the equation or on both sides.”

Although quantification of redundancy factors is a very complex task, significant effort has been devoted by researchers to achieve this goal. Hendawi and Frangopol [26] proposed a system factor modifier placed on the resistance side of the limit states to account for the system redundancy in the design of individual components. Similarly, Ghosn and Moses [22] presented a system factor to serve the same purpose. Four limit states are investigated to determine the system factors:

1. Member failure limit state: to check the safety of an individual component using elastic analysis.
2. Ultimate limit state: to determine the ultimate capacity of the intact bridge system.
3. Functionality limit state, which is defined as a maximum acceptable displacement of a main component under live load.
4. Damaged condition limit state: to find the ultimate capacity of a damaged bridge system.

The aforementioned load multipliers LF_1 , LF_u , LF_f , and LF_d correspond to the four limit states, respectively. They are calculated using incremental analysis considering the elastic and inelastic material behavior of structural components. Finally, the system factors are determined by comparing the strength reserve ratios (i.e., R_u , R_f , and R_d) related to different limit states with the required redundancy ratios that are obtained through a system reliability calibration to provide adequate redundancy. The system factors are calibrated for bridges with typical configurations: (a) simple-span, prestressed concrete and steel I-beam bridges with 4, 6, 8, 10, and 12 beams, (b) simple-span, prestressed concrete bridges with 2, 3, and 5 spread boxes as well as multi-box beam bridges with up to 11 adjacent boxes, and (c) two-span continuous I-beam bridges associated with three system limit states (ultimate, functionality, and damaged). The calibration process of the system factor is complicated because it requires finite element modeling and nonlinear incremental structural analysis. The factors obtained are only for common types of bridges with limited number of components. For other bridges with unique geometries and nontypical material properties, the associated system factors are not provided.

Zhu and Frangopol [56–58] proposed a new definition of redundancy factor applied to the load side in the strength limit state for component design. This redundancy factor is defined as the ratio of the mean resistance of a component in a system when the system reliability is prescribed to the mean resistance of the

same component when its reliability index is the same as that of the system. For example, consider a single component with resistance R and load P which are treated as random variables. Given the distribution types of R and P , mean value of load $E(P)$, coefficients of variation of resistance and load $V(R)$ and $V(P)$, and the prescribed component reliability index $\beta_c = 3.5$, the mean value of the component resistance $E_c(R)$ can be determined (e.g., by using Monte Carlo simulation). In two specific cases where both R and P follow normal or lognormal distribution, $E_c(R)$ can be directly calculated by solving Eqs. (45.13) and (45.14), respectively:

$$\beta_c = \frac{E_c(R) - E(P)}{\sqrt{(E_c(R) \cdot V(R))^2 + (E(P) \cdot V(P))^2}} \quad (45.13)$$

$$\beta_c = \frac{\ln \left[\frac{E_c(R)}{E(P)} \sqrt{\frac{1+V^2(P)}{1+V^2(R)}} \right]}{\sqrt{\ln [(1 + V^2(R)) (1 + V^2(P))]} \quad (45.14)}$$

For a three-component parallel system whose components are the same as the single component just described (e.g., geometry and material properties, distribution parameters), the load acting on the system is assumed to be $3P$, and the correlation coefficient between the resistances of components i and j is assumed to be $\rho(R_i, R_j)$. According to the definition of redundancy factor, the target system reliability index should be the same as the component reliability index, which is 3.5 herein. Therefore, the mean value of component resistance in the system, denoted as $E_{cs}(R)$, can be calculated by using Monte Carlo simulation. Having obtained the mean resistance of a component in a system when the system reliability index is 3.5, $E_{cs}(R)$, and the mean resistance of the same component when the component reliability index is 3.5, $E_c(R)$, the redundancy factor, denoted as η_R , which is defined as the ratio of $E_{cs}(R)$ to $E_c(R)$, can be determined.

Since system reliability is affected by system modeling, number of components in the system, correlations among the component resistances, and post-failure material behavior of components, the effects of these parameters on the system redundancy should be considered in the quantification of the redundancy factor. Three brief examples are presented herein to illustrate these effects. The first example is a four-component structure. Based on different definitions of system failure, three types of systems can be modeled: (45.1) series model, the system fails if any component fails; (45.2) parallel model, the system fails only if all components fail; and (c) series-parallel model, the system fails if components 1 and 2 fail simultaneously or components 3 and 4 fail at the same time. The resistance R and load effect P associated with each component are assumed to be the same and to follow normal distribution. The coefficients of variation of R and P are considered 10%. The mean value of load affect, denoted $E(P)$, is assumed to be 10. Three correlation cases among the resistances of components are investigated herein: (a) $\rho(R_i, R_j) = 0$, no correlation; (b) $\rho(R_i, R_j) = 0.5$, partial correlation; and (c) $\rho(R_i, R_j) = 1.0$, perfect correlation. Therefore, the mean values of resistance of a single component when its reliability is 3.5 are obtained for the

three correlation cases using Eq. (45.13). Similarly, the mean values of component resistances $E_{cs}(R)$ when the system reliability index is also 3.5 can be calculated for the three systems associated with different correlation cases. Finally, the redundancy factors η_R for series, parallel, and series-parallel systems are obtained as (45.1) 1.062, 0.785, and 0.878 when $\rho(R_i, R_j) = 0$; (45.2) 1.059, 0.859, and 0.933 when $\rho(R_i, R_j) = 0.5$; and (45.3) 1.0, 1.0, and 1.0 when $\rho(R_i, R_j) = 1.0$. It is noticed that the redundancy factor associated with series system is the highest, while its counterpart associated with parallel system is the lowest. As the correlation among the component resistances increases, the redundancy factor decreases in the series system but increases in the parallel and series-parallel systems. The redundancy factor in the perfect correlation case is independent of the system modeling type.

These observations indicate that the component in the series system requires larger redundancy factor in the design to reach the targeted system reliability level. However, in the parallel system, components can be designed more economically. Higher correlation among the component resistances leads to higher redundancy factor in the parallel and series-parallel systems, which implies that the component needs to be designed stronger. An opposite conclusion is drawn for the series system. In the perfect correlation case, the redundancy factor is always 1.0. This is expected because a system whose components are identical and their failure modes are perfectly correlated can be reduced to a single component. Therefore, the redundancy factor does not change with the system type.

The second example is to study the effect of a number of components on the redundancy factor. An additional three-component structure is investigated, and its results will be compared with those from the four-component systems just discussed. Two types of systems are formed for this three-component structure: series and parallel. The components are considered as identical and the loads acting on them are assumed to be similar. The statistical parameters associated with resistances and loads (i.e., $V(R)$, $V(P)$, and $E(P)$) in the previous four-component structure are used herein. Assuming the target reliability index both for single component and the systems is 3.5, the redundancy factors of the series and parallel systems are found to be: (45.1) 1.049 and 0.812 when $\rho(R_i, R_j) = 0$; (45.2) 1.047 and 0.879 when $\rho(R_i, R_j) = 0.5$; and (45.3) 1.0 and 1.0 when $\rho(R_i, R_j) = 1.0$. By comparing these factors with the values in the four-component systems, it is seen that as the number of components increases from three to four, the redundancy factor associated with series system increases, while its counterpart associated with the parallel system decreases. However, this conclusion is not valid in the perfect correlation case where the redundancy factor is constant.

All the materials used in practical cases have their own behaviors. The ability of components to carry loads beyond the elastic limits affects the redistribution of loads within a system and the availability of alternative load paths. Therefore, the post-failure material behavior of components needs to be considered in the quantification of the redundancy factor [58]. The last example in this section studies the impact of post-failure behavior on the redundancy factor using the aforementioned three-component parallel system. The load acting on the system is $3P$. The resistances and loads of components follow normal distribution with the parameters mentioned

previously. Two types of post-failure behavior are examined: ductile and brittle. A ductile component can still take load after yielding; however, a brittle component completely loses its capacity when it fails. This difference results in different limit state equations of the parallel system in the ductile and brittle cases, and therefore, the mean resistances in these two cases will be different. If the target reliability index is predefined as 3.5, the redundancy factors associated with the ductile and brittle cases are obtained as: (45.1) 0.98 and 1.033 when $\rho(R_i, R_j) = 0$; (45.2) 0.989 and 1.026 when $\rho(R_i, R_j) = 0$; and (45.3) 1.0 and 1.0 when $\rho(R_i, R_j) = 1.0$. It is noticed that the redundancy factor of the ductile system is much lower than that of the brittle system in the no correlation and partial correlation cases. This means the component with brittle material needs to be designed much stronger than the one with ductile material.

It is seen from the three examples that the redundancy factor is significantly affected by the system modeling, number of components, correlations among the component resistances, and post-failure material behavior. This emphasizes the necessity of quantifying redundancy factors for a variety of systems with different parameters mentioned previously. To achieve this goal, nondeterministic idealized systems are used to evaluate the redundancy factors for ductile and brittle systems with up to 500 components considering different system types, several correlation cases, and two probability distribution types. As shown in Zhu et al. [59], the obtained redundancy factors in ductile and brittle systems can be often larger than the upper bound (i.e., 1.05) or lower than the lower bound (i.e., 0.95) as defined in the AASHTO LRFD Bridge Design Specifications.

3 Fatigue in Bridges and Ships

Fatigue damage accumulation is a major concern for several types of metallic structures including highway bridges, railway bridges, offshore structures, and both steel and aluminum naval vessels. Fatigue can be defined as “the tendency of a metal to break under repeated cyclic loading at a stress considerably less than the tensile strength in a static test” [45]. Repeated fluctuating loads which cause fatigue damage accumulation include traffic loads on bridges, wind loads on masts, and wave loads on ships. At regions of stress concentrations where an initial crack or crack-like defect exists, crack propagation may occur when elastic stresses are applied. This stress concentration causes plastic zones to be formed at the crack tip. Initiation and propagation of cracks in the plastic localized region occur due to the cumulative damage acting over a certain number of stress fluctuations. These cracks can eventually cause the fracture of the component [4]. In modern steel bridges and naval vessels, stress concentration occur at different components due to the geometric configuration, the presence of initial material flaws, or as a result of the welding process.

Design guidelines and specifications provide methods to compute the fatigue life associated with various details widely employed in steel and aluminum structures (see, e.g., BS5400 [5], BS7910 [6], Eurocode 9 [15], Eurocode 3 [14], AASHTO [1]). These design guidelines mainly implement the $S-N$ (i.e., stress-life) approach

for fatigue design and assessment due to its simplicity and sufficient agreement with experimental test results. Fatigue assessment approaches based on fracture mechanics can also be used to assess the crack conditions at a certain detail and predict the time-variant crack size.

A brief discussion on the $S-N$ approach and the linear elastic fracture mechanics in fatigue assessment is presented next. Uncertainties associated with different model parameters are also discussed. Additionally, the widely implemented methodologies for quantifying and reducing these uncertainties are presented.

3.1 Fatigue Assessment Based on Fracture Mechanics

In this method, the stresses near the crack tip are related to the range of the stress intensity factor, ΔK . Paris' law [42] relates the crack growth rate to the range of the stress intensity factor as follows:

$$\frac{da}{dN} = C \cdot (\Delta K)^m \quad (45.15)$$

where a is crack size, N is number of cycles, and ΔK is range of the stress intensity factor. C and m are material parameters. The range of the stress intensity factor can be expressed as

$$\Delta K = K(a) \cdot S_{re} \cdot \sqrt{\pi a} \quad (45.16)$$

where S_{re} is the stress range and $K(a)$ is the generalized stress intensity factor which depends on the crack orientation and shape. This factor can be expressed as [16]

$$K(a) = F_e \cdot F_s \cdot F_w \cdot F_g \quad (45.17)$$

in which F_e , F_s , F_w , and F_g are correction factors taking into account the effects of the elliptical crack shape, free surface, finite width, and nonuniform stress acting on the crack, respectively. Solutions for these correction factors can be found in Tada et al. [50].

Using Eqs. (45.15) and (45.16), the number of cycles associated with a growth in the crack size from an initial size of a_o to a size of a_t can be calculated as

$$N = \frac{1}{C \cdot S_{re}^m} \cdot \int_{a_o}^{a_t} \frac{1}{(K(a) \cdot \sqrt{\pi a})^m} da \quad (45.18)$$

Considering the average daily number of cycles N_{avg} to be constant, the time interval (in years) associated with a crack growth from a_o to a size of a_t can be calculated as

$$t = \frac{1}{365 \cdot N_{avg} \cdot C \cdot S_{re}^m} \cdot \int_{a_o}^{a_t} \frac{1}{(K(a) \cdot \sqrt{\pi a})^m} da \quad (45.19)$$

The integration in Eq. (45.19) can be performed numerically to find the crack growth profile for the analyzed detail. However, the cases where $K(a)$ is not constant may take considerable computational effort especially if probabilistic performance

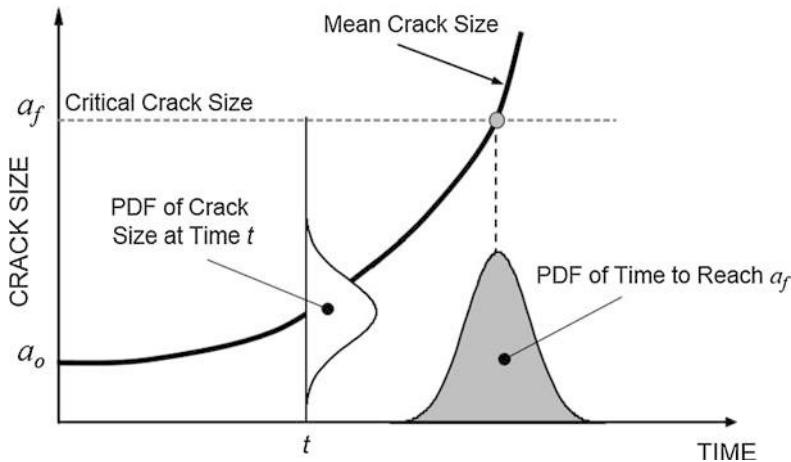

Fig. 45.2 Crack growth under uncertainty

assessment is required. For such probabilistic analysis, uncertainties associated with the parameters C , m , a_o , N_{avg} , and S_{re} should be accounted for by considering their associated probabilistic distributions. The parameters C and m are material properties whose descriptors can be found through the results of experimental programs, while the stress range and the number of cycles depend on the loading conditions at the detail. The final outcome of stochastic fatigue crack growth analysis is to obtain the probabilistic crack growth profile with respect to time. Other useful information can also be found from such analysis. For instance, the PDF of the time required for the crack to reach a given size can be identified. Accordingly, such analyses can yield the PDF of the time to reach the critical crack size (or the time to failure) which can be employed to find an estimate of the reliability and failure hazard associated with the detail based on lifetime functions [32]. Furthermore, the PDF of the crack size at a given time instance can be also be quantified. Figure 45.2 shows schematically the results of such process.

Although the model based on Paris' law does not consider factors such as the effect of variable amplitude loading, mean stress, and the stress ratio, it has been widely used for predicting the crack growth profile, analyzing the fatigue reliability, and establishing the optimum inspection and maintenance plans. In order to identify the probabilistic fatigue crack growth profile by using Paris' law, several stochastic approaches have been proposed. Guedes Soares and Garbatov [23] proposed a probabilistic approach based on Paris' law to study the time-variant fatigue reliability of steel ship details. Assuming that $K(a)$ is constant, an expression for the expected crack size over time was given by

$$a(t) = \left[a_o^{1-\frac{m}{2}} + \left(1 + \frac{m}{2} \right) \cdot C \cdot (S_{re})^m \cdot K(a)^m \cdot \pi^{\frac{m}{2}} \cdot N(t) \right]^{\frac{1}{(1-m/2)}} \quad (45.20)$$

where $N(t)$ represents the time cumulative number of cycles.

In this approach, the crack growth was predicted by implementing Taylor-series expansion of the crack size at the mean values of C , a_o , and S_{re} . Other parameters of the crack growth model were treated as deterministic. A similar approach was implemented by Chung et al. [8] to predict the fatigue crack growth and obtain the optimum nondestructive inspection times for fatigue-prone details in steel bridges. However, their approach implemented Monte Carlo simulation to predict the crack growth profile. These approaches only predict the crack propagation under uncertainty, and the crack initiation can be incorporated by assuming that an initial defect with size a_o exists in the detail.

The fracture mechanics approach was also employed by Kim and Frangopol [28] to find the optimum inspection schedule for fatigue critical details which minimize the damage detection delay. This delay is defined as the time elapsed between the damage occurrence and the damage detection. In their study, Eq. (45.19) was used in a Monte Carlo simulation process to predict the time-dependent crack growth. The study was extended in Kim and Frangopol [29] to find the inspection schedule which simultaneously minimizes the damage detection delay and the life-cycle inspection cost. Soliman et al. [49] also accounted for the uncertainties in the fatigue crack growth model parameters by using Monte Carlo simulation in a study to find the optimum nondestructive inspection times and types for a bridge structure with multiple critical fatigue details. Although the parameter m in Eq. (45.19) was considered deterministic in the previous studies, several studies show that this parameter should be considered as a random variable with high correlation between the parameters C and m . However, Kim et al. [30] shows that considering the uncertainty associated with m will have a minor effect on the fatigue crack growth simulation results.

Since the descriptors of input parameters will have a significant effect on the simulation results, the proper implementation of uncertainty quantification and reduction techniques is necessary to improve the accuracy of such prediction model. With respect to the stress range and the number of cycles, perhaps the most effective technique for uncertainty quantification is to use the information obtained from structural health monitoring of analyzed details [7,31,33]. In such programs, sensors are installed at the critical members to record the strain histories under normal loading conditions for a sufficient period of time. Next, a cycle counting algorithm such as the rainflow [12] method is implemented to establish the stress-range bin histograms and the cycle count. This information can be used to find an accurate estimate of the stress range and number of cycles [11] which is used for fatigue analysis.

Other parameters, such as the initial crack size, can be identified using field inspection outcomes for surface growing cracks. However, in most of the cases, an initial crack size is assumed depending on the capabilities of the inspection method. For visually inspected components, it can be assumed to be 2.5 mm [45], while a smaller value (e.g., 0.5 mm) can be considered for other nondestructive inspection techniques. However, for probabilistic analysis, this parameter is generally considered as a random variable. Yazdani and Albrecht [55] suggest that the mean value should be 0.5 mm. Other smaller values have been also reported in literature, for

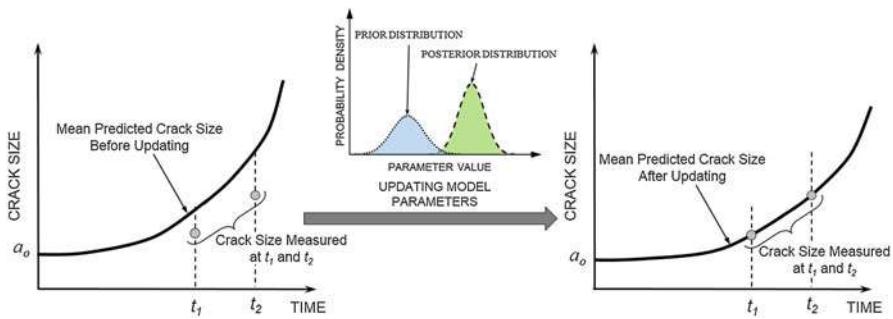

Fig. 45.3 Fatigue crack growth updating based on inspection outcomes

Instance, Moan and Song [38] considered the mean value to be 0.11 mm. Several distribution types for this parameters have also been reported including lognormal distribution [30, 49] and exponential distribution [38]. Additionally, the coefficient of variation of the initial crack size has been reported to range from 0.2 to 0.5 [8, 30]. Accordingly, a significant variability in the value of the initial crack size can be seen. Similar variability in the descriptors of the random variables C and m can also be found. Accordingly, attempts to quantify the uncertainties associated with these parameters should be made to improve the accuracy of the stochastic analysis.

To help quantifying the uncertainties associated with such model parameters, the Bayesian approach can be used to find a better representation of the model parameters' descriptors given field inspection information. In this approach, the information from inspection actions is used to represent the likelihood function which can be combined with the prior knowledge of the model parameters to yield an updated posterior distribution of the model parameters. Hence, the performance prediction is performed using the posterior parameters to achieve more reliable results. Figure 45.3 schematically shows this process. This approach was investigated by [24], in which the probability of detection was used in an updating procedure to predict the posterior distribution of the initial crack size at a certain point in time, and the measurement was used as the new data to update the PDF of the initial crack size. However, inspection optimization and scheduling was not considered as a goal of their study. Perrin et al. [43] used Bayesian techniques and Markov Chain Monte Carlo (MCMC) for fatigue crack growth analysis based on data collected during experimental investigations. Their results showed the feasibility of updating the model parameters based on crack size measurements. Li et al. [34] used Bayesian updating to study the effect of the sensor degradation on the estimation of the remaining useful life of structures. Soliman and Frangopol [47] proposed an approach to establish integrated management plans that provide optimal intervention times and types while making use of the available inspection and monitoring information to improve the performance prediction process, and, hence, better and effective decisions can be made. In this process, information from field measurement is used to represent the likelihood function which can be

combined with the prior information on model parameters to find their posterior distributions. The posterior distributions can be found as

$$P(\boldsymbol{\theta}|\mathbf{d}) = \frac{P(\boldsymbol{\theta}) \cdot P(\mathbf{d}|\boldsymbol{\theta})}{\int P(\boldsymbol{\theta}) \cdot P(\mathbf{d}|\boldsymbol{\theta}) d\boldsymbol{\theta}} \quad (45.21)$$

where $P(\boldsymbol{\theta}|\mathbf{d})$ is the posterior distribution of model parameters $\boldsymbol{\theta}$ given the additional information \mathbf{d} , $P(\boldsymbol{\theta})$ represents the prior distribution of model parameters, $P(\mathbf{d}|\boldsymbol{\theta})$ is the likelihood function of obtaining information \mathbf{d} conditioned by $\boldsymbol{\theta}$, and \mathbf{d} and $\boldsymbol{\theta}$ are the vectors of observed data and model parameters, respectively.

By knowing the prior distributions and the likelihood function, the posterior distributions can be established using sampling approaches based on Markov chain Monte Carlo simulation such as the Metropolis algorithm [36] or the slice sampling algorithm [39]. The considered likelihood function is [43]

$$P(\mathbf{d}|\boldsymbol{\theta}) = \prod_{i=1}^n \left[\frac{1}{\sqrt{2\pi} \cdot \sigma_e} \cdot \exp \left(-\frac{1}{2} \left(\frac{d_i - a_{p,i}}{\sigma_e} \right)^2 \right) \right] \quad (45.22)$$

where d_i and $a_{p,i}$ are the observed and predicted data, respectively, at the i th inspection; σ_e represents a single-error term combining the measurement and modeling errors which is assumed to follow a normal distribution with zero mean and a standard deviation σ_e (i.e., $N(0, \sigma_e)$). The vector of observed data, consisting of crack size measurements identified during fatigue inspections, is

$$\mathbf{d} = \{a_{ins,1}, a_{ins,2}, a_{ins,3}, \dots, a_{ins,n}\} \quad (45.23)$$

where $a_{ins,1}$ = measured crack size at the i th inspection and n = number of inspections. Based on the sample space of inspection outcomes, subsequent inspection times can be found. In Soliman and Frangopol [47], this updating process was integrated in a comprehensive life-cycle management approach to find updated inspection times based on field measurements. An optimization process, executed iteratively for possible crack size measurements, was constructed and solved to find the optimum inspection time which minimizes the total cost which included the inspection cost as well as the failure cost. The outcome of this process is shown schematically in Fig. 45.4.

Although fatigue assessment models based on fracture mechanics are well established, the standardization and formalization of these approaches, especially with respect to stochastic analysis, is still required.

3.2 The S-N Approach

The $S-N$ approach is adopted by most of the specifications for design and assessment of fatigue critical components in bridges and naval vessels. The $S-N$ approach provides a linear or piecewise linear relationship between the logarithm

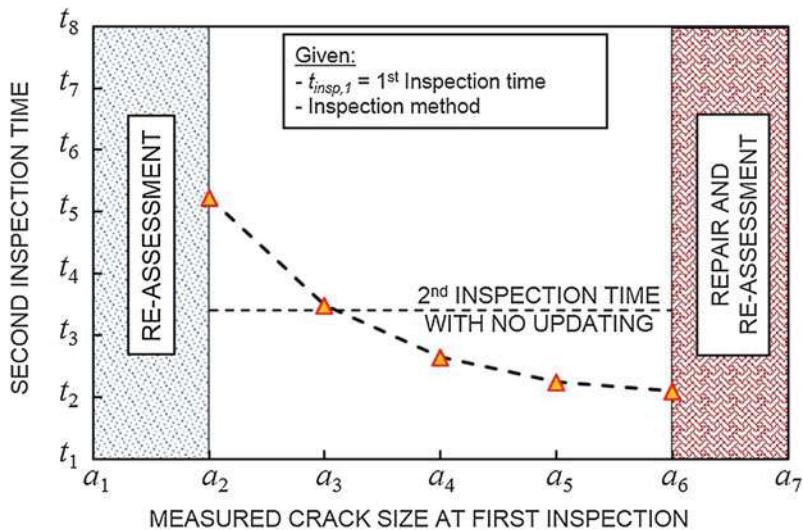

Fig. 45.4 Updated inspection times based on field measurements

of the stress range and the logarithm of the expected number of cycles to failure for several types of details. In order to construct the $S-N$ line for a certain detail, several specimens are tested in the laboratory under different cyclic stress amplitudes until a crack with predefined size propagates through the detail. The number of cycles to failure is plotted against the applied stress range of each specimen, and regression analysis is performed to plot the mean $S-N$ line in the logarithmic scale. In order to achieve a satisfactory probability of survival for designed structures, a design line is usually defined in the codes through shifting the mean line horizontally to the left by a certain amount.

The $S-N$ relationship within each portion of the $S-N$ lines can be expressed as

$$N = A \cdot S^{-m} \quad (45.24)$$

where N is the number of cycles to failure under the stress range S , A is a fatigue detail coefficient for each category, and m is the slope parameter of the $S-N$ line.

In most of the structural components in bridges and ships, fatigue-prone details are normally subjected to variable amplitude stress-range cycles. Accordingly, an equivalent constant amplitude stress range is computed to calculate the fatigue damage under this loading. Miner's rule [37] is the most widely employed method to quantify the fatigue damage accumulation due to variable amplitude loading. If the histogram of stress range is identified for the detail, and assuming a linear damage accumulation, Miner's damage accumulation index is

$$D = \sum_{i=1}^{n_{ss}} \frac{n_i}{N_i} \quad (45.25)$$

where n_{ss} is the number of stress-range bins in a stress-range histogram, n_i is the number of stress cycles in the i th bin with stress range S_i , and N_i is the number of cycles to failure under the stress range S_i . In this model, the failure of the detail occurs when $D = 1.0$. It should be noted that this approach neglects the effect of loading sequence (i.e., the order in which the cycles are applied) which can be significant in some cases [46]. However, for most structural engineering problems where the residual stresses are high and the plasticity is restricted, this model is sufficient to achieve reasonable accuracy [17].

Based on Miner's damage accumulation rule, an equivalent constant amplitude stress range can be defined as

$$S_{re} = \left[\sum_{i=1}^{n_{ss}} \frac{n_i}{N_T} \cdot S_i^m \right]^{\frac{1}{m}} \quad (45.26)$$

where $N_T = \sum_{i=1}^{n_{ss}} n_i$. By knowing the average annual number of cycles N_{avg}^A , an estimate of the fatigue life can be computed as

$$t \text{ (years)} = \frac{N}{N_{avg}^A} \quad (45.27)$$

Several stress analysis methods can be used for the fatigue assessment of steel and aluminum details, namely, the nominal stress, structural hot spot stress, and notch stress. The choice of the stress type and its corresponding $S-N$ relationships depends on the type of details, available measurement data, and the used specifications. The nominal stress approach is adopted by several design and assessment guides such as the Eurocode 9 [15] and the AASHTO [1]. In this approach, the stress range refers to the stresses acting on the considered location neglecting the stress concentration arising from both the weld effects and the structural configuration. Accordingly, The $S-N$ lines inherently consider these effects. This approach is characterized by the ease of application since the calculation of nominal stresses can be simply computed for most structural engineering problems. However, assessing fatigue life of a specific detail using this approach requires the existence of a similar match in the design or assessment guidelines, which requires experimental testing of a large number of details. For steel bridges, the $S-N$ lines in the design and assessment guidelines cover most of the details adopted in practice. However, for steel and aluminum ships, several of the details adopted in practice may not be found in the design guidelines which increases the difficulty of applying the nominal stress approach and calls for the application of either the hot spot or notch stress approaches.

In the structural hot spot stress approach, the stress induced in the proximity of the weld is used. This stress includes the stress concentration due to the structural configuration but not due to the weld itself. Accordingly, this stress is compared to $S-N$ lines which similarly incorporate the effect of weld stress concentration.

Accordingly, computing the hot spot stress requires more advanced structural analysis when compared to the nominal stress. However, using this approach requires a lower number of $S-N$ lines to be developed, which reduces the cost of experimental investigations. To compute the stress without the excluding the concentration due to weld, a single reference point at a prescribed distance from the weld toe can be used. Alternatively, the hot spot stress can be extrapolated by measurement performed at multiple reference points.

In the notch stress approach, the total stress acting at the crack initiation location including the stress concentration due to both the structural configuration and the weld geometry is considered. The notch stress is usually more difficult to obtain; however, it can be used to find the fatigue life of the structural detail using the $S-N$ curve for a base non-welded metal.

For design purposes, it is generally preferred to use the nominal stress approach which requires an exact match of the detail to be found in the design specifications. When dealing with SHM data, it may not be practical to find the stress concentration at the weld toe using strain measurement, due to the high stress gradient at this location. Thus, depending on the available data, the nominal stress approach can be used if a similar detail can be found in design guides. Otherwise, the structural hot spot stress approach can be used.

Although the fatigue life estimation by using the $S-N$ approach is straightforward, uncertainties associated with the fatigue damage process requires more robust probabilistic analysis to evaluate the fatigue life of structural components. Accordingly, reliability-based methodologies for fatigue life assessment have been proposed. These methodologies use the time-variant reliability index as the performance indicator. Through the definition of minimum acceptable reliability levels, the fatigue life is considered to be reached when the reliability reaches its minimum threshold.

The reliability index β is related to the probability of failure P_f (i.e., the probability of violating a certain limit state), through the following relationship:

$$\beta = \Phi^{-1}(1 - P_f) \quad (45.28)$$

in which $\Phi^{-1}(\cdot)$ is the inverse of the standard normal cumulative distribution function. For the estimating the reliability-based remaining fatigue life, the following performance function can be used [3, 25, 31, 48]:

$$g(t) = \Delta - D(t) \quad (45.29)$$

where Δ is Miner's critical damage accumulation index, indicating the allowable accumulated damage, and $D(t)$ is Miner's damage accumulation index indicating the demand. According to Miner's damage accumulation model, the failure of the detail will occur at $\Delta = 1.0$. However, significant variability has been reported in this value. For instance, Collette [10] reports values of Miner's critical damage accumulation for various test programs ranging from 0.5 to more than 10 with most of the values close to one. Accordingly, Miner's critical damage accumulation index is generally treated as a random variable which follow a lognormal distribution.

Most of the studies recommend the mean value to be 0.9 [3] or 1.0 ([9, 48]; [31]) with a coefficient of variation of 0.48 [3, 9] or 0.3 [54].

Based on Eq. (45.24), Miners's damage accumulation index can be computed as

$$D(t) = \frac{N(t)}{A} \cdot S_{re}^m = \frac{t \cdot N_{avg}}{A} \cdot S_{re}^m \quad (45.30)$$

where A and m are the $S-N$ relationship parameters, S_{re} is the equivalent constant amplitude stress range, t is the operational time of the structure, and N_{avg} is average number of cycles. In this model, the $S-N$ parameter A can also be treated as a random variable following a lognormal distribution whose parameters can also be established based on regression analysis of test data.

Based on Eqs. (45.29) and (45.30) and assuming that all the random variables (i.e., S_{re} , A , and Δ) follow the lognormal distribution [3, 31], the fatigue reliability index β can be derived as follows:

$$\beta(t) = \frac{\lambda_\Delta + \lambda_A - m \cdot \lambda_{S_{re}} - \ln N(t)}{\sqrt{\xi_\Delta^2 + \xi_A^2 + (m \cdot \xi_{S_{re}})^2}} \quad (45.31)$$

where λ and ξ are the lognormal parameters associated with different random variables. If the target reliability threshold β_{target} is known, the fatigue life t_f can be determined as follows [48]:

$$t_f = \frac{e^{k-m \cdot \lambda_{S_{re}}}}{N_{avg}} \quad (45.32)$$

where

$$k = \lambda_\Delta + \lambda_A - \beta_{target} \cdot \sqrt{\xi^2} \quad (45.33)$$

and

$$\xi^2 = \xi_\Delta^2 + \xi_A^2 + (m \cdot \xi_{S_{re}})^2 \quad (45.34)$$

Eq. (45.32) represents a direct way to estimate the reliability-based fatigue life for a specific detail once the associated stress-range distribution is known. The performance function in Eq. (45.29) can be used to calculate the reliability index using computer software such as RELSYS [13]. Alternatively, Eq. (45.31) can be used directly to calculate the reliability index under the assumption that all the random variables have a lognormal PDF. After establishing the time-variant fatigue reliability profile, the service life is considered to be achieved when the reliability level reaches the minimum allowable reliability level. With respect to fatigue, this reliability threshold is considered to be ranging from two to four [35].

In newly constructed bridges and naval vessels, fatigue-prone components are designed to have either an infinite fatigue life or a fatigue life that is long enough to avoid failure during the service life. For bridges, fatigue cracks should be repaired as soon as they are discovered in order to prevent the occurrence of sudden failures.

In some structures, such as cable stayed bridges where it is difficult to inspect all the details frequently, monitoring devices can be installed to provide warning when alarming crack growth is detected. However, for large-scale structures which rely to a great extent on welding connections such as ships, thousands of crack initiation locations exist and fatigue cracking is inevitable. In such cases, fatigue repairs and inspections can significantly impact the life-cycle operational cost of a vessel, and the structure can be operating with undetected growing cracks. Methodologies to identify the effect of these growing cracks on the structural performance, reliability, and redundancy levels are still required.

4 Conclusions

The ultimate goal of the design process is minimizing the life-cycle cost while maintaining safety at desired levels [18]. Structural systems are subjected to damage and deterioration in time which may lead to sudden failures. Therefore, in addition to basic safety measures such as the reliability index, quantifying the structural redundancy is beneficial. This chapter briefly discussed the redundancy of structural systems in a life-cycle context. Several measures for system redundancy were reviewed. Then, the time-dependent aspects of redundancy are described, and a methodology for assessing time-dependent redundancy is presented. Finally, several quantifications of the redundancy factor used for structural component design are discussed. The chapter also discussed the probabilistic aspects of the fatigue life estimation problem.

In a probabilistic context, system reliability methods should be incorporated to examine structural system behavior. There are several factors which might have significant impact on the redundancy of structural systems, such as material behavior, system modeling type, and correlation effects, among others. These factors need to be included not only in the redundancy assessment of existing structures but also in the design of new structures.

Much research is still necessary to solve uncertainty quantification problems related to structural redundancy and fatigue in real-life applications. Aleatoric and epistemic uncertainties have to be considered and both forward uncertainty propagation and inverse uncertainty quantification have to be used in order to design robust structures and assess and predict the safety of existing structures.

Matthew Collette

Abstract

Uncertainty quantification in ship structural performance remains uneven. While the ship structure community has long developed probabilistic models for the ocean environment and structural responses, complete quantification frameworks remain the exception not the rule. Much of the current uncertainty focus is around design code development, and more piecemeal responses in areas where current design codes are not adequate. This chapter briefly reviews the current state of the art in ship structural performance, including examples of failures in service. Then, the current design code landscape is reviewed. In design codes today, partial safety factors make scattered appearances, but a wide adoption of such measures is still some time off. While more general concepts of risk are gaining traction in the marine industry for risk-based approval, direct structural performance simulation remains the exception rather than the rule. Different uncertainty types and underlying data are then presented and reviewed. Initially, basic design parameters and underlying operational data are discussed, and then strength and loading models are presented. The fragmented nature of uncertainty quantification is clear across all these topics – while many key responses are described in stochastic frameworks, an equal number of modeling, fabrication, and operational parameters are subject to a large amount of epistemic uncertainty today. This limits the number of integrated uncertainty quantification computations that can be completed today. Finally, an overview of published uncertainty frameworks to date is presented. While none of these frameworks are all-encompassing, they demonstrate both the practical application of uncertainty quantification to current problems and a foundation for future probabilistic modeling advances.

1 Introduction

The application of uncertainty approaches to ship structural performance remains a paradox. While the ship structure community has been at the forefront of probabilistic model development in the past century, holistic and formal uncertainty quantification is almost unheard of in the ship structure community. Instead, the industry developed a set of piecemeal approaches to handle uncertainty. Different techniques, characterizations, and solution methods are used in different areas of the structural design problem. This fragmented approach allows tailoring of the uncertainty method to the specific subproblem at hand. However, the fragmented approach prevents easy integration of various uncertainty sources into a holistic uncertainty or risk measure. Finally, certain parts of structural analysis and decision making still do not explicitly consider uncertainty. Instead they follow traditional allowable-stress decision formats with a single, integrated safety factor based on experience.

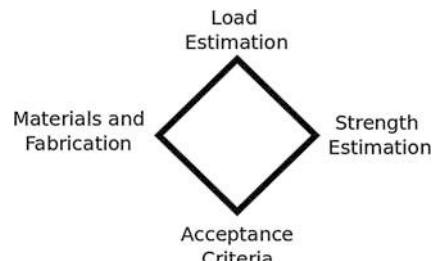

The fragmented uncertainty approach currently in use in the marine industry is a product of several underlying trends. The ocean environment is fundamental stochastic over short time periods, so the need for a probabilistic approach is clear. However, the decentralized growth in analysis methods and regulatory frameworks throughout the long history of the industry has resulted in many independent domains which treat uncertainty in their own way. Movement toward a more integrated uncertainty approach has also been retarded by several unique features of the ship design and analysis problem. Ships are highly flexible assets – inherently capable of moving through different environments across the globe. Furthermore, they are often repurposed or have their original service life extended. Thus, at the outset of their design, their lifespan and future operating conditions are largely unknown. Likewise, regulators are often faced with the need to certify vessels being repurposed whose initial design assumptions and history are largely unknown to

them. Ships are also procured in one-off or short-series production environments. This production environment limits both the time and resources available for custom engineering. For the ship's structure, prototype strength testing and material and production variability surveys are normally cost-prohibitive and not attempted. In this context, existing uncertainty approaches in the marine industry remain fragmented despite past attempts to unify them (e.g., [1]).

The lack of a rigorous uncertainty model has not been without peril in the marine industry. Under the piecemeal approach currently in use, it is possible for new developments in technology to violate the often opaque network of safety factors that keep ship structures safe. This opaque safety factor network arises from assumptions about analysis procedures and construction material and tolerances that are not made explicit in the procedure. Rather, factors of safety are adjusted by experience until satisfactory performance is achieved. But in doing so, load estimation, strength models, material and fabrication standards, and acceptance criteria become tied into a single analysis procedure. It is then no longer possible to substitute a more advanced technique in one area, as the true division of the safety factor and underlying uncertainty between analysis areas is unknown. This is shown in Fig. 46.1 as a diamond, indicating that changes cannot be made to any point of the diamond without impacting the other corners. This concept is based upon work by Sielski [2], where the same idea was represented as an allowable-stress triangle with implied materials and fabrication standards. In Fig. 46.1, the acceptance criteria and strength estimates are more general and the material and fabrication standards are explicit. However, the larger meaning remains – the design approach is a carefully balanced integration of standardized procedures for each point on the diamond. When this balance is disturbed, what appears to be a satisfactory structural design often suffers damage in service.

One example of this pitfall is the introduction of high-strength steel on the trans-Alaskan pipeline service (TAPS) oil tanker design in the 1960s and 1970s. While the high-strength steel raised the ultimate strength of the tanker structure, the fatigue strength of the structural connections used did not increase proportionally. However, fatigue life predictions were not explicitly made for most ship structures at this time – a simple low working stress was being used to handle both strength and fatigue concerns. Combined with higher-than-average wave loading on a route through the Gulf of Alaska and Northern Pacific ocean, numerous ships suffered significant fatigue cracking. This in turn required extensive repairs and an enhanced

Fig. 46.1 Implied balance in current structural design codes and procedures

inspection regime for these vessels to ensure a sufficient level of safety. Barsom and Rolfe present a case study of this problem in Chapter 17 of their fracture mechanics textbook [3].

A second example is the result of the “take tons off sensibly” (TOTS) program in the US Navy. Here, the US Navy reused a smaller hull form from the successful DD-963 class destroyer for the larger CG-47 class cruiser. In an effort to expand the combat capability and increase the weight available for upgrades in the CG-47 class cruiser design, the US Navy and the shipyards involved extensively reviewed the design of the vessel for potential weight savings. By optimizing the structural design, and using higher-strength steel plating, significant weight savings were obtained [4]. Unfortunately, all sources of uncertainty around structural loading and response were not quantified during this optimization. In fact, the hullform is atypical with large bow flare that can dramatically increase impulsive loads from wave impact. Additionally, a new deck-piercing vertical launch system (VLS) for missiles was added to the foredeck near the forward end of the superstructure, creating complex local stress fields. A slight knuckle also exists in the deck forward of the superstructure before the VLS module, leading to an eccentric load path on the deck under compressive loads. While the traditional factors of safety were sufficient to avoid failures in the non-optimized structure without the VLS, the optimized structure suffered frequent deck buckling at the knuckle and fatigue damage in-service [5]. Costly replating and structural retrofits of most vessels in this class were then required. The experience with the TAPS vessels and the CG-47 class highlights the need for better uncertainty management in the marine structural industry.

In addition to in-service failures, the growth of both complex numerical modeling and on-board instrumentation is further highlighting the need for better uncertainty management. The growth in the power of numerical modeling in the past two decades is encouraging engineers to increase the detail of the analysis used in design. This increased power to estimate responses is leading to more aggressive optimization of structures. However, these more advance models also typically require many more inputs of fundamentally stochastic parameters. Without expanding the uncertainty analysis and quantification used in this analysis, a highly precise answer is obtained with unknown variance. Likewise, the rapid growth in in-service monitoring and data recording has led to an increase desire to make structural diagnosis and prognosis decisions for actual structures. However, for most vessels, the as-built and as-repaired condition is rarely fully documented. Such structure-specific analysis also requires an enhanced understanding and quantification of these sources of uncertainty.

The remainder of this chapter summarizes the current state of the art and challenges in uncertainty approaches in ship structural performance. Current approaches in marine industry design codes are presented in Sect. 1. Section 2 discusses the types of uncertainty underlying the ship structural performance problem. Specific focus is given to both uncertainties in the physical system and uncertainties in the modeling and idealization of the structure. Section 3 presents a brief listing and overview of several proposed integrated uncertainty frameworks, and Sect. 4 presents conclusions.

2 Current Uncertainty Handling in Design Codes

All ship structure codes fundamentally balance load capacity and demand to ensure safety in service. Historically, such codes were based on experience and simplified, deterministic calculations that were at best broadly representative of the real loading and structural failure modes occurring in service. Formulations for load magnitudes at specified exceedance probabilities first became possible after a landmark paper in 1953 [6]. This paper extended the electronic filter analogy to a ship operating in waves, allowing the spectrum of the ship's response to be calculated for known wave spectra. Just over a decade later, Dunn [7] advocated a reliability-based approach to the broader problem of design including strength. Dunn framed this argument in terms of stochastic variables following defined distributions, with safety measured probabilistically. Dunn took his inspiration from work with electronics and missile system which were adopting similar formats in the marine industry at this time.

From these initial works, uncertainty rapidly entered the ship structural community via conventional structural reliability analysis (SRA). This development paralleled the rapid advance of reliability in the civil engineering industry. However, unlike civil engineering, reliability did not make the jump to structural design codes via load and resistance factor design (LRFD). While several proposals were made for using reliability, safety indexes, partial safety factors, and LRFD in ship design codes [1, 8, 9], industry-wide adoption of LRFD or partial safety factors has not occurred in the marine industry.

Instead, uncertainty handling via reliability is incorporated into certain areas of design codes. The international association of classification societies (IACS) has developed a standardized code, known as the common structural rules (CSR). The CSR are also a response to the International Maritime Organization (IMO) move toward goal-based standards. Goal-based standards specify the desired safety or performance outcome for a design, instead of specifying prescriptive safety solutions. However, the IMO specification for the goal-based standards only requires that uncertainty be addressed [10] but does not specify how. The current CSR includes the option of using a partial safety factor approach for hull girder collapse limit states. However, other sections of the CSR are still formulated as working stress. IACS has also worked to standardize stochastic descriptions of the ocean environment for design and standardize that extreme loads should be calculated with an exceedance probability of 10^{-8} per wave cycle.

Structural reliability approaches are codified as optional or extra procedures for unusual vessels or situations. These approaches typically go far beyond static LRFD codes. They include direct involvement of the design engineer in building the stochastic uncertainty model. For example, the classification society DNV-GL has issued a classification note on this topic DNV [11]. This note includes guidance on setting up the reliability problem, characterizing the stochastic variables via distributions, computing and evaluating the resulting reliability, and performing inspection updating. However, the application of such approaches remains optional.

The emergence of marine risk-based design methods [12] outside of reliability has also increased the demand for uncertainty modeling. Risk-based design attempts

to quantify risk levels for a variety of events, including many not directly related with structural performance. Much of this work has remained in academic circles to date (e.g. the work of [13] on ship collision probability). Furthermore, performance issues of ship grounding, collision, stability, fire, and evacuation have been investigated in far more detail than structural response. However, a few transitions into codes that address structures have occurred. The ABS classification society has issued a guidance note on approval of novel concepts [14] that codifies how uncertainties are to be handled by a range of quantitative risk assessment procedures beyond structural reliability analysis.

In summary, the current state of the art for handling uncertainties in the marine structural community is fragmented. Certain concepts, such as the wave environment and extreme load exposure levels, are well codified in stochastic models. Other topics such as structural reliability assessment and quantitative risk analysis have been partially codified. However, these tools are typically reserved for novel or special concepts today. Furthermore, no industry-wide standard exists for the implementation of such methods.

3 Uncertainty Types and Values

3.1 Types of Uncertainty

To better understand the nature of uncertainty handling in ship structural design, it is useful to categorize the uncertainties by two different approaches. The first is to separate the uncertainty by its corresponding physical component or mathematical model that it impacts. This section is structured according to this principle. Initially, uncertainties impacting the material and as-fabricated state of the structure are presented. These are followed by uncertainties related to the structure's loading, which includes both environmental descriptions as well as the operational profile associated with the structure. Finally, uncertainties associated with numerical and experimental calculations are addressed.

The second approach in classifying uncertainties is the familiar if philosophically contentious division into *aleatory* and *epistemic* uncertainties. Aleatory uncertainties, those which are fundamentally stochastic properties, primarily impact the basic material and environmental properties for ship structures. In general, statistical data is available for many of these properties. Epistemic uncertainties are those for which there is a general lack of knowledge about the magnitude and distribution of the uncertainty term. For ship structures, operational profiles and behavior, model uncertainty, and the impact of the human engineer comprise the primary epistemic uncertainties. As-fabricated properties, which include the impact of welding residual stresses, misalignment, and similar departures from the ideal structural design, represent a gray zone between the aleatory and epistemic worlds. For some of these topics, limited statistical data exists, while for others there is little generally applicable data available. This division matters in performance prediction,

Table 46.1 Summary of basic material property data uncertainty from Hess et al. [15]

Variable	Mean value	COV	Recommend distribution
Plate thickness, t	1.05 t	0.044	Lognormal
Yield stress, σ_y , ordinary strength steel	1.3 σ_y	0.124	Lognormal
Yield stress, σ_y , high-strength steel	1.19 σ_y	0.083	Lognormal
Ultimate strength, σ_u all steels	1.05 σ_u	0.075	Normal
Elastic modulus, E, all steels	0.987 E	0.076	Normal

as the toolbox for predicting performance with aleatory uncertainties is much richer than that with epistemic uncertainties.

3.2 Uncertainty Data Related to Basic Design Parameters

3.2.1 Structural Geometric and Material Uncertainty

As objects built in either bespoke or short-run production settings, ship structures are primarily assembled from standardized structural components. Hence, statistical data on underlying material and structural shape properties are critical sources of variability. Hess et al. [15] provide a recent listing of material data, including basic material properties such as yield strength and elastic modulus. A summary of this data is shown in Table 46.1. Additionally, deviations from nominal material properties or nominal structural dimensions for structural components are provided. Two-parameter distributions of normal, lognormal, and extreme value distribution are provided for most parameters, with the exception of Poisson's ratio, which is treated as deterministic. While fatigue cracking of built-up structures will be considered later, the fracture toughness of naval steels is an important base material characteristic for crack resistance. Unfortunately, no general distribution of fracture toughness has been proposed to date, with distributions available by steel type, or in the solely in the format of raw data. Notably, Ship Structure Committee report SSC-352 provides extensive Charpy toughness data on a wide range of ship steels from mild steel to high-strength alloys, with about 10,000 individual test results [16]. Sumpter and Kent [17] provide a more recent but more limited investigation into the fracture properties of higher-toughness ship steels.

For the most part, aleatory-type data is available for the underlying material properties and dimensional data of the structural component of ships. Important exceptions to this statement are mainly related to market impact on the structural material. For example, the recent surge in ultra-large containerships (over 10,000 twenty-foot equivalent units (TEU) in capacity) has led to the demand for plates exceeding 50 mm or even 75 mm in thickness, where there is little statistical data to date. Hess et al. [15] also note that contractual ordering practice – paying per pound or per plate piece – can result in bias toward plates that are either at the higher end (paying per pound) or the lower end (paying per piece) of the overall thickness distributions reported.

Through the shipbuilding process, additional stresses and deformations occur in the structure that must be considered for structural performance. The assembly of small structural components into large structures via fusion welding induces residual stresses and geometric imperfections into the structure. As buckling-critical thin shell structures, such deformations and stresses will reduce the ultimate collapse load of the structure. Recent studies have provided data for residual stresses in as-built laboratory specimens (e.g., [18]). Longer-range residual stresses are also known to act on structures. These longer-range stresses result from the subsequent assemblies of smaller structural components into units, blocks, and grand-blocks and finally the finished vessel via welding. Statistical data of as-built finished vessels would be ideal; however, few sources of such data exist.

Smith et al. [19] provides one of the largest databases on such stresses and deformations. Smith et al. summarized field measurements from box-girder bridges and ship structures taken in the 1970s that included both geometric imperfections and residual stresses. Smith et al. then developed slight, average, and severe distortion measurements which they correlated to the mean value and 3% and 97% cumulative probability values of a lognormal distribution fit to their data. The underlying data for this method is now approaching 40 years of age. Its current applicability is uncertain as welding technology has substantially improved over time. Smaller numerical and experimental studies of simple structures have been published since then. These approaches used methods such as FEA analysis of welding operations and taking measurement via the neutron diffraction method (e.g., [20, 21]). However, the community still lacks general predictive statistics that can be run a priori. Therefore, there is both aleatory and epistemic uncertainty present in most deformation and residual stress estimation today.

Unfortunately, the geometric imperfections and residual stresses do not remain constant over a vessel's life. Seaway loading, impact of cargo, tugboats, piers, and assorted floating objects can all increase the amount of geometric distortion present in the structure with time. Firm stochastic information about the impact of these through-life changes is not generally available, though a few studies have begun to shed light on these topics. Jennings et al. [22] provide detailed measurements of in-service structural deformations at 23 locations divided among 13 different ships, including both commercial and military vessels. While deflection data on a grid of points is reported, no statistical distributions are fitted and the total number of samples is rather small considering the variety of structures and locations covered.

Shakedown is another time-varying phenomenon that can reduce the residual stresses in structure over time. In welded plate structures, the peak residual stresses are usually colocated with the welds. These stresses are tensile and result from the need to hold the weld to a roughly constant length as it cools from the solidification point to room temperature. For equilibrium, they must be balanced by compressive stresses away from the weld toe. Typically, the tensile block residual stresses approach the yield strength and strain of the material. The compressive stresses are lower owing to the larger volume they impact and the need for the structure to be in equilibrium. When further tensile loading is applied to the structure in service, the tensile block plastically deforms as it can no longer support higher stress levels.

When this loading is removed, the tensile block unloads elastically to a new, lower, stress level. In this process, applied loads wash out or “shakedown” the residual stresses in the structure.

Much like as-built residual stresses, the community currently lacks widely applicable models to estimate shakedown effects. Gannon et al. [23] reported up to 40% reduction in residual stresses in a stiffened panel with applied loads of roughly 50% of the yield stress. Syahroni and Berge reported on shakedown of peak residual stresses at fatigue notches, including experimental investigation [24]. Similar to Gannon et al. they found applied tensile loads largely reduced the residual stresses at the fatigue notches. The experiments indicated that it is possible to completely eliminate the residual stresses when the tensile overload is 85% of the yield stress of the base metal. While this process has been theoretically explained and experimentally verified, practical uncertainty characterization has not yet been completed. Thus, while basic material properties are well understood, the as-built and in-service shape and stresses in the structure still include epistemic uncertainties.

3.2.2 Structural Degradation Data

In addition to the time-varying changes to deformations and residual stresses, naval structures also degrade over time. Chief among the causes of degradation is corrosion. The marine environment is highly corrosive to most ferrous metals, and corrosion of untreated structural steel is often rapid. Both overall corrosion and pitting corrosion of the structure impact the structure’s ability to function. Overall corrosion impacts structural stress and collapse loads, while pitting corrosion can compromise the hull or tank envelop function of the structure. Further complicating matters, both the environmental and underlying structural stress and deflection characteristics change significantly between ships or even between parts of the same ship. To date, two main approaches have been taken for probabilistic corrosion models. One is based on full-scale measurements from ships in service. For example, Paik et al. [25] fit a shipboard-location-dependent corrosion model to 33,820 oil tanker data points. They adopted a simple stochastic linear corrosion model for the increase of corrosion depth with time and determined the linear coefficient to best follow a Weibull distribution. However, the variability of the data was quite large with underlying population coefficients of variation in excess of 0.8 for most locations and frequently above 1.0. Wang et al. [26] provide similar data using over 110,000 samples, but only provide corrosion amounts at fixed cumulative probabilities, not underlying distribution.

The second corrosion approach taken is to develop a more theoretical model based on scientific studies of smaller coupons and then extend this to the full-scale structure. Melchers [27, 28] provides models for both general and pitting corrosion from this perspective, including coefficient variability and a proposed Frechet distribution for extreme pit depth. However, impacts such as structural cleaning and structural deformations that may disturb corrosion products and recoating are not yet included in such theoretical model. The ideal corrosion model, which can take environmental parameters as a variable and predict probabilistic corrosion over time,

has not yet been formulated; however, reasonable statistical data is now available from these two approaches for common ship structures.

Structural fatigue cracking is another time-varying change to the structure's integrity, load paths, and remaining structural capacity. As one of the few large, weld-fabricated structures that see frequent complete reversal of primary stress fields from tension to compression, naval structures are prone to structural fatigue cracking. In turn, structural fatigue cracking has historically been marked by high variability. Aleatory uncertainties have been shown to be large for structural fatigue crack initiation. It is not uncommon to have otherwise-identical fatigue details fail in laboratory testing with more than one order of magnitude difference in fatigue life under equal loading. Such uncertainty can be recorded in laboratory experiments. However, there are equally significant epistemic uncertainties in fatigue life prediction for most ship structures. Ship structures have historically been fabricated with looser construction tolerances than assembly-line structures such as aerospace structures, and as a result, the weld toe profile, misalignment, and residual stress present in the final as-built structure are often unknown at the design stage. These factors can equally influence the final fatigue life as much as the aleatory uncertainties inherent in the fatigue of large welded structures.

To date, the most common practice is to lump all these uncertainties together and capture aleatory uncertainty measures from laboratory experiments under the assumption that the laboratory specimens represent industrial fabrication tolerances. There have been a few papers focused on the fatigue-related uncertainty in isolation. Wirsching [29] presented the first major study into fatigue crack initiation reliability, including uncertainty in the S-N equation. Collette and Incecik tested simplified reliability formulations against aluminum structural test data and summarized recommended uncertainty measures [30]. Ayyub et al. summarized similar data and proposed LRFD rules for naval ship structures [31], while Folsø et al. performed a similar exercise for commercial ships, including significant data analysis [32]. Depending on the production processes followed, statistical recommendations from the wider engineering community, such as those included in the International Institute of Welding (IIW) publications, may also be applicable to ship structures. For fatigue crack propagation, far fewer studies have been conducted into reasonable values for uncertainty terms in the crack growth laws. In summary, the aleatory aspects of fatigue degradation are relatively well documented for laboratory tests of ship structural components. The epistemic uncertainties have received far less attention to date.

3.2.3 Structural Operational Data

In addition to basic material and structural uncertainty parameters, there are significant uncertainties surrounding the operational condition of the structure. Element such as the operational loading, crew's weather-routing decisions, and the wave climate will all significantly impact the actual loading experienced by the structure. Similar to the basic material data presented above, these uncertainties include both epistemic and aleatory contributions. The state of knowledge varies widely for the

individual topics within the scope of operational data. The operational impact of loading, wave climate, and crew's weather routing will each be reviewed in turn.

The operational weight distribution is the first major contribution to the structural loading of the vessel. Differences in weight and buoyancy along and across the hull lead to large hydrostatic forces and bending moments throughout the structure. While the hydrostatic external loading from the seawater pressure is known with high precision with the vessel at rest, the weight distribution on the vessel is not constant and subject to extreme variability. While the ship's center of gravity is verified after launching, the distribution of mass along the hull is typically not verified, and thus the as-built weight distribution is subject to uncertainty. Once operational, the crew will adjust cargo, fuel, consumables, and ballast water as necessary to maintain adequate trim and stability. These large variable loads are termed still water loads and are typically marked by high uncertainty. Guedes Soares and Moan [33] provide a database of measured still water loads for seven standard ship types and summarized uncertainty measures. The measured data indicated that a normal distribution is appropriate, but that the per-ship coefficient of variation (COV) may be quite high, approaching 0.4.

The ocean wave climate is often represented by engineering idealizations during the assessment of ship structures. The real ocean environment may include multidirectional wave systems (e.g., swell and wind-driven seas from different storm systems) as well as local bathymetric influences. Engineering design idealizes this situation using linear wave theory to reduce the ocean environment into single- or two-parameter unidirectional energy spectra. These spectra are given as functions typically parameterized by wave height and wave period. To represent the different sea states that are likely to occur in a given area, a scatter diagram is created where the relative frequency of specific wave height and period combinations are listed based on observations. The International Association of Classification Societies (IACS) publishes a recommended wave scatter diagram and spectral formulation for worldwide service in Recommendation [34]. Such formulations allow the wave environment to be presented in a framework that includes aleatory uncertainties. Primary epistemic uncertainties include the relevance of the worldwide model to local conditions, the difficulty in predicting extreme values and departure from linear wave theory for extreme wave heights [35], and potential future impacts of climate change on the scatter diagrams [36].

Within the context of the ocean wave environment, the vessel's crew can still decide heading angle and ship's speed with respect to the wave field. Furthermore, using weather forecasts for wide areas of the ocean, the crew can attempt to avoid the worst weather by planning the routing several days in advance. This ability to weather route means that the ocean environment experienced by the vessel may differ from that observed by wave buoys or otherwise stationary observers. Data on crew's decisions with respect to speed and heading can be gathered from two different approaches. Statistical data mining of ship logs can be used to develop operational profiles for vessels, indicating the probability of taking a specific speed and heading given a prevailing sea state. Sikora [37] presents recent data for operational profiles of naval combatants and auxiliaries.

Alternatively, seakeeping calculations for a new design can be made to approximate conditions where the crew would slow down or change heading for comfort or machinery limitation reasons. While many operationally based studies have proposed weather routing algorithms for logistics and fuel savings, few authors have directly addressed the impact of such uncertainties on loading and strength calculations. Sternsson and Björkenstam [38] studied the logs of one type of commercial ship and noted that weather routing significantly reduced the vessel's exposure to wave heights above 7 m, which constitutes most of the extreme hull girder loading. Shu and Moan [39] used numerical simulation to study the impact of crews changing heading or speed based upon the seakeeping performance of the vessel. Their results showed a significant decrease in the vertical bending moment on the ship if such reductions are considered. Most recently, Papanikolaou et al. [40] also examined the uncertainty surrounding on-board decision support systems to assist in such heading and speed choices. In summary, a probabilistic operational profile is now commonplace in ship design, and modification to account for weather routing and crew response is possible. However, the community lacks general statistical data for the uncertainties that go into determining the values in such a profile.

3.3 Uncertainty Data Related to Modeling and Experiments

In addition to the uncertainty surrounding the basic design parameters, further uncertainty in naval structural performance enters from the use of experimental and numerical methods to predict the structure's performance. This uncertainty can also be broken down into aleatory and epistemic categories; however, a more nuanced breakdown is also useful. Unlike basic design variables, modeling and experiments fundamentally involve:

- idealization of the actual responses of interest,
- representation via a potentially imperfectly implemented model of the idealization,
- interaction with a human engineer who may have their own limited understanding of both the idealization and the model.

Experience has shown that such human impacts can be significant, especially for calculations done in a very small community or infrequently, where both the tool reliability and operator knowledge may be less than ideal.

Additionally, compared to basic design parameters, stochastic model of uncertainty in idealizations and models is generally less mature in the marine industry. However, this topic has grown in importance and research activity lately. Several initial studies into modeling and tool uncertainty took place in the 1990s and will be reviewed in this section. A major landmark was the joint International Towing Tank Conference (ITTC) and International Ship and Offshore Structures Congress (ISSC) workshop on stochastic uncertainty modeling for

ship design loads and operational guidance, the papers from which were published in a special issue of *Ocean Engineering* [41].

3.3.1 Uncertainty in Strength Models

Uncertainty in ship structural strength models depends largely on the type of model used to predict stress or strength. Ship structures are investigated in two main approaches, allowable stress and collapse models. Allowable-stress-based approval criteria require linear models to transform the applied loading into stresses. Such stresses are often investigated by a mix of elastic bending theory (e.g., simple beam theory) and linear finite element analysis. Structural deformation and vibration can also be investigated by such approaches. While such an analysis cannot indicate the true margin before collapse, it relies on only limited material and geometric parameters, reducing its exposure to errors in basic design variables that were presented in the previous section. Errors and uncertainty from idealization, modeling, and human error for such models have been investigated, but only limited data is available. A comparison between linear finite element analysis and model results for a containership in the mid-1990s indicated that linear FEA model was able to capture bending and shear stresses within 7% of the true values on average, though the coefficient of variation was relatively high, between 12% and 20%. However, the model struggled much more with torsional-related warping stresses and deformations with errors up to 40% of the true value. In 1996, Östergaard et al. [42] studied a different containership via a series of five different analysis methods, including both FEA and a series of beam analysis approaches. While no full-scale or experimental data was available, the coefficient of variation between the methods was determined to be 9% for the principle stress but 45% for the shear stress. Again, this indicates in part that torsional stresses were harder to capture.

Over the last 20 years since these studies were made, the power of finite element programs has grown. The meshes used for linear analysis today would be much finer than those employed in either study discussed. Regulatory bodies have also made substantial efforts to standardized finite element modeling procedures by issuing detailed modeling guidelines and automating large sections of model creation (e.g., [43, 44]). Such approaches should reduce the variability between different analysts modeling the same structure. However, more recent data on the idealization error of such models has not been published, nor has the role of the human engineering in making modeling decisions been quantified. At the present time, it is difficult to give firm error estimates for the application of FEA approaches.

Idealization and modeling errors also grow in situations where the underlying physics is not clear or is difficult to model via linear methods. Fatigue crack initiation is one such area for ship structures. As most fatigue cracks initiate from notches at weld toes in ship structures, they cannot be directly analyzed by linear FEA. In linear FEA, the local stress approaches infinity at the weld toe owing to the geometric discontinuity at the weld toe. To overcome this, a variety of stress-measuring locations, extrapolation procedures, or geometry model modification procedures have been proposed. Standardized methods have been developed, such as the nominal stress, hot-spot stress, and notch stress approaches. All of these develop

a reference stress related to the stress believed to be causing crack initiation that is calculable with linear finite element analysis. However, while the concept of the reference stress has been standardized, the implementation and modeling do vary, leading to significant modeling uncertainty.

In a 2002 benchmark study, Fricke et al. [45] studied the same weld toe via seven different hot-spot analysis techniques. The predicted fatigue life of the detail varied between 1.8 and 20.7 years, indicating a high level of modeling and idealization uncertainty. A similar study has also been made of notch stress analysis techniques [46], again showing significant variability. While such studies have shown that the variability in fatigue idealizations is high, statistics for a particular given method of analysis on a type of structure are generally not available. In a study investigating aluminum fatigue experimental test results with author-reported hot-spot stress analysis, Collette and Incecik [30] showed that the different test programs were from distinct statistical populations. Thus, a common uncertainty measure was not recommended. Idealization and modeling errors for fatigue analysis remain a topic of investigation for the marine community.

The second major ship structure modeling approach is collapse models where the nonlinear failure of the structure is directly estimated. This is typically done either via simplified semi-analytic models or nonlinear finite element models. As ships are thin-walled shell structures, collapse strength is dependent on far more basic variables than the linear FEA allowable stress method reviewed above. Imperfections, residual stresses, and yield stress variations can all strongly impact the computed collapse strength. Additionally, the modeling is more complex than linear elastic analysis. The uncertainty in such collapse models has been actively investigated for over 30 years.

As would be expected, collapse models for smaller portions of a structure (e.g., an unstiffened plate in isolation) generally perform with less variability than models for more complex assemblies of structural components. This is a result of simpler and better-fitting idealizations at the component level. For a series of stiffened panels tested in compression, results have shown that most simplified analysis methods can predict the strength of the panel within roughly 10% of the true load and the coefficient of variation of the prediction also typically close to 10% [47]. However, these predictions are with fairly complete information about the as-built material yield stresses, imperfections, and residual stresses in the structure – e.g., the underlying material and geometry uncertainties have largely been removed. Modeling such simple structural experiments also present minimal opportunity for human analyst error as the topology, boundary conditions, and relevant failure modes are normally clear by inspection.

For a more complex calculation of the collapse of ship hull, a benchmark calculation between a range of mostly simplified analysis methods was made in 1994 [48] on a 1/3 scale frigate hull that was also tested experimentally. The results showed much greater scatter with most methods having errors between 10% and 20%, with some methods missing by as much as 40%. However, the structure of this test case was much more slender than typically commercial vessels, which may explain some of the struggles of the simplified methods. Recent guidance has

suggested that simplified collapse methods have a bias factor less than 5% and a COV approaching 10% when compared to nonlinear finite element analysis for conventional ships [49].

Errors in nonlinear finite element analysis are not yet clear. In principle, the FEA models are able to capture many more failure modes and mode interactions more successfully than the previous generation of simplified analysis codes. In practice, the number of modeling and idealization decisions that must go into generating and solving such a large model are easily an order of magnitude higher than the simplified analysis codes. Thus, the opportunity for idealization and human analyst errors is higher. Unfortunately, data on FEA model idealization error is quite limited at the moment. Rigo et al. [50] compared six different FEA analyses of an aluminum-stiffened panel with established geometry and boundary conditions. The six analysis runs were done by different authors who used different codes, meshes, and element types. In general, the ultimate strength prediction of the panel fell within a 4% error band, indicating good agreement, though the post-collapse behavior did differ more strikingly.

In 2012, Paik et al. [51] compared ten different overall collapse prediction codes on six different ships. The codes included both nonlinear FEA and various simplified methods. In general, the scatter of the results across all methods was on the order of 10–20%, including the FEA codes. Even within FEA analysis, similar results were seen. For example, the same commercial code (ANSYS) was used by two participants. For most of the vessels, they investigated the results between the two participants differed 10–20%. This indicates the idealization decisions made by the analyst for nonlinear FEA may be a first-order uncertainty in the calculation. Moan et al. [52] provide a framework for more formally assessing such uncertainties, but again without data for the general analyst. Such overall ship collapse analysis with nonlinear finite element analysis has only been tractable for about the past decade with standard FEA codes, so this area is still one in rapid development.

3.3.2 Uncertainty in Loading Models

Similar to strength models, seaway loading models come in various forms. The loading on vessel may be estimated by empirical or semiempirical equations, linear idealizations of the wave-body interaction problem, or nonlinear methods. The nonlinear methods may be further divided into those based on nonviscous potential flow theory and those that included viscosity. Finally, experimental model tests can be run using scale models of the full-scale structure in wave basins or tanks. These five methods form a hierarchy of fidelity, and in general it takes more than an order of magnitude of effort to move up one level. A further complication comes from the need to figure out load combination factors – in general, the different components of load are estimated independently and then need to be combined into design load cases for strength analysis. These load combination factors are also subject to modeling and idealization uncertainty. Loading model uncertainty can also be broken down into aleatory and epistemic categories, as well as categories dealing with modeling or idealization, implementation, and human application errors.

Schellin et al. [53] compared experimental loads on a containership to the predicted load from four different linear, potential-flow analysis tools. These tools included both 2-D and 3-D idealizations of the fluid flow. Extrapolating to design loads with probabilities of 10^{-4} and 10^{-8} showed large variability between the codes, with the 2-D methods somewhat closer and generally above the experimental results. The 3-D method provided predictions that were roughly 75% of the value of the experiments, but why this higher-fidelity method struggled is unclear. A more recent study examined many of the same issues and concluded the bias from the linear seakeeping tools on extreme loads was 0.9 with a COV of 0.1 [54]. However, uncertainties in the nonlinearities that often occur around extreme events were not addressed by either study. In general, such terms remain difficult to estimate today.

Non-extreme load prediction also matters for fatigue assessment of ship structures. Li et al. [55] compared five different hydrodynamic approaches for calculating the fatigue damage on an instrumented containership in oblique seas. The methods ranged from linear 2-D approximations to 3-D nonlinear panel methods. Full-scale stresses were also recorded onboard for comparison. Two different structural models were used to convert the loads to stresses, a beam theory approach, and a finite element model. Many of the methods overestimated the cumulative fatigue damage by a factor of 1.5 to 2 for 20-min records in low sea states, with the highest-fidelity method being the most accurate, generally within about 10% of the true value for one side of the vessel, but off 20–30% on the other side of the vessel. While general design values of bias factors remain elusive, it is clear that the uncertainty associated with load estimation is a first-order component of structural performance assessment.

As the hydrodynamic responses become more non-linear, these uncertainties increase further. A recent study benchmarked a large roll-on/roll-off ferry subject to impulsive slamming loads [56]. Scale model tests from a flexible model were available for this ferry and were used in a blind benchmarking study with six participants. Impulsive loads generally consist of a locally high peak pressure against a small portion of the vessel that excites an overall structural response (termed whipping) in the entire vessel. This study concentrated on the whipping response post-slam, not the local impact pressures. The participants used both 2-D and 3-D FEA models to capture the overall structural response. Notably, the 3-D FEA models struggled to predict the correct modal frequencies and shapes of the experiment more than the 2-D models; this was attributed to the more complex modeling involved. The results for structural fatigue damage from whipping responses were highly scattered with error factors between 2 and 4 common between participants. The fatigue damage mentioned in this paragraph and the previous paragraph is proportional to the predicted stress raised to the third or fourth power. Therefore, the errors in stress analysis are smaller than the raw fatigue damage indicates. However, the limited studies to date make it clear that there is still a high level of variability present in trying to approximate the dynamic response of ship structures. Additionally, estimation of model errors in the local pressure regions has not yet been addressed.

Beyond numerical calculations, scale model experiments are widely used to estimate structural loads. The hydrodynamic experimental community has been at the forefront of uncertainty management in the marine domain. In 2008, the International Towing Tank Conference (ITTC) published recommendations on uncertainty analysis, followed up by a 2011 procedure for uncertainty measurement in seakeeping experiments. This procedure in turn follows the 1995 International Standards Organization ISO-GUM uncertainty approach, in which uncertainties are subdivided into two types, “A” and “B,” with standard uncertainty measures defined. Type “A” uncertainties deal with the repeatability of a given experiment on the experimental apparatus, while Type “B” addressed modeling errors, measuring and calibration errors, and other errors that are likely to be constant throughout an experiment. These values are facility dependent, and thus general values cannot be given. However, a detailed overview of the approach plus sample values for a surface submarine test are given in [57]. Compared to numerical predictions, the uncertainty from such an assessment is clearer and easier to propagate through downstream calculations.

4 Proposed Frameworks to Date

The fragmented nature of uncertainty data and quantification techniques reviewed in the proceeding section have prevented the adoption of a standard uncertainty quantification framework for regulatory approval of ship structures. As reviewed above, hybrid approaches are in place for most regulatory bodies, with mixed uncertainty handling techniques. However, several academic and research studies have proposed the development of more integrated frameworks, which tie multiple uncertainties together in a chained calculation. These studies are largely pointers toward what may be possible in the future, compared to current application. Many of these still only address a fraction of the uncertainties discussed above and generally simplify or ignore the epistemic uncertainties.

Most of frameworks have built off of structural reliability theory from civil engineering applications, though a few have tried to bring in other risk approaches. In general, the early proposals have focused on LRFD design approaches and replacing existing design-stage rules with rules that more consistently treat uncertainty. More recently, authors have focused on the entire through-life problem of understanding, modeling, and predicting adequate structural performance of a degrading ship structure over time. Most of these approaches include structural reliability to include loading and resistance uncertainties, and some include inspection updating as well as uncertainties in degradation models. Recently, some attention has been paid to tying structural performance uncertainty into a more general description of design risk, including consequences of structural failure. Significant bodies of work are highlighted in Table 46.2.

Table 46.2 Recent integrated uncertainty works

Main author	Description	Key references
Mansour	A structural reliability-based design approach for ships, handling material, loading, and model uncertainty. Design stage only. Documented in several Ship Structure Committee reports and journal articles	[8, 9]
Ayyub (1)	A structural reliability-based approach simplified to a load and resistance factor design (LRFD) approach. Design stage only. Published in reports and a special issue of a journal	[1, 15, 31]
Garbatov	A time-varying reliability of a ship's structure including the impact of corrosion, fatigue crack growth, and crew maintenance actions. Uncertainty included in most model and underlying parameters	[58, 59]
Frangopol	A time-varying reliability formulation with redundancy and optimal inspection/maintenance planning adapted from similar civil engineering approaches for bridges. Includes parametric uncertainty in underlying model variables	[60–62]
Faber	A Bayesian-network risk assessment for ship structural failures. Focuses on post-failure performance and consequence based on estimated statistics of structural failure and then optimization of required structural performance for minimal lifecycle costs	[63, 64]
Ayyub (2)	A time-varying structural reliability assessment of ship structures including corrosion and fatigue. Uncertainty included via structural reliability approaches, system-level reliability approaches used to integrate multiple-component reliability measures	[65]
Moan	A structural fatigue reliability including operations in multiple different sea conditions and inspection updating	[66]

5 Conclusions

The inclusion of uncertainty in the analysis of ship structural performance is uneven. While the marine industry has a long history of incorporating probabilistic design concepts into structural analysis and approval, holistic uncertainty approaches are almost entirely lacking. In design codes today, partial safety factors make scattered appearances, but a wide adoption of such measures is still some time off. While more general concepts of risk are gaining traction in the marine industry outside of structures for risk-based approval, direct structural performance simulation remains the exception rather than the rule. In looking toward what is needed for such a transition, the lack of key data required for structural performance analysis under uncertainty is a retarding factor. While some aleatory uncertainties around material properties and environmental conditions are well established, many topics remain in the epistemic realm with little data to guide an analyst today. This is especially true for the in-service structural condition, hydrodynamic load estimation, and the influence of the human analyst on the increasingly complex hydrodynamic and structural

models used. Despite this circumstance, several authors have proposed integrated frameworks that tie multiple pieces of uncertainty together and increasingly include inspection updating and lifecycle performance and risk measures. Such studies point the way to increased use of uncertainty in the future evaluation of ship structural performance.

The author wishes to acknowledge helpful discussion with Dr. Paul Hess of Code 331 at the Office of Naval Research in the USA in framing this chapter.

Uncertainty Quantification's Role in Modeling and Simulation Planning, and Credibility Assessment Through the Predictive Capability Maturity Model

W. J. Rider, W. R. Witkowski, and Vincent A. Mousseau

Abstract

The importance of credible, trustworthy numerical simulations is obvious especially when using the results for making high-consequence decisions. Determining the credibility of such numerical predictions is much more difficult and requires a systematic approach to assessing predictive capability, associated uncertainties and overall confidence in the computational simulation process for the intended use of the model. This process begins with an evaluation of the computational modeling of the identified, important physics of the simulation for its intended use. This is commonly done through a Phenomena Identification Ranking Table (PIRT). Then an assessment of the evidence basis supporting the ability to computationally simulate these physics can be performed using various frameworks such as the Predictive Capability Maturity Model (PCMM). Several critical activities follow in the areas of code and solution verification, validation and uncertainty quantification, which will be described in detail in the following sections. The subject matter is introduced for general applications but specifics are given for the failure prediction project.

The first task that must be completed in the verification & validation procedure is to perform a credibility assessment to fully understand the requirements and limitations of the current computational simulation capability for the specific application intended use. The PIRT and PCMM are tools used at Sandia National Laboratories (SNL) to provide a consistent manner to perform such an assessment. Ideally, all stakeholders should be represented and contribute to perform an accurate credibility assessment. PIRTs and PCMMs are both described in brief detail below and the resulting assessments for an example project are given.

1 Introduction to Predictive Capability Maturity Model (PCMM)

The PCMM was developed at SNL for the DOE Advanced Simulation and Computing (ASC) program as a means of assessing completeness of modeling and computational simulation activities for a particular application. There have been 3 generations of PCMM with an emphasis evolving from assessment to evidence inventory [8, 9, 11, 12]. Tables 47.1 and 47.2 show one of the PCMM templates commonly used. There are 6 elements to computational simulation that require investigation with respect to maturity level. Each element has several factors to consider. In the early PCMM versions these were divided into subcategories to be assessed separately but in the newer, current version these are areas to explore, consider and aggregate when determining an overall evaluation of the element. The stakeholders, from analysts to the customers, must determine what the appropriate goals, or required maturity levels, are for each of the elements for the required simulation. The supporting evidence determines the current level of maturity and qualifies the assessment. The difference between the current state and desired maturity level identifies the gaps that need to be addressed. Before the project progresses it must be determined and accepted by all involved whether these gaps are acceptable (and thereby, the required maturity level reduced) or what the mitigation plan is to reduce this gap. Often these gaps cannot be closed due to funding, time or technical constraints. Therefore, it must be determined whether a compromise between the stakeholders is possible and viable.

The PCMM assessment performed by the analysis team for the example is given in Table 47.1 with the specific “grades” highlighted in light green. The programmatic maturity level goal/target was determined to be a level 2 for all

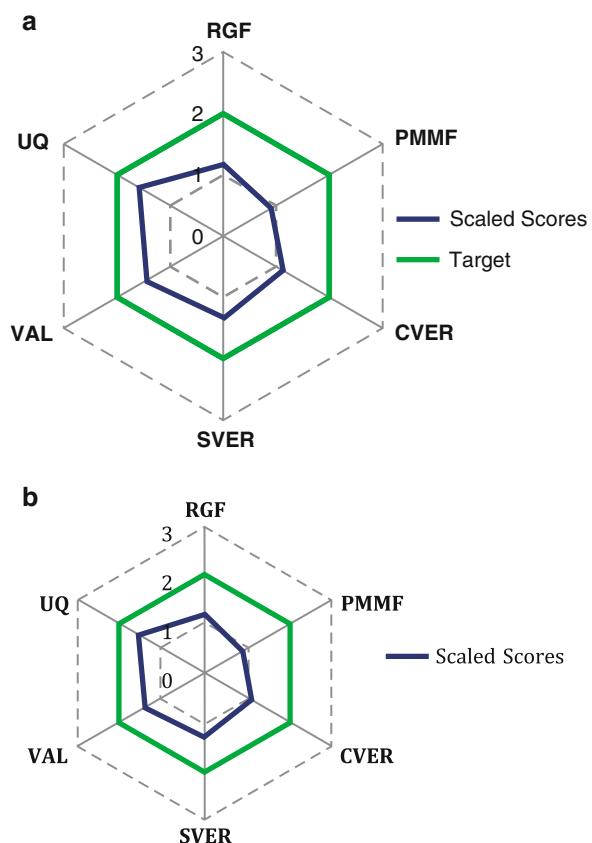

Table 47.1 The commonly seen PCMM Template with current state quality levels in green transparent boxes

MATURITY ELEMENT	Maturity Level 0 Low Consequence, Minimal M&S Impact, e.g. Scoping Studies	Maturity Level 1 Moderate Consequence, Some M&S Impact, e.g. Design Support	Maturity Level 2 High-Consequence, High M&S Impact, e.g. Qualification Support	Maturity Level 3 High-Consequence, Decision-Making Based on M&S, e.g. Qualification or Certification

Fig. 47.1 Kiviat plots for PCMM assessment score display

elements at the beginning of the project. A Kiviat diagram can be used to provide a visual metric of the state of each of the elements as compared to the specified target level. This simple chart quickly shows which element of providing a credible prediction is lacking, and which are meeting the target. For the puncture example, the associated Kiviat diagram is shown in Fig. 47.1 which reveals the state of the PCMM graphically.

The PCMM was defined to allow the assessment of the state of modeling and simulation (M&S) in a manner that balances all aspects of the M&S workflow. PCMM provides a structured breakdown of the component work within an engineering M&S study. Classically it contains six elements, each requiring specific focus when the PCMM is applied. These six elements are geometry/representation fidelity, model fidelity, code verification, solution verification (numerical error estimation), validation and uncertainty quantification/sensitivity analysis. Each of these elements entails significant complexity and contributes to the overall quality.

Part of the original role of PCMM was to organize and structure the achievement of high credibility M&S for the purposes of decision-making. As PCMM was developed at an engineering laboratory, the focus was necessarily centered upon

engineering analysis and thus biased. Over time these biases have become evident upon the application of PCMM to other M&S endeavors. In the process the framework has been modified, extended and its biases lay bare. Each extension has helped the model itself mature and yielded an enhanced understanding regarding its application and form. Among the most important of these extensions is the expansion of the process surrounding PCMM to include pre- and post-conditions and targets and an overall iterative framework for applying the assessment. We have come to view PCMM more as a communication and planning tool than a vehicle for assessment. It is in this broader sense that the PCMM may find its greatest utility in use, the definition of high-credibility M&S for decision making from inception to completion with greater quality. A third way to constructively engage with PCMM is through viewing it as defining the elements of the modeling and simulation workflow. In any workflow the PCMM encapsulates the different issues and topics that must be confronted. Recent work on PCMM has provided a recommended workflow together with the assessment elements.

2 Need for Frameworks

One of the big problems that the entire V&V enterprise has is its sense of imposition on others. Every simulation worth discussing does “V&V” at some level, and almost without exception they have weaknesses. Doing V&V “right” or “well” is not easy or simple. Usually, the proper conduct of V&V will expose numerous problems with a code, model, and/or simulation. It’s kind of like exposing yourself to an annual physical; it’s good for you because you learned something about yourself you didn’t know, but you might have to face some unpleasant realities.

In addition, the activity of V&V is quite broad and something almost always slips between the cracks (or chasms in many cases). To deal with this breadth, the V&V community has developed some frameworks to hold all the details together. Sometimes these frameworks are approached as prescriptions for all the things you must do. Instead we suggest that these frameworks should not be recipes, nor should they be thought of as prescriptions, they are things to be seriously considered. If listed aspects of PCMM are disregarded, it should be justified through rigorous analysis. They are “thou should,” not “thou shalt,” or even “you might.”

Several frameworks exist today and none of them is fit for all purposes, but all of them are instructive on the full range of activities that should be at least considered, if not engaged in.

CSAU – Code Scaling Assessment and Uncertainty [1, 2] developed by the Nuclear Regulatory Committee to manage the quality of analyses done for power plant accidents. It is principally applied to thermal-fluid (i.e. thermal-hydraulic) phenomena that could potentially threaten the ability of nuclear fuel to contain radioactive products. This process led the way and has been updated recently [13]. It includes processes and perspectives that have not been fully replicated in subsequent work. PCMM is attempting to utilize these lessons in improving its completeness.

PCMM – Predictive Capability Maturity Model developed at Sandia National Laboratories for the stockpile stewardship program in the last 10 years. As such it reflects the goals and objectives of this program and Sandia's particular mission space. It was inspired by the CMMI developed by Carnegie Mellon University to measure software process maturity. PCMM was Sandia's response to calls for greater attention to detail in defining the computational input into quantitative margins and uncertainty (QMU), [12] the process for nuclear weapons' certification completed annually.

CAS – Credibility Assessment Scale [3] developed by NASA. They created a similar framework to PCMM for simulation quality in the wake of the shuttle accidents and specifically after Columbia where simulation quality played an unfortunate role. In the process that unfolded with that accident, the practices and approach to modeling and simulation was found to be unsatisfactory. The NASA approach has been adopted by the agency, but does not seem to be enforced. This is a clear problem and potentially important lesson. There is a difference between an enforced standard (i.e., CSAU) and one that comes across as well intentioned, but powerless directives. Analysis should be done with substantial rigor when lives are on the line. Ironically, formally demanding this rigor may not be the most productive way to achieve this end.

PMI – Predictive Maturity Index developed at Los Alamos [5, 19] This framework is substantially more focused upon validation and uncertainty, and it is a bit lax with respect to the code's software and numerical issues. These aspects are necessary to focus upon given advances in the past 25 years since CSAU came into use in the nuclear industry.

MURM – Model Utilization Risk Management was developed by the Applied Physics Laboratory [10] to provide an explicit scoring system for risks associated with using M&S in decision-making. The MURM's intent is to provide a scale for considering the risk-based maturity of the capability and the risk-based assessment of the decision. This should provide the decision-maker with the information necessary to make an informed choice in utilizing M&S in a process.

Computational simulations are increasingly being used in our modern society to replace some degree of expensive or dangerous experiments and tests or where tests can't be conducted. The reliance on computational fluid and solid mechanics are ever more commonplace in modern engineering practice. The challenge of climate change may be another avenue where simulation quality is scrutinized and could benefit from a structured, disciplined approach to quality. Ultimately, these frameworks serve the role of providing greater confidence (faith) in the simulation results and their place in decision-making. Climate modeling is a place where simulation and modeling plays a large role, and the decisions being made are huge.

The question lingers in the mind, "what can these frameworks do for me?" Our answer follows:

1. V&V and UQ are both deep fields with numerous deep subfields. Keeping all of this straight is a massive undertaking beyond the capacity of most professional scientists or engineers. A framework provides a blueprint for

conducting detailed studies and making certain that no aspect of the technical work remains untouched. Such assessments are prone to missing important details associated with topics that may not be within the expertise of those doing the work.

2. Human behavior shows that everyone will default to focusing on where they are strong and comfortable, or interested. For some people it is mesh generation, for others it is modeling, and for yet others it is analysis of results. Such deep focus may not lead (or is not likely to lead) to the right sort of quality. Where quality is needed is dependent upon the problem itself and how the problem's solution is used. The frameworks provide a holistic view of quality where deep focus does not necessarily lead to myopic behavior. It also encourages a more collaborative aspect for the conduct of V&V by highlighting where expertise needs to be sought beyond those conducting the work.
3. These are useful outlines for all of the activities that a modeling and simulation project might consider. Project planning can use the frameworks to develop help set objectives and subtasks and prioritize and schedule work. The frameworks also provide a rubric for the peer review of such efforts and allow for the proper determination of the breadth of capabilities that might be needed for peer review.
4. These are menus of all the sort of things you might do, not all the things you must do. Combining the outcomes from the PIRT and the intended use of the simulation and modeling provides a means of sorting through the menu. It also allows the determination of the activities not conducted to be explicit rather than implicit in the assessment.
5. They provide a sequenced set of activities, prepared in a sequenced rational manner with an eye toward what the modeling and simulation is used for (intended use). Again, the framework provides suggestions and not a straight-jacket. Different sequencing can be executed if reasoned analysis calls for it. The frameworks give a structured manner where the work can be extended or improved in a rational manner if resources become available.
6. They help keep activities in balance. A generally holistic quality mentality is encouraged and deviations from full coverage are explicitly available. The framework if properly utilized will help keep you honest.
7. You will understand what is fit for purpose, when you have put too much effort into a single aspect of quality. Both the impact of neglected aspects of the modeling and simulation effort and steps to remove such neglect can be easily accessed via the framework.
8. V&V and UQ are developing quickly and the frameworks provide a "cheat sheet" for all of the different aspects. It assures that the analysis, assessment and examination remains current. Generally the list of potential activities can never be exhausted given fixed resources most projects operate under. The frameworks provide a means of looking towards and measuring continuous improvement.
9. A framework's flexibility is key and not every application necessarily should focus on every quality aspect, or apply every quality approach in equal

- measure. Again the whole aspect of balancing a holistic view of quality with an appropriate narrowing effort put toward more critical aspects of a particular modeling and simulation effort is necessary.
10. Validation itself is incredibly hard in both breadth and depth. It should be engaged in a structured, thoughtful manner with a strong focus on the end application. Validation is easy to do poorly; the frameworks provide steps where the underlying work for high quality validation is readily available.
 11. The computational science community largely ignores verification of code and calculations. Even when it is done, it is usually done poorly, or insufficiently. The frameworks provide a focus on this aspect of V&V so that it is not entirely ignored by any effort utilizing them.
 12. Error estimation and uncertainty too rarely include the impact of numerical error, and estimate uncertainty primarily through parametric changes in models. These efforts are highlighted in frameworks and lead to higher quality assessments and provide the means for improving many efforts.
 13. Another element of the frameworks is the accounting for numerical errors which is usually much larger than acknowledged. Lots of parametric and model calibration is actually accounting for the numerical error, or providing numerical stability rather than physical modeling.
 14. A framework helps identify gaps and associated risks for each modeling and simulation effort. These gaps can be targeted as additional work to improve quality.
 15. Lastly, a framework can help you incorporate project resource constraints and identify associated risks and consequences in forgoing various V&V activities. They also provide an explicit focus on both what is done, but also what is not done. None of this is an alternative to a hard hitting and technically focused peer review. Bringing in independent experts and fresh perspectives is utterly invaluable to the honesty and integrity of quality assessment.

3 Different Frameworks and Their Vision

3.1 The Original PCMM

As originally constructed (and reported in [9]) the PCMM addressed six elements that were identified to be essential for successful application of modeling and simulation. These elements were:

- Representation and geometric fidelity
- Physics and material model fidelity
- Code verification
- Solution verification
- Model validation
- Uncertainty quantification (UQ) and sensitivity analysis (SA)

In the PCMM process a general set of attributes were identified for each of these elements to permit characterization of each element into one of four maturity levels (0-3) This resulted in defining a matrix of maturity levels verses PCMM elements as illustrated in Table 47.2.

As can be seen from the information contained in Table 47.2, the PCMM maturity levels constitute a hierarchy that represents increasingly greater levels of sophistication and computational fidelity (and expense and resources). The levels contained within this hierarchy can be summarized as follows.

- Level 0: At this level there is little or no assessment of completeness and accuracy and the capabilities for the element being assessed are highly reliant on personal experience and judgment.
- Level 1: For this level an informal assessment of completeness and accuracy has been performed using internal peer review groups.
- Level 2: This level applies a formal process to assess completeness and accuracy of the element being evaluated. At this level use is made of external peer reviews for at least some of these assessments.
- Level 3: Finally, at this level a formal assessment of the element has been completed with the assessments predominantly being conducted by external peer reviews.

We note that the assessment of the levels of maturity does not, by itself, indicate the degree to which the M&S capability will be successful at meeting the requirements identified to address a particular application (e.g. a licensing application or a regulatory requirement, or a design specification). To identify the degree to which such a capability will be present for a particular application, one would compare the assessed maturity level for the PCMM elements with an objective level of maturity that is identified as necessary for the application of interest. Any application will provide specific quantities of interest associated with defining a successful outcome for the intended purpose.

3.2 Variations on a Theme

PCMM is a framework to organize that entire V&V and UQ landscape into neat little boxes. Of course reality is never so neat and tidy, but structure for such a complex and potentially unbounded activity is good. PCMM has gone through numerous revisions, extensions and rearticulations, and the safest conclusion is that the framework will never be complete. While for any given use of PCMM a different and focused version may have utility, any effort to achieve this may be futile. Such a framework can produce better results, but will never be a “silver bullet”.

A close examination of PCMM provides an insight to its intrinsic bias toward a certain class of engineering calculations. This is clearest in the emphasis on geometric fidelity and solution verification, which belie its basis in meshbased

calculations. Nonetheless, peeling back a layer, one should not lose sight of the nature of these entries in the framework. The geometry is really a view of the representation of reality in the overall computational simulation, while the solution verification is the estimate of error in the same. Both aspects are essential to determining the quality and assigning confidence to the simulation results. Other aspects of the PCMM translate across fields more readily. Code verification and software quality are necessary elements in providing reliable computer codes for simulation. Modeling and its credibility are universal in the field. Finally validation provides the tangible and measured connection to reality, and uncertainty quantification is key to decision-making.

Other elements have been added due to their importance and focus when applying the framework. Recent work has taken the validation element and broken it up into four separate activities to be examined. Two elements now involve the quality and acquisition of experimental data; followed by the assessment of the simulation with respect to the data. The validation exercise is divided into two sections, one with data and validation applied to the underlying and low-level models in the code, and the second applying to the application-level or high-level modelling and associated data for comparison. In addition, we considered adding additional elements to PCMM associated with the requirements arising from the simulation customers, and the impact of the code user/analyst/engineer on the results obtained. This area is sensitive and controversial because the human impact of M&S analysis is a “hot-button” issue with many and is tabled for now.

A useful concept in examining complex, difficult problems is the characterization of the problem as “wicked”. A wicked problem has a number of characteristics that make it special and difficult to solve. For example, the problem cannot be fully understood before attempting to solve it. As the problem is tackled, new aspects of the problem are unveiled, and the solution to the problem needs to be rescoped. This is a continual aspect of the problem, and it bedevils those who attempt to apply project plans and complete predictability to the problem. There are even super-wicked problems that are more difficult due to counter-intuitive feedbacks between the problem itself and the solution. Characteristics of super-wicked problems are that those solving the problem are also causing the problem, and future results are irrationally discounted presently among others. V&V with PCMM as an example can probably be characterized as being wicked and perhaps even super-wicked. Thus the activity defies full articulation.

Despite this intrinsic futility we would claim that PCMM is useful. In a real sense the activities within PCMM could be thought of as a menu of activities that one might consider in determining and driving simulation quality. This is as important as the measurement of the quality itself. Being such a complex and potentially unbounded activity means that there is large probability for details to slip from attention. PCMM provides the list of activities for simulation quality improvement and assessment, which can be utilized effectively by code development and application projects to draw upon. A reasonable recommendation is to examine the PCMM for “low hanging fruit” that can easily be incorporated into the simulation process. As we will now describe this process can be further refined by dividing

the PCMM into two pieces; one that applies primarily to code development and the foundation of simulation capability, and a second that is more specific to the application of interest. Another practicality is the potentially overwhelming nature of PCMM. It is therefore rational and reasonable to apply less than the complete framework initially.

Thus a useful observation is that one can decompose the whole computational confidence issue into two relatively neat and tidy pieces: that which is more tool (code)-specific, (or foundational) and that which is problem or application-specific. Thus some work provides the general characterization of the computational tools to be used for analysis, while other work is directly applied to the application of that tool. For example, the general software development approach and documentation can be used over and over for different applications, while the specific options from a code used for a given application are narrow and specific to that application. This principle can be applied repeatedly across the span of activities that comprise the quality pedigree for a given code and its intended application. This principle applies for nearly every area of code quality investigation as laid out below.

3.3 Foundational PCMM

Software quality is one of the obvious lynchpins of the foundation for a code. The practices applied in the development of the code provide the degree of confidence in the code's correctness and stability. High quality code practices provide important tractability to the overall pedigree of the simulation. These practices will apply to every application of the code. We acknowledge that a subset of the software activities will be more directly relevant to a given activity and may be subject to different requirements.

Code verification is another simulation code quality practice that applies across the entire spectrum of potential applications. Code verification in a nutshell provides the evidence and confidence that the solution algorithm in the code is implemented correctly, and the given mathematical description is actually being solved. This is a distinctive to numerical simulation and applies in a complementary manner to the overall software quality approach. Again, some of the code verification will be more specifically applicable to a certain problem attacked by the code.

The decomposition of validation into two sets allows part of the validation activity to be considered foundational. Many models are common to a large number of simulations and comprise the core of the modeling capability of the code. These models must be validated so that their fidelity can be fully assessed away from the intended application. Furthermore, these models can be compared to special purpose experiments that have relatively small errors compared to many application settings. This separation allows some of the modeling capability to be assessed in a manner that should greatly increase confidence in the code. When these errors are convoluted with the integral-large scale data from the applications, the source of discrepancy can become hidden.

Accompanying the basic low-level validation of the code should be assessment of the concomitant uncertainty and sensitivity of the models associated with the code's simulation foundation. This should include the impact of model form and parameters as well as numerical integration effects (i.e., some solution verification). Again, this activity is undertaken to provide a baseline uncertainty and sensitivity away from the convoluted situation offered by the full application setting.

The capability of the code to model circumstances is provided by the user interface. This aspect of the assessment is relatively small in scope, but quite important. In many respects the flexibility offered by the user interface bounds what a code user can achieve. The importance of this activity has increased dramatically in recent years as user interfaces have become codes unto themselves (i.e., the input is itself executable where for example python, or other advanced scripting languages are used).

The foundational aspect of the customer requirements is applied to whomever is providing the resources for the development of the code. This customer can be distinct from the application use of the code, but not necessarily. Nevertheless, the customer has imposed requirements on the code development, and the assessment should provide a check to whether these have been complied with.

3.4 Application Specific PCMM

For any given application there is a computational representation of the problem being solved. This can take many forms including detailed meshes that can be compared with a CAD description. In other cases the representation is simplified as a lumped parameter model and the geometric fidelity is intentionally suppressed.

In every case there is a model of reality that is contained in the computational simulation. This model may be a set of continuously differential equations, integral conservations laws, or algebraic relations. In each case there should be an assessment of the model's capacity to simulate the desired situation in the application. For example one might have a code that contains the incompressible Navier-Stokes equations, and the degree to which incompressibility applies should be examined. Two-phase flow is replete with complexity where for example one should see whether the description in the code is appropriate for the situation (is slip between the phases important, and do the equations appropriately describe the phenomena?).

For software quality and code verification the application specific assessment is bounded. The appropriate question is how much of the foundational aspect of the code's quality is specific to the application. Given the features of the code that the application depends upon are they tested in the software quality or code verification suites? How deep is this coverage and does it provide confidence in the code pedigree in a manner specific to a given application?

Solution verification is quite often overlooked in the practical use of M&S in engineering there. There is no excuse for this. The degree that the model representation and detail impacts solutions must be assessed as part of the overall

uncertainty estimation. Too often the numerical error is simply calibrated for, or muddled with other modeling errors. The key to this step is the clear separation and articulation of this aspect of error and uncertainty apart from other sources. In many cases the solution verification may involve a simple bounding estimate that gives the idea of the magnitude of the effect on the results.

The integral validation aspect of PCMM comes naturally to the nuclear engineer. The unnatural part of the exercise is properly casting the process with all the other elements of PCMM. PCMM is in essence the deconvolution of many effects that often comprise the validation exercise. The foundational aspects of validation, uncertainty and solution verification attempt to peel away this complexity leaving the core of error to be examined. This is the task with integral validation to first understand how well the uncalibrated code models the circumstance, and then calibrate the solution without undoing any of the foundational work. Thus the calibration can be fully exposed to scrutiny and hopefully underlie the capacity to more directly attack the basis of lack of credibility.

Application uncertainty and sensitivity analysis is then quite clearly defined. Again the separation between foundational model validation with requisite uncertainty gives a basis for attacking the specific application uncertainty with clarity. Both aspects of uncertainty impact results and are included in the assessment, but the goal of clearly identifying the application model-specific uncertainties is obtainable through following the structure outlined here.

User qualification has a large impact on the results, yet is rarely assessed. An ideal case would be to have independent models of the same application. This is often not possible despite numerous studies showing that the user effect is large (larger than model differences in cases).

Finally the entity paying for the application work has requirements. These requirements should be assessed for how well the simulation has met these.

4 Phenomena Identification Ranking Table (PIRT)

A PIRT should list all of the important physics phenomena occurring in the physical event being simulated at the specified level of interest [18]. For each individual phenomenon an assessment/ranking must be declared for the “Importance” of this particular phenomenon in the application simulation or, in other words, what is the resulting consequence if the phenomena model is wrong. The rankings are specified as high (“H”), medium (“M”) or low (“L”). Then “Adequacy” determinations must be made with respect to how well the phenomena is represented with a mathematical model, how well it is implemented within the simulation code of choice (Sierra/SM for this project/example) [15], and the level of validation that has been performed for the application space of interest. Once again a ranking is determined for each of these three “Adequacy” areas.

For quick visual adequacy analysis, a color-coding scheme is used to identify areas of inadequacy or gaps. Green signifies that the adequacy is acceptable; yellow indicates that the adequacy is marginal and red indicates that the adequacy level

Table 47.3 PIRT for simulation of interest

Phenomena	Consensus	Adequacy		
	Importance	Math model	Implementation in code	Validation
Phenomena #1	H	H	M	L
Phenomena #2	M	H	L	L
Phenomena #3	M	H	M	L

Table 47.4 Final PIRT for failure prediction example problem

Phenomena	Consensus	Adequacy		
	Importance	Math model	Implementation in code	Validation
Large elastic-plastic deformation of metals	H	H	M	M
Ductile material failure	H	M	M	L
Contact	H	H	M	M
Friction between punch and test item	M	M	M	L
Enforcement of boundary conditions	L	H	H	L
Inertial loads	H	H	H	M

is unacceptable and needs to be addressed. The colors are assigned with respect to the “Importance” ranking. If a phenomena’s “Importance” ranking is low, then any level of adequacy is deemed acceptable. If the “Importance” ranking is medium, then acceptable adequacy rankings are medium and high. An adequacy ranking of low produces a yellow square that indicates a marginal adequacy level. When the “Importance” ranking is high, then the only acceptable adequacy level is “high” earning a green square. For a medium adequacy determination a yellow square is used, however, for a low adequacy assessment a red square is used to indicate an unacceptable adequacy level for that particular category. A sample PIRT with 3 identified physics phenomena is given in Table 47.3 showing various adequacy levels with colored gap indicators.

For the presented project, an assessment of the numerical prediction of important phenomenological aspects of an abnormal fracture problem was evaluated at the start of the project, and presented in Table 47.4. Six different physics phenomena were identified (large elastic-plastic deformation of metals, ductile material failure, contact, friction between punch and test item, enforcement of boundary conditions, inertial loads). All of them were rated of “high” importance except for “friction between punch and test item” which was considered of “medium” importance. Two areas of concern are quickly identified by their “red” coloration that required attention: “Ductile Material Failure” and “Enforcement of Boundary Conditions” with respect to validation adequacy. Both of these were of high importance but ranked low on the validation adequacy scale. Since the intent of the project was to better understand failure mechanics modeling and its limitations, validate its applicability for the application being studied and characterize its reliability

and usability, the fact that “Ductile material failure” was ranked inadequate was worrisome and addressed in the scope of the project.

The boundary condition assumption gap was also identified and investigated. The model enforces a perfect non-slip boundary condition between the plate and the anchoring fixture. In reality it is possible that the test article could slip in the clamping fixture. Everything was done experimentally to minimize the slippage during impact and penetration. Several experiments were performed to assess the level of non-compliance of the non-slip boundary condition and physically interrogated this situation. The experimentalists deemed that the plate was not slipping in the clamping fixture. Therefore, the theoretical boundary condition enforcement was deemed acceptable and the “Importance” ranking of “Enforcement of Boundary Conditions” was downgraded to “L” in the final PIRT assessment (shown in black print in Table 47.4) that elevated the “validation adequacy” coloration to green.

5 PCMM Example: Qualification of Alternatives to the SPUR Reactor (QASPR)

Here we give an example of what an actual capability assessment looks like in a bit of detail. In this case we will be showing the outcomes and process outline for the QASPR project [16] and associated codes, Xyce [4] and Charon [7, 17] (Fig. 47.2). The assessment was conducted at Sandia National Laboratories, Albuquerque by Laboratory staff. QASPR was begun an admittedly ambitious effort to replace the experimental testing of integrated circuits and associated semi-conductor material in a high radiation environment. Sandia sought to replace the expensive and risky SPUR reactor with an extensively validated and verified computational capability. The specific assessment was for the maturity of the III-V Npn model predictability within a defined threat environment for the Xyce and Charon codes. In particular, the device model for the MESA developed using Npn InGap/GaAs.

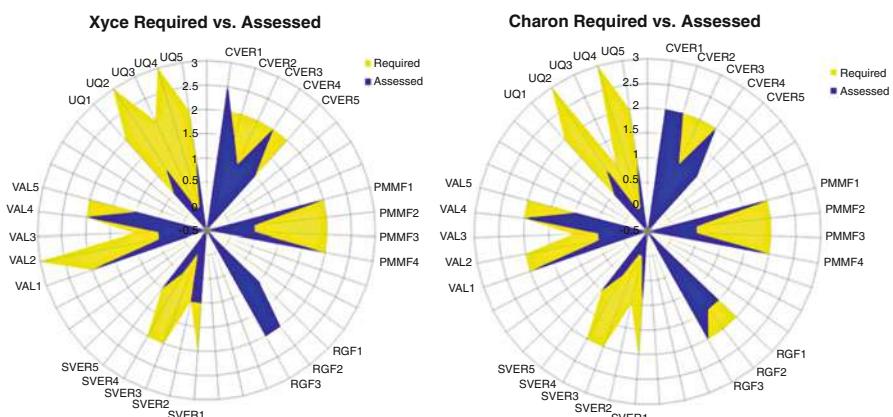

Fig. 47.2 QASPR: PCMM Kiviat Plots showing the assessed status of Xyce and Charon

The first thing to do is pull together a team to conduct the assessment starting with a lead stakeholder. In this case the stakeholder is acting as the customer for the work done by the code. In other cases this may or should be another person altogether. The assessment can take input from any member of the team although each member should not necessarily contribute to each part of the PCMM. Secondly we have a (trained) PCMM assessor who also acts as a moderator for the activity. Next we have a PCMM subject matter expert (SME) whose expertise includes key aspects of V&V. The team is then rounded out by SME's in each major role for the development and use of the code(s). In this case we have SMEs for UQ, V&V analysis, experiments, applied circuit analysis, calibration and code development for both Xyce and Charon (different people).

The first step done was to meet with the entire team to brief them on the process and gain buy-in. In addition the team receives "training" on the PCMM and the assessment process. In the case of QASPR the project had already conducted an extensive PIRT. Rather than repeat this work, the first step was to review and vet the existing PIRT for the assessment that follows. The team then held a set of meetings to conduct the assessment. It is important that the team be well-represented throughout. After a set of meetings the team prepared some focused feedback on the state of the QASPR project's codes as well as the PCMM process itself.

Part of this effort used an Excel spreadsheet as the vehicle for the assessment, and much of the feedback keyed on this. There was feeling that clarification of the language could be done particularly within the UQ section. Some elements seemed to overlap one another. Overall the Excel Tool was judged to be very beneficial and helps capture a great deal of detail, but can be overwhelming at times during the assessment. We might consider creating a reduced version for real time assessment. Overall it is a great organization tool for the assessor. This sort of feedback should always be included to continually improve the process.

A real positive is that the PCMM assessment generated discussion across different teams consisting of analysts, developers, and experimentalists. As an example of the discussion: For qualification, solution verification will be critical (e.g., input/output file verification) and will need to be better formalized – analysts are now aware of this and QASPR will need to better formalize this workflow. We need another assessment iteration to determine the value of some members on the larger team for the purposes of assessment. Experimentalists seemed to be the odd man out, but may be due to QASPR development of Physical Simulation PCMM (the PCMM ideas applied to physical testing or experimentation). The assessment is also captured in some graphical output, and overall spreadsheet content.

At the end of the assessment we crafted a path forward for further assessments.

1. First, review PCMM elements with PCMM SME prior to assessment to insure all the descriptors are well understood. This was done in real time during the assessment which caused delays.
2. The Excel Tool will be used for future assessments.
3. Evidence may be moved and maintained on a SharePoint site.

4. We will do another iteration of the assessment with the larger group.
5. We will continue to schedule review to minimize the time required by participants based on roles.

The next assessment will focus on PnP devices and potentially circuits and an update of the Npn capability should also be done.

6 The Role of Frameworks like PCMM and PIRT in Credibility

“Integrity is telling myself the truth. And honesty is telling the truth to other people.”

– Spencer Johnson

As tools the frameworks of PIRT and PCMM are only as good as how they are used to support high quality work. Using these tools will not necessarily improve your credibility, but rather help you assess it holistically. Ultimately the credibility of your modeling & simulation capability is driven by the honesty and integrity of your assessment. It is easy to discuss what you do well and where you have mastery over a topic. The real key to assessment includes a will and willingness to articulate where an effort is weak and where the fundamental foundational knowledge in a field is the limiting factor in your capacity for solving problems. The goal in credibility assessment is not demonstration of mastery over a topic, but rather a demonstration of the actual state of affairs so that decisions can be made with full knowledge of the weight to place and risks inherent in modeling & simulation (M&S).

A topic like quality is highly subjective and certainly subject to a great deal of relativity where considerations of the problem being solved and the M&S capabilities of the field or fields relevant come into consideration. The frameworks serve to provide a basic rubric and commonly consistent foundation for the consideration of M&S quality. As such, PIRT and PCMM are blueprints for numerical modeling. The craft of executing the M&S within the confines of resources available is the work of the scientists and engineers. These resources include the ability to muster effort towards completing work, but also the knowledge and capability base that you can draw upon. The goal of high quality is to provide an honest and holistic approach to guiding the assessment of M&S quality.

In the assessment of quality the most important task to accomplish is an honest discussion of the technical elements of the work with complete disclosure of faults and shortcomings. There are significant physiological and social factors that lead to a lack of honesty in evaluation and assessment. No framework or system can completely overcome such tendencies, but might act as a hedge against the tendency to overlook critical details that do not reflect well on the assessment. The framework assures that each important category is addressed. The ultimate test for the overall integrity and honesty of an assessment of M&S credibility depends upon deeper technical knowledge than any framework can capture.

Quite often an assessment will avoid dealing with systematic problems for a given capability that have not been solved sufficiently. Several examples of

this phenomenon are useful in demonstrating where this can manifest itself. In fluid dynamics, turbulence remains a largely unsolved problem. Turbulence has intrinsic and irreducible uncertainty associated with it, and no single model or modeling approach is adequate to elucidate the important details. In Lagrangian solid mechanics the technique of element death (where poorly deformed elements are removed to allow the simulation to continue) is pervasively utilized for highly strained flows where fracture and failure occur. It is essential for many simulations and often renders a simulation to be non-convergent under mesh refinement. In both cases the communities dependent upon utilizing M&S with these characteristics tend to under-emphasize the systematic issues associated with both. This produces a systematically higher confidence and credibility than is technically justifiable. The general principle is to be intrinsically wary of unsolved problems in any given technical discipline.

Together the PIRT and PCMM adapted and applied to any M&S activity form part of the delivery of defined credibility of the effort. The PIRT gives context to the modeling efforts and the level of importance and knowledge of each part of the work. It is a structured manner for the experts in a given field to weigh in on the basis for model construction. The actual activities should be strongly reflected in the sort of assessed importance and knowledge basis reflected in the PIRT. Similarly the PCMM can be used for a structured assessment of the specific aspects of the modeling and simulation.

The degree of foundational work providing the basis for confidence for the work is spelled out in the PCMM categories. Included among these are the major areas of emphasis some of which may be drawn from outside the specific effort. Code verification being an exemplar of this where its presence and quality provides a distinct starting point for the specific aspects of the estimation of the numerical error for the specific M&S activity being assessed. Each of the assessed categories forms the starting point for the specific credibility assessment.

One concrete way to facilitate the delivery of results is the consideration of the uncertainty budget for a given modeling activity. Here the delivery of results using PIRT and PCMM is enabled by considering them to be resource guides for the concrete assessment of an analysis and its credibility. This credibility is quantitatively defined by the uncertainty and the intended application's capability to absorb such uncertainties for the sort of questions to be answered or decision to be made. If the application is relatively immune to uncertainty or only needing a qualitative assessment then large uncertainties are not worrisome. If on the other hand an application is operating under tight constraints associated with other considerations (sometimes called a design margin) then the uncertainties need to be carefully considered in making any decisions based on modeling and simulation.

This gets to the topic of how modeling & simulation are being used. Traditionally M&S goes through two distinct phases of use. The first phase is dominated by "what if" modeling efforts where the results are largely qualitative and exploratory in nature. The impact of decisions or options is considered on a qualitative basis and guides decisions in a largely subjective way. Here the standards of quality tend to focus on completeness and high-level issues. As modeling and simulation proves its

worth for these sorts of studies, it begins to have greater quantitative demands placed on it. This forms a transition to a more demanding case for M&S where design or analysis decision is made. In this case the standards for uncertainty become far more taxing. This is the place where these frameworks become vital tools in organizing and managing the assessment of quality.

This is not to say that these tools cannot assist in earlier uses of M&S. In particular the PIRT can be a great tool to engage with in determining modeling requirements for an effort. Similarly, the PCMM can be used to judge the appropriate level of formality and completeness for an effort to engage with. Nonetheless these frameworks are far more important and impactful when utilized for more mature, “engineering” focused modeling and simulation efforts.

Any high level integrated view of credibility is built upon the foundation of the issues exposed in PIRT and PCMM. The problem that often arises in a complex M&S activity is managing the complexity of the overall activity. Invariably gaps, missing efforts and oversights will creep into the execution of the work. The basic modeling activity is informed by the PIRT’s structure. Are there important parts of the model that are missing, or poorly grounded in available knowledge? From PCMM, are the important parts of the model tested adequately? The PIRT becomes a fuel for assessing the quality of the validation, and planning for an appropriate level of activity around important modeling details. Questions regarding the experimental support for the modeling can be explored in a structured and complete manner. While the credibility is not built on the PCMM and PIRT, the ability to manage its assessment is enabled by their mastery of the complexity of modeling and simulation.

In getting to the quantitative basis for assessment of credibility, the definition of the uncertainty budget for a computational simulation activity can be enlightening. While the PCMM and PIRT provide a broadly encompassing view of MS quality from a qualitative point of view, the uncertainty budget is ultimately a quantitative assessment of quality. Forcing the production of numerical values to the quality is immensely useful and provides important focus. For this to be a useful and powerful tool, this budget must be determined with well-defined principles and fairly good disciplined decision-making.

One of the key principles underlying a successful uncertainty budget is the determination of unambiguous categories for assessment. Each of these broad categories can be populated with sub-categories, and finer and finer categorization. Once an effort has committed to a certain level of granularity in defining uncertainty, it is essential that the uncertainty be assessed broadly and holistically. In other words, it is important, if not essential that none of the categories be ignored.

This can be extremely difficult because some areas of uncertainty are truly uncertain, no information may exist to enable a definitive estimation. This is the core of the difficulty for uncertainty estimation, the unknown value and basis for some quantitative uncertainties. Generally speaking, the unknown or poorly known uncertainties are more important to assess than some of the well-known ones. In practice the opposite happens, when something is poorly known the value often adopted in the assessment is implicitly defined quantitatively as “zero”. This is

implicit because the uncertainty is simply ignored, and it is not mentioned, or assigned any value. Again, the availability of the frameworks comes in handy to help the assessment identify major areas of effort.

A reasonable decomposition of the sources of uncertainty can fairly generically be defined at a high level: experimental, modeling and numerical sources. We would suggest that each of these broad areas be populated with a finite uncertainty, and each of the finite values assigned be supported by well-defined technical arguments. Of course, each of these high level areas will have a multitude of finer grained components describing the sources of uncertainty along with routes toward their quantitative assessment. For example, experimental uncertainty has two major components, observational uncertainty and natural variability. Each of these categories can in kind be analyzed by a host of additional detailed aspects. Numerical uncertainty lends itself to many sub-categories: discretization, linear, nonlinear, parallel consistency, and so on.

The key is to provide a quantitative assessment for each category at a high level with a non-zero value for uncertainty and a well-defined technical basis. We note that the technical basis could very well be “expert” judgment as long as this is explicitly defined. This gets to the core of the matter; the assessments should always be explicit and not leave essential content for implicit interpretation. A successful uncertainty budget would define the major sources of uncertainty for all three areas along with a quantitative value for each. In the case where the technical basis for the assessment is weak or non-existent, the uncertainty should be necessarily large to reflect the lack of technical basis. Like statistical sampling, the benefit to doing more work is a reduction in the magnitude of the uncertainty associated with the quantity. Enforcing this principle means that follow-on work that produces larger uncertainties requires the admission that earlier uncertainties were under-estimated. The assessment process and uncertainty budget are inherently learning opportunities for the overall effort. The assessment is simply an encapsulation of the current state of knowledge and understanding.

Too often in modeling and simulation uncertainty, efforts receive a benefit through ignoring important sources of uncertainty. By doing nothing to assess uncertainty they report no uncertainty associated with the quantity. Insult is done to this injury when the effort realizes that doing work to assess the uncertainty then can only increase its value. This sort of dynamic becomes self-sustaining, and more knowledge and information results in more uncertainty. This is a common and often seen impact of uncertainty assessment. Unfortunately this is a pathological issue. The reality is that this indicts the earlier assessment of uncertainty is actually too small. A vital principle is that more work in assessing uncertainty should always reduce uncertainty. If this does not happen the previous assessment of uncertainty was too small. This is an alltocommon occurrence that occurs when a modeling & simulation effort is attempting to convey a too large sense of confidence in their predictive capability. The value of assessed uncertainty should converge to the irreducible core of uncertainty associated with the true lack of knowledge or intrinsic variability of the thing being modeled. In many cases the uncertainty is

interacting with an important design or analysis decision where a performance margin needs to be balanced with the modeling uncertainty.

An ironic aspect to uncertainty estimation is the tendency to estimate large uncertainties where expertise and knowledge are strong, while under-estimating uncertainty in areas where expertise is weak. This is often seen with numerical error. A general trend in modeling & simulation is the tendency to treat computer codes as black boxes. As such, the level of expertise in numerical methods used in modeling & simulation can be quite low. This has the knock-on effect of lowering the estimation of numerical uncertainty, and utilizing the standard methodology for solving the equations numerically. Quite often the numerical error is completely ignored in analysis. In many cases the discretization error should dominate the uncertainty, but aspects of the solution methodology can color this assessment. Key among these issues is the nonlinear error, which can compete with the discretization error if care is not taken.

This problem is compounded by a lack of knowledge associated with the explicit details of the numerical algorithm and the aspects of the solution that can lead to issues. In this case the PCMM can assist greatly in deducing these structural problems. The PCMM provides several key points that allow the work to proceed with greater degrees of transparency with regard to the numerical solution. The code verification category provides a connection to the basis for confidence in any numerical method. Are the basic features and aspects of the numerical solution being adequately tested? The solution verification category asks whether the basic error analysis and uncertainty estimation is being done. Again the frameworks encourage a holistic and complete assessment of important details.

The final aspects to highlight in the definition of credibility are the need for honesty and transparency in the assessment. Too often assessments of M&S lack the fortitude to engage in a fundamental honesty regarding the limitations of the technology and science. If the effort is truly interested in not exposing their flaws, no framework can help. Much of the key value in the assessment is defining where effort can be placed to improve the modeling and simulation. It should help to identify the areas that drive the quality of the current capability.

If the effort is interested in a complete and holistic assessment of its credibility, the frameworks can be invaluable. Their value is key in making certain that important details and areas of focus are not over- or under-valued in the assessment. The areas of strong technical expertise are often focused upon, while areas of weakness can be ignored. This can produce systematic weaknesses in the assessment that may produce wrong conclusions. More perniciously, the assessment ignores systematic shortcomings in a modeling and simulation capability. This can lead to a deep under-estimate in uncertainty while significantly over-estimating confidence and credibility.

For M&S efforts properly focused on an honest and high integrity assessment of their capability, the frameworks of PCMM and PIRT can be an invaluable aid. The assessment can be more focused and complete than it would be in their absence. The principle good of the frameworks is to make the assessment explicit and

intentional, and avoid unintentional oversights. Their use can go great lengths to provide direct evidence of due diligence in the assessment and highlight the quality of the credibility provided to whomever utilizes the results.

“We should not judge people by their peak of excellence; but by the distance they have traveled from the point where they started.”

– Henry Ward Beecher

7 Conclusion and Outlook

We believe it is time for the community to shoulder some of the blame and rethink our approach to engaging other scientists and engineers on the topic of M&S quality. V&V should be an easy sell to the scientific and engineering establishment. It has not been and it has often been resisted at every step. V&V is basically a rearticulation of the scientific method we all learn, use and ultimately love and cherish. Instead, we find a great deal of animosity toward V&V, and outright resistance to including it as part of the M&S product. To some extent it has been successful in growing as a discipline and focus, but too many barriers still exist. Through hard learned lessons we have come to the conclusion that a large part of the reason is the V&V community’s approach. For example, one of the worst ideas the V&V community has ever had is “independent V&V”. In this model V&V comes in independently and renders a judgment on the quality of M&S. It ends up being completely adversarial with the M&S community, and a recipe for disaster. We end up less engaged and hated by those we judge. No lasting V&V legacy is created through the effort. The M&S professionals treat V&V like a disease and spend a lot of time trying to simply ignore or defeat it. This time could be better spent improving the true quality, which ought to be everyone’s actual objective. Archetypical examples of this approach in action are federal regulators (NRC, the Defense Board...for a discussion of PCMM in a regulatory context see the subsequent Chapter by Mousseau and Williams). This idea needs to be modified into something collaborative where the M&S professions end up owning the quality of their work, and V&V engages as a resource to improve quality.

The fact is that everyone doing M&S wants to do the best job they can, but to some degree don’t know how to do everything. In a lot of cases they haven’t even considered some of the issues we can help with. V&V expertise can provide knowledge and capability to improve quality if they are welcome and trusted. One of the main jobs of V&V should be to build trust so that they might provide their knowledge to important work. In sense, the V&V community should be quality “coaches” for M&S. Another way the V&V community can help is to provide appropriately leveled tools for managing quality. PCMM can be such a tool if its flexibility is increased. Most acutely, PCMM needs a simpler version. Most modeling and simulation professionals will do a very good job with some aspects of quality. Other areas of quality fall outside their expertise or interest. In a very real sense, PCMM is a catalog of quality measures that could be taken. Following

the framework helps M&S professionals keep all the aspects of quality in mind and within reach. The V&V community can then provide the necessary expertise to carry out a deeper quality approach.

If V&V allows itself to get into the role of judge and jury on quality, progress will be poor. V&V's job is to ask appropriate questions about quality as partners with M&S professionals interested in improving the quality of their work. By taking this approach we can produce an M&S future where quality continuously improves.

Abstract

This chapter describes the use of the Predictive Capability Maturity Model (PCMM) (Oberkampf et al., Predictive capability maturity model for computational modeling and simulation. Technical report, SAND2007-5948, Sandia National Laboratories, 2007) applied to a nuclear reactor simulation. The application and PCMM will be discussed relative to review by the Nuclear Regulatory Commission. In a regulatory environment, one takes on the role of a lawyer presenting evidence to a judge with a prosecuting attorney allowed to cross-examine. In this type of “hostile” environment, a structured process that logically presents the evidence is helpful.

In addition, many simulations are now multi-scale, multi-physics, and multi-code. For this level of complexity, it is easy to get lost in the details. The PCMM method has been adapted for this multi-physics multi-code software. Since the key is to provide the regulator with confidence that the software is capable of predicting the quantity of interest (QoI) with a well-quantified uncertainty, the PCMM approach is a natural solution.

1 Introduction

In a regulatory environment, the uncertainty quantification must withstand a strong peer review process. All uncertainty quantification offered must be proven accurate. The Predictive Capability Maturity Model (PCMM) [9] provides an easy-to-understand structure for developing evidence that all of the different modes of uncertainty have been addressed. For more details on PCMM, please see [14]. The PCMM methodology can be considered a modernized version of the code scaling, applicability, and uncertainty (CSAU) [3] which has already been embraced by the Nuclear Regulatory Commission as an appropriate way to define the uncertainty in a simulation tool.

PCMM addresses the major sources of uncertainty:

1. **Code bugs** – documentation and regression testing are two powerful tools that fall under the heading of software quality engineering (SQE) to minimize code bugs.
2. **Code verification** – addresses the uncertainty due to mistakes in implementing numerical methods.
3. **Solution verification** – quantifies the uncertainty due to numerical methods applied in suboptimal conditions like coarse mesh spacing and large time steps required for solution speed.
4. **Validation** – quantifies uncertainty due to the physics models. Verification asks, “Are you solving the equations correctly?” Validation asks, “Are you solving the correct equations?”
5. **Parameter uncertainty** – quantifies the uncertainty due to uncertainty in model parameters.
6. **Calibration** – is the mathematical process by which one reduces uncertainty in model parameters due to the addition of new experimental data.

These six topics are covered by the four PCMM evidence bins, *code verification*, *solution verification*, *model validation*, and *uncertainty quantification and sensitivity analysis*. PCMM provides a structured approach to gather the “evidence” and present it in a logical fashion.

The remainder of this chapter is organized as follows. Section 2 provides an initial overview of uncertainty quantification. This is followed in Sect. 3 by a discussion of the prerequisite work required for conducting an uncertainty quantification study. Sect. 4 introduces changes and improvements to the PCMM process presented in [14]. A sample PCMM analysis is presented in Sect. 5, followed in Sect. 6 by a discussion of the presentation of the evidence file. Conclusions are provided in Sect. 7.

2 Uncertainty Quantification Overview

One often witnesses uncertainty quantification being conducted by directly studying parameter uncertainty. There are three assumptions that are implicitly made following this process that are seldom addressed or even verbalized:

1. The code is relatively bug-free and one knows what is in the code.
2. The equations in the code are solved correctly.
3. The correct equations are solved.

If any of the three previous statements are false, the exercise of conducting a parameter uncertainty quantification study may provide useless information. If any of the three assumptions above do not hold, the potentially substantial perturbations of an uncertainty quantification study are likely to yield incorrect results. So before

one begins an uncertainty quantification process, one needs to gather evidence that the above three assumptions are true.

Statistical methods are sometimes employed by engineers because they sound “too good to be true.” One can treat the simulation tool as a black box, only study the parameters in the input processor, and, if utilizing Wilks formula (see Sect. 2.2 and Appendix A.1), only run the code 59 times for uncertainty quantification. It is important to understand the underlying assumptions of the statistical method and be convinced that it is being applied correctly.

It is normally assumed that the validation data covers the application space. For many applications this is not the case. The experiments at relevant pressures, temperatures, or flow rates are either too expensive or too dangerous to perform. In this case one must use scaling analysis to extrapolate the empirical correlations calibrated to the validation experiments to the range of applicability needed for the application. This creates a new mode of uncertainty that must be understood and addressed.

2.1 Total Uncertainty

It is important to recognize that uncertainty comes from a variety of different sources including numerical, model form, parameter, and many others. It is also important to recognize that these different forms of uncertainty interact with each other in possibly highly nonlinear interactions.

For example, the numerical viscosity induced by the numerical method may be larger than the turbulent viscosity from the turbulence model. Both of these viscosities impact the solution but it is the largest one that dominates. Verification is designed to ensure that the numerical viscosity is not the larger of these two. Validation is then designed to ensure that the model-form uncertainty for a given turbulence model is small. Finally the parameter uncertainty of a specific turbulence model can be addressed upon confirming that the numerical uncertainty and model-form uncertainty are both small.

To highlight key ideas, a framework for addressing total uncertainty is proposed that admittedly ignores important sources of uncertainty like scaling and code bugs and does not correctly capture the nonlinear relationship among different modes of uncertainty. Hopefully future research will fill in or improve this framework for total uncertainty. However, until improvements are proposed, this total uncertainty framework begins to incorporate the complexity of uncertainty quantification beyond parameter uncertainty and accommodates resource allocation arguments via comparisons among coarse metrics representing errors contributed by the individual components of total uncertainty.

The key to total uncertainty quantification is consistency across the different PCMM steps. The quantity of interest (QoI) or QoIs defined by the Phenomena Identification and Ranking Table (PIRT) process discussed further in Sect. 4.1 are the key to analyzing total uncertainty. Using the same QoIs and the same metrics, one can define numerical, model-form, and parametric uncertainty in a consistent fashion.

The first step in the total uncertainty framework is to conduct thorough verification analysis of the code(s) under study. Numerical error is used as a surrogate for “numerical uncertainty” (note that numerical error is usually better quantified as a systematic bias than as a random uncertainty, although numerical error models could incorporate both components). Chapters II and III in [10] provide formal procedures for verification assessments. Numerical errors that are too large compared against desired criteria indicate that additional numerical work is required before moving on to the next step in the total uncertainty framework. For later use, a coarse metric measuring numerical error is calculated by taking the norm of the difference between the computed QoI and the computed QoI on an infinitely refined mesh:

$$\|QoI_{\text{computed}} - QoI_{\Delta x \rightarrow 0}\| = \text{numerical error}. \quad (48.1)$$

The purpose of solution verification is to estimate this numerical error. There is a numerical tool called robust multiple regression (RMR) [13] that aids one in computing this error estimate.

The second step in the total uncertainty framework, once rigorous verification is completed, is to assess model-form uncertainty through its surrogate model-form error. Although formal statistical methods exist that formally integrate model parameter calibration (Sect. 3.6.2) with model-form error assessment (see, e.g., [11]), the total uncertainty framework takes a more traditional approach to quantifying model-form error. Chapter IV in [10] provides formal procedures for validation assessments. Model-form errors that are too large compared against desired criteria indicate that additional physical or empirical modeling work is required before moving on to the final step in the total uncertainty framework. For later use, a coarse metric measuring absolute model-form error is calculated by taking the norm of the difference between the computed QoI and the experimentally measured QoI:

$$\|QoI_{\text{computed}} - QoI_{\text{experimental}}\| = \text{model form error}. \quad (48.2)$$

If the ultimate QoI to uncertainty quantification is unobservable (no existing validation data), one must rigorously justify extrapolation of code calculations to this QoI. For example, scaling arguments may be made (see Sect. 2.3).

The final step in the total uncertainty framework, once rigorous validation is completed, is to assess model parameter uncertainty. This is conducted by formal propagation of model parameter uncertainties through code calculations of the QoIs. Such uncertainties may be obtained through expert opinion (Sect. 3.6.1) or Bayesian calibration (Sect. 3.6.2), for example. The result is a sample of QoIs from their (unknown) probability distributions. Let QoI_{bound} represent a bound from a QoI distribution for regulatory purposes, estimated from the QoI samples (modification of the following discussion is necessary if an interval is of interest instead). Example possibilities include the 95th or 99th percentiles, or fifth or first percentiles, or the bound obtained from Wilks formula. A coarse metric measuring model parameter uncertainty is calculated by taking the norm of the difference between the computed QoI and the QoI distributional bound:

$$\|QoI_{\text{computed}} - QoI_{\text{bound}}\| = \text{model parameter error.} \quad (48.3)$$

Using the coarse metrics of equations (48.1)–(48.3), it is possible to quickly identify which source of error should be prioritized for future reduction: that associated with the largest metric value (always subject to cost considerations), i.e.,

$$UQ_{\max} = \max (\|QoI_{\text{computed}} - QoI_{\Delta x \rightarrow 0}\|, \|QoI_{\text{computed}} - QoI_{\text{experimental}}\|, \\ \|QoI_{\text{computed}} - QoI_{\text{bound}}\|).$$

Although notional, this framework captures an important concept in equation form: uncertainty is a function of numerical methods, physical models, and the parameters in those physical models. The PCMM process recognizes this important concept and provides for equal importance of verification, validation, and uncertainty quantification.

2.2 Wilks Formula

The use of Wilks formula [15] has become popular in recent years in the nuclear power industry. The original work from 1941 was designed for use on assembly lines. For this application, the “parameters” were controls on the assembly line that allowed for fine adjustment. The “distribution” of the parameter was well known since it was uniform and simply the range on the physical control knob. Wilks formula is solid mathematically and a very useful tool when properly applied.

The challenge to properly applying Wilks formula to software instead of an assembly line comes from meeting the implied assumptions. In the four subsections below, the four main assumptions behind the use of Wilks formula in a software context are discussed.

2.2.1 No Code Crashes

Wilks formula must be applied to a random sample of code outputs. If the code crashes during any of the minimum 59 runs that Wilks formula requires for a 95%/95% tolerance-bound calculation, this assumption is likely violated. The sample of parameters and thus outputs is not random if code crashes are functionally related to parameter settings. Therefore one needs a very robust code for successful application of Wilks formula. In addition, as will be discussed later, one needs accurate parameter distribution functions to prevent the code from traversing unphysical parts of state space which can lead to code crashes.

2.2.2 Known Parameter Distributions

There is no requirement on the form of the parameter distribution, but it must be known. Note this technically excludes the use of expert opinion, unless the expert actually knows the parameter distribution. Often with expert opinion, the expert gives a guess at the minimum and maximum parameter values, and a uniform distribution on these bounds is assumed. Although the formula does not mandate that the parameters themselves be statistically independent, it does require that the interdependence of the parameters be explicitly known. This requisite knowledge of

the joint parameter distribution is another difficult requirement for expert opinion-based specifications.

It is interesting to observe that poor choices of parameter ranges and the joint distribution function may be the cause of code crashes. This leads to a nonlinear feedback into the system where the “expert opinion” distribution is then modified to eliminate the code crashes. This process of shrinking the expert opinion-based parameter ranges until code crashes are eliminated is in reality a measure of code robustness and has little to do with uncertainty quantification.

2.2.3 All Parameters are Analyzed

The requirement that all relevant code parameters be exposed to uncertainty quantification is perhaps the hardest assumption to implement in software. There are a very large number of parameters that impact the code calculation of the QoIs. This includes initial conditions and boundary conditions, all discretization parameters, all solver parameters, and all physical model parameters whether they are buried in the code or exposed through the input file. This also includes all of the model modifications that have been made over the years to improve the robustness of the software, such as protection against division by zero, under-relaxation, and “ramps” that connect discontinuous models.

The average code user may only have access to about 10% of the parameters that impact the QoIs. These are precisely the parameters that have been exposed by the code team for study. Finding and exposing the remainder of the parameters for study can be a difficult challenge.

2.2.4 No Biases

The machinery in Wilks formula is not designed to deal with biases. This is a particularly hard obstacle for simulation tools to overcome. This is due to the fact that all numerical errors (inside of the asymptotic convergence range) show up as a bias. That is, as the time step and mesh spacing are reduced, the code approaches the exact solution monotonically. Model-form error also has this same signature in that it introduces a bias to the solution.

2.2.5 Application

Notwithstanding the above, Wilks formula can still be applied if systematic bias adjustments to code output are obtainable through statistical inference. Wilks formula is a valuable tool in statistical analysis. In its intended application to assembly lines, the required knowledge of parameters and their distributions was easy to accommodate. One should use Wilks formula with caution when applying it to software where knowing all of the parameters and their distributions is not practical. Note that there is no provision in Wilks formula to only analyze important parameters; all parameters that impact the QoI must be analyzed.

It should be recognized that many mathematical formulas still provide useful knowledge when applied in settings where all of the assumptions behind them cannot be rigorously verified. Although there are certainly cases where Wilks formula is not conservative, current experience indicates that Wilks formula is accurate or conservative when applied to software. More detail about Wilks formula is contained in Appendix A.1.

2.3 Scaling

Many times due to cost or safety, one cannot perform the validation experiments at the correct power, pressure, or temperature. For single-physics applications, one can often define nondimensional parameters that describe how information can be scaled from one part of state space to another. The Reynolds number in CFD is a good example of how physics can be accurately scaled.

This, however, becomes significantly more complicated for multi-physics applications. There may be a dozen different nondimensional numbers that describe a multi-physics simulation. It is often impossible to match all of the relevant nondimensional numbers. In that case, the experimentalist will attempt to match the important nondimensional numbers and provide justification that the others do not have a significant impact on the solution.

It is not easy to defend applying empirical formulas outside of their range of applicability. The more physics that can be incorporated into the model, the easier it is to justify using an empirical model to extrapolate outside of its validation data range. Well-designed scaling arguments can provide a justification for extrapolation. However, these arguments are easy for a regulator to question.

Whenever possible, respect the validation data range; when this is not possible, ensure that an easily defensible scaling argument justifies extrapolation. It should be noted that CSAU is one of the predecessors of the PCMM process. In CSAU, scaling was considered one of the most important discussions in terms of establishing confidence in software.

3 Prerequisite Work

Determining which physical phenomena are important is the first step in any uncertainty quantification. This is accomplished through the PIRT process. However, this is just the start of a long labor-intensive process. One then needs to find the models in the code that describe the important physical phenomena and expose the parameters in these important models for uncertainty quantification.

In many engineering applications, the models are designed one way in the journal publication but implemented a different way in the software. Testing what the model was supposed to be, based on the journal paper, is not valuable. One needs to test the model “as built” based on how it was implemented in the software.

In addition to the parameters, the QoIs also need to be exposed for study. This can be an error-prone process if the QoIs are computed from the graphics output files instead of directly from the simulation code. The quantity and quality of the data in a graphics file may not support accurate calculation of the QoI. This produces a new mode of uncertainty related simply to errors in computing the QoI.

Assuming all the parameters and QoIs are exposed for study, the next step is to construct parameter distribution functions. Traditionally this is done based on expert opinion. However, Bayesian methods have the ability to construct (not necessarily analytically) the parameter distribution functions that can then be used for uncertainty quantification. This Bayesian process requires large amounts of

high-quality data to construct the parameter distribution functions. The Dakota software for uncertainty quantification analysis from Sandia National Laboratories contains Bayesian calibration capabilities [4–6].

There is an additional form of uncertainty known as user effect. This is caused by different equally qualified engineers making slightly different modeling assumptions. To minimize this user effect, the simulation code teams need to train the code users in best practices and user guidelines. Theoretically, properly trained code users will get very similar answers [12]. There is also a parallel document that describes user guidelines and best practices for Dakota [1].

3.1 Top-Down Parameter Exposure

In legacy multi-physics codes, there can be a large number of physical models, and each of these models can have many parameters. There is a natural way to “prune” the parameter “tree” hierarchy that was initially published in [7]. A key realization is that there are a small number of classes of physical phenomena. One can then determine the sensitivity of each class. If the sensitivity of a class is small, then one does not need to analyze the parameters that make up the models in that class.

For example, wall friction is a class. One can construct a tree of wall friction by first separating it into single-phase and two-phase wall friction. These then decompose into laminar and turbulent wall friction. The laminar and turbulent wall frictions then decompose further into flow regimes. This tree structure can require a large number of lines of code and a large number of parameters to describe.

In the top-down approach, a sensitivity multiplier is applied to the top of the tree, namely, wall friction. If perturbations on wall friction do not impact the QoI, then there is no need to invest any further in uncertainty quantification of the lower-level models. Often a general purpose tool will have a large number of models, and only a small number may be employed for any given application. The top-down approach takes advantage of this idea to minimize the amount of uncertainty quantification work.

It is important to note that if the class wall friction is important, then the same top-down idea can be used to determine important subclasses. For example, one could next determine the importance of single-phase and two-phase wall friction. Recursive application of the top-down approach will continually define smaller and smaller sections of the physical models that need to be studied.

3.2 Bottom-Up Parameter Exposure

Once an important physical phenomenon has been identified from the top-down approach, the bottom-up approach is then applied. In the bottom-up approach, one starts with a single model for an important physical phenomenon. One now determines all of the parameters in that model and their acceptable ranges and distributions. Another important part of the bottom-up approach is to define the range of applicability of the model.

Many of the closure laws are empirical in nature. This means that they are only proven accurate inside of the validation data range used to create the empirical model. In other words empirical correlations work well to interpolate experimental data. However, it is important to know when an empirical model is being extrapolated outside of its range of applicability. At a minimum, the code user needs to be warned that this is happening and ideally the uncertainty should be increased when an empirical correlation is employed outside of its range of applicability. Furthermore, application of an empirical correlation outside its range of applicability may introduce undetectable bias into the calculation that may grow with extrapolation distance.

3.3 General Parameter Exposure

One can only quantify the uncertainty of parameters that have been exposed to study. Often in legacy codes, only a small percentage of parameters are exposed for study. That means that one needs to modify the source code to allow for the parameters to be perturbed. Depending on the complexity and level of documentation, this can be a very labor-intensive process.

It is important to recognize that an uncertainty quantification exercise on the preexisting exposed parameters may provide false information. If only a few of the important parameters are available for study, there is little to no scientific value in a partial uncertainty quantification exercise. One needs to follow a dependable process, like the top-down and bottom-up process defined previously, to demonstrate that all important parameters are studied.

There is a downside to parameter exposure that has to be understood and minimized if possible. Traditionally, uncertainty quantification software works off the code input processor. One perturbs parameters for study by changing their value in the input file. There is a good reason why many important parameters are not exposed for study in the input file. The quality of the software is determined by its physical models. One does not want a code user to be able to modify the code physics. This defeats the idea of software quality engineering that ensures that the code models are correct. If the code user can change the physics through input, then one cannot build a pedigree for the code physics.

Whenever possible, it is best to expose parameters for study through a different mechanism than the input file. One wants a file that is hard to read and hard to modify and ideally the code user does not even know that it exists. One needs to recognize that parameter exposure is important for accurate uncertainty quantification, but one also needs to be cautious how many “tunable” parameters are exposed to the code user.

3.4 As Built

It is an interesting exercise to compare the closure law described in a journal paper (as designed) with what is coded in the software (as built). Sometimes it is difficult

to even recognize the closure law in the software – especially for legacy software. The closure law in the journal paper only has one requirement – the correlation needs to approximate the experimental data.

The closure law in the software has many requirements that include derivatives and correct asymptotic behavior. This is often exacerbated by applying the closure law outside of its range of applicability. Every time the code crashes in the closure law, some code developer has to “bulletproof” the correlation. This “bulletproofing” exercise can make the relation between what is in the code and what is in the journal paper hard to reconcile.

Closure laws are often based on assumptions like steady state and fully developed. This results in discontinuities in time and space in the closure laws. Discontinuities in time are often dealt with by under-relaxation. This process smooths the discontinuous closure law in time but as a consequence modifies the closure law physics. The discontinuities in space are often dealt with by applying “ramps” between closure laws. Here, one smooths the closure laws by taking an average of two adjacent control volumes. This ramp or averaging process also modifies the closure law physics.

Therefore to assess the uncertainty contribution of a closure law, it is important to look at the software and study the closure law as built, not as designed in the journal paper.

3.5 QoI Extraction

One of the challenges for uncertainty quantification (as well as verification and validation) is how to compute the QoI. In an ideal situation, the simulation tool would compute the QoI in a manner that was consistent with the numerical methods, the computational grid, and the physical models of the simulation software. This is not always possible. What is more often the case is that the code exports the required information to an output file and then the uncertainty quantification software must build the QoI from the output file. This process can be error prone because there are often approximations made to minimize the size of the output file. Unless these approximations are made clear, the QoI constructed from the approximated output files may contain significant error. This can lead to large perceived errors in verification and validation when, in reality, the error arose from how the output files were written by the code and how they were interpreted by the uncertainty quantification software.

3.6 Parameter Distributions

The key to uncertainty quantification is to obtain parameter distributions. It is often difficult to estimate parameter distributions for empirical correlations because the parameters often come from fits to experimental data. These parameters seldom have a physical interpretation so it is difficult to estimate their distributions. There are two main methods that can be used to obtain parameter distributions.

3.6.1 Expert Opinion

In expert opinion, someone who is knowledgeable about the field is asked what they expect the parameter distributions to be. Based on their experience, they often provide a uniform parameter distribution with estimates of the minimum and maximum values. Because the parameters define curve fits to experimental data, unless the expert has detailed knowledge of the experiment, this approach is very error prone. That is to say, there is a large uncertainty in the uncertainty quantification process.

Another problem of expert opinion-based parameter distributions is that bad choices for parameter distributions often lead to code crashes. This is caused by combinations of parameters leading to unphysical regions of state space. It is important to understand the relationship among parameters (joint distribution). When expert opinion-based distributions are employed, the parameters are often assumed to be statistically independent. The consequences of this erroneous assumption can be code crashes. There is then a natural tendency to make a second bad assumption to counteract the first bad assumption of parameter independence by “modifying” the expert opinion-based parameter distributions to eliminate the code crashes. In the end, one ends up with parameter distributions based entirely on the robustness of the code.

3.6.2 Bayesian Calibration

In the Bayesian calibration process, parameter distributions are constructed directly from experimental data and a model form. This replaces a very subjective approach, like expert opinion, with a very precise, mathematically sound approach, like Bayesian calibration. This makes defending the parameter distribution easier because it and all implied uncertainties are precisely defined by a process that is repeatable by an uncertainty quantification analyst. First, the basis of the Bayesian calibration theory is discussed, followed by an example for wall heat transfer and wall friction.

Theory

Denote the vector of model parameters to be calibrated by θ . Model and experimental outputs are represented by $f(x, \theta)$ and y , respectively, where x quantifies input settings describing the experimental scenario. With ε denoting observational error, in the absence of systematic model bias, the n experimental and model outputs are related as follows:

$$\begin{pmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{pmatrix} = \begin{pmatrix} f(x_1, \theta) \\ f(x_2, \theta) \\ \vdots \\ f(x_n, \theta) \end{pmatrix} + \begin{pmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \vdots \\ \varepsilon_n \end{pmatrix},$$

which in shorthand notation is written $y = f(\theta) + \varepsilon$. Typically the errors are assumed to be independently distributed as mean zero Gaussian having common

variance σ^2 , $\boldsymbol{\epsilon} \sim \mathcal{N}(\mathbf{0}_n, \sigma^2 \mathbf{I}_n)$, where $\mathbf{0}_n$ and \mathbf{I}_n denote the n -vector of zeros and the identity matrix of size n , respectively. However, this specification may be generalized by adopting less restrictive covariance structures or non-Gaussian form for the errors. In the above error specification, σ^2 joins θ as unknowns to be statistically inferred. Given values for θ and σ^2 , the joint sampling distribution of the experimental data \mathbf{y} is Gaussian having mean $\mathbf{f}(\theta)$ and covariance $\sigma^2 \mathbf{I}_n$. Viewed as a function of the parameters θ and σ^2 , this sampling distribution is referred to as the *likelihood* function and is denoted $\mathcal{L}(\theta, \sigma^2 | \mathbf{y})$.

Bayesian analysis further assumes a joint *prior* distribution for (θ, σ^2) , written $\pi(\theta, \sigma^2)$. This distribution encompasses current knowledge about these parameters and is derived through expert opinion or previously available experimental data. It is most often assumed that θ and σ^2 are a priori independently distributed, allowing the prior to be written in the product form

$$\pi(\theta, \sigma^2) = \pi_1(\theta) \pi_2(\sigma^2).$$

In fact, often the individual components of θ are assumed a priori independent, as in Sect. 3.6.1. In this case, the joint prior distribution of θ has the product form

$$\pi_1(\theta) = \prod_{i=1}^{n_\theta} \pi_1^i(\theta_i),$$

where n_θ is the number of parameters θ and $\pi_1^i(\cdot)$ is the marginal distribution of θ_i , $i = 1, \dots, n_\theta$. The ultimate goal of Bayesian calibration is to determine the *posterior* distribution of parameters θ and σ^2 , denoted $\pi(\theta, \sigma^2 | \mathbf{y})$ and given by

$$\pi(\theta, \sigma^2 | \mathbf{y}) \propto \mathcal{L}(\theta, \sigma^2 | \mathbf{y}) \pi(\theta, \sigma^2).$$

That is, the posterior distribution is proportional to the likelihood function multiplied by the prior distribution. In other words, the experimental data \mathbf{y} is used to update prior knowledge about the parameters θ and σ^2 through the likelihood function $\mathcal{L}(\theta, \sigma^2 | \mathbf{y})$. Relative to the prior distribution, values of θ and σ^2 associated with greater likelihood values (i.e., more likely to have generated the observed data) are more probable.

The posterior distribution of θ and σ^2 is generally not available analytically due to the fact that the normalizing constant

$$c = \int \mathcal{L}(\theta, \sigma^2 | \mathbf{y}) \pi(\theta, \sigma^2) d\theta d\sigma^2$$

is not easily obtained in most realistic applications. Consequently, sampling methods such as Markov chain Monte Carlo (MCMC) are used to generate a sample (say of size M) $\{(\theta_i, \sigma_i^2), i = 1, \dots, M\}$ from this posterior distribution. Given a model $g(\cdot)$ that depends on θ (and perhaps other parameters), uncertainty quantification

about model output is then obtained by summarizing the sample of model outputs $\{g(\theta_i), i = 1, \dots, M\}$. MCMC and predictive inference are infeasible if the model $f(\cdot)$ calculates slowly for each parameter setting θ . In this case, a physical or mathematical surrogate for $f(\cdot)$ must be employed in both Bayesian calibration and uncertainty quantification.

When systematic bias is present in model calculations, the statistical model used to describe the experimental data must be extended. This can be accomplished in several ways depending on the nature of the bias. Here a particular case is considered in which the n -vector of experimental data was collected across ℓ laboratories ($\ell < n$):

$$\mathbf{y} = \begin{pmatrix} \mathbf{y}_1 \\ \mathbf{y}_2 \\ \vdots \\ \mathbf{y}_\ell \end{pmatrix}.$$

Assuming it is reasonable that factors specific to each particular laboratory could modify inference about the distribution of θ , the following sampling model is posited for data from the i -th laboratory, $\mathbf{y}_i = \mathbf{f}_i(\theta + \delta_i) + \boldsymbol{\epsilon}_i$, where $\mathbf{f}_i(\cdot)$ represents model output corresponding to experimental data from the i -th laboratory. In this scenario, θ represents settings of the model parameters common to the population of laboratories contributing data, while δ_i specifies a perturbation of this common parameter that adjusts for biases introduced by the i -th laboratory. The variance of observational errors $\boldsymbol{\epsilon}_i$ corresponding to laboratory i is denoted σ_i^2 . The perturbations δ_i are assumed a priori to be independently distributed from a mean-zero Gaussian distribution having covariance matrix $\Phi(\phi)$ for $i = 1, \dots, \ell$. Here, ϕ is the set of parameters fully describing the covariance structure of the perturbation vectors δ . For example, if the individual components of δ are taken to be independently distributed, ϕ is a n_θ -vector, and $\Phi(\phi)$ is the diagonal matrix having entries ϕ_i for $i = 1, \dots, n_\theta$. In the unrestricted case, ϕ is a $n_\theta(n_\theta + 1)/2$ -vector parameterizing the symmetric, positive definite matrix $\Phi(\phi)$. The covariance parameters ϕ are assigned a joint prior distribution, $\phi \sim \pi_3(\phi)$. Bayesian calibration proceeds as in the no-bias case, resulting in samples of $(\theta, \sigma_1^2, \dots, \sigma_\ell^2, \delta_1, \dots, \delta_\ell, \phi)$ from their joint posterior distribution. Predictive inference then proceeds as in the no-bias case; for example, uncertainty quantification about model output is obtained by summarizing the sample of model outputs $\{g(\theta_j), j = 1, \dots, M\}$.

The first model introduced above in which a common parameter is fit to the available data is referred to as a *fixed* effects model, while the second model discussed above in which a common parameter is randomly perturbed to match data from multiple cohorts is referred to as a *mixed* effects model.

Application

Mixed effects models as described in the previous section were utilized to calibrate three parameters of the Dittus-Boelter correlation for wall heat transfer and two

parameters of the McAdams correlation for wall friction. The Dittus-Boelter correlation has the following form:

$$f_{DB}(x, \theta) = \theta_1 x_1^{\theta_2} x_2^{\theta_3},$$

where x_1 is the Reynolds number and x_2 is the Prandtl number. The nominal value of θ is set to $\theta_0 = (0.023, 0.8, 0.4)$, and the prior distribution of θ is taken to be uniform on the hyperrectangle defined by the Cartesian product of the intervals $[0, 2\theta_{0,i}]$ for $i = 1, 2, 3$. The McAdams correlation has the following form:

$$f_M(x, \theta) = \theta_1 x^{\theta_2},$$

where x is the Reynolds number. The nominal value of θ is set to $\theta_0 = (0.204, -0.2)$, and the prior distribution of θ is taken to be uniform on the square defined by $[0, 2\theta_{0,1}] \times [2\theta_{0,2}, 0]$.

Figure 48.1 presents data from three laboratories used for the Dittus-Boelter calibration and data from 11 laboratories used for the McAdams calibration. Figures 48.2 and 48.3 show posterior samples of common θ and perturbed $\theta + \delta$ by laboratory, for the Dittus-Boelter and McAdams calibrations, respectively. As discussed in the previous section, common θ represents parameter settings pertaining to the entire population of laboratories contributing data to the calibration, while perturbed $\theta + \delta_i$ provides the best fit to data from the i -th laboratory. Posterior samples of common θ represent uncertainty contributions from the Dittus-Boelter and McAdams correlations in the uncertainty quantification results of Sect. 5.

3.6.3 Types of Distributions

In this section the effects of different choices for constructing parameter distribution functions are discussed in an example with two hypothetical parameters shown in Fig. 48.4.

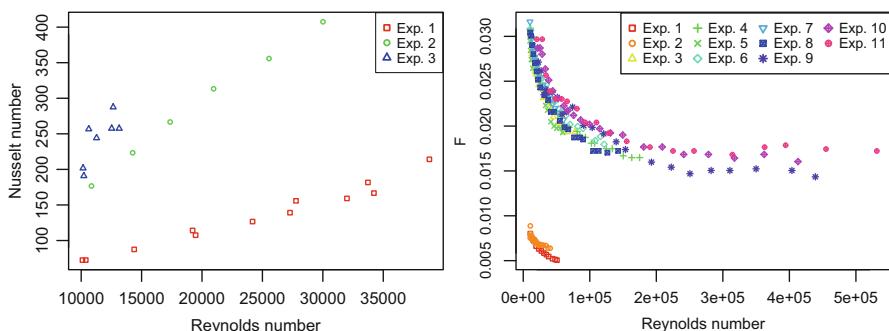

Fig. 48.1 Experimental data used for Dittus-Boelter (left) and McAdams (right) calibrations

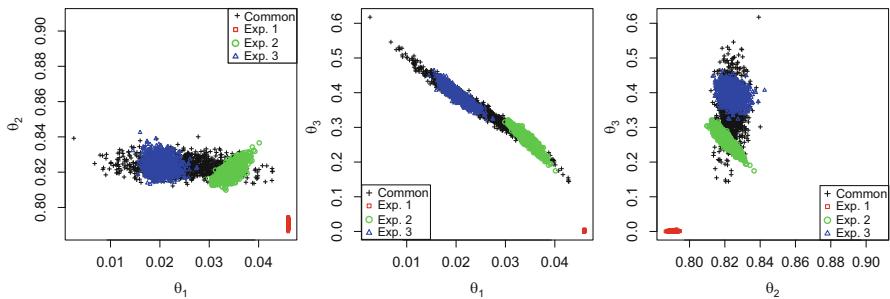

Fig. 48.2 Bivariate projections of posterior samples of common θ (black) and perturbed $\theta + \delta$ corresponding to each laboratory (see legends) from Dittus-Boelter calibration

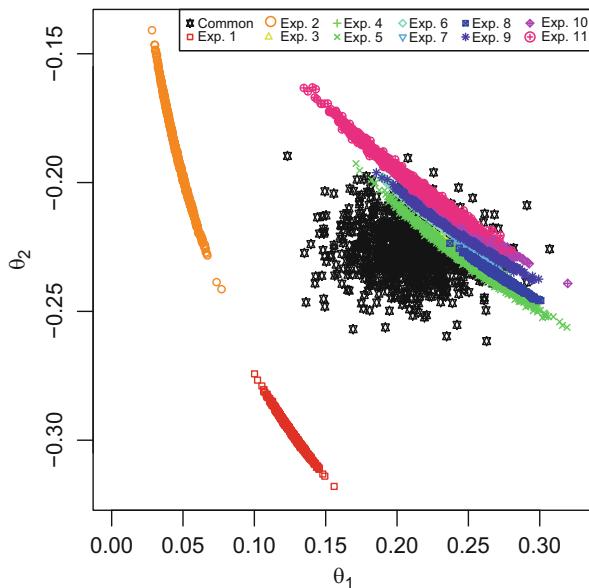

Fig. 48.3 Posterior samples of common θ (black) and perturbed $\theta + \delta$ corresponding to each laboratory (see legend) from McAdams calibration

Expert Opinion Distributions

In Fig. 48.4 the expert opinion is shown as the large blue bounding box. Unlike the Bayesian calibration-based distributions, the expert opinion-based distribution has no or little experimental data basis. Therefore the large range in parameters, which are typically assumed statistically independent and often uniformly distributed, can lead to poor choices and bad simulation results.

Marginal Distributions

Assume the parameters are statistically independent, having marginal distributions obtained from Bayesian calibration to experimental data. The support of these

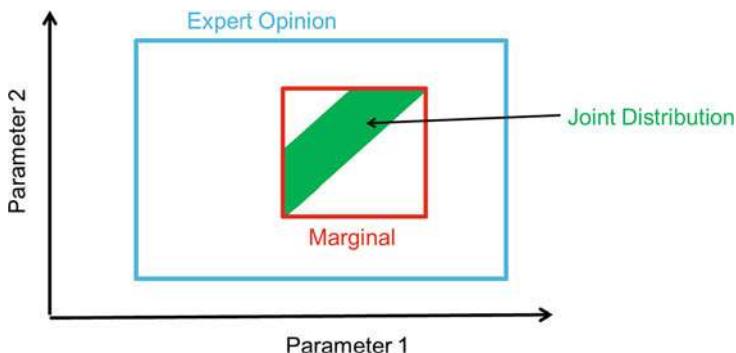

Fig. 48.4 Parameter distributions

distributions is represented as the red bounding box in Fig. 48.4. The experimental-based parameter distributions are now peaked within their ranges, reflecting marginal preferences for parameter values associated with output more consistent with the experimental data. Sampling these marginal distributions thus results in a lower likelihood of bad simulation results relative to the expert opinion case.

Joint Distributions

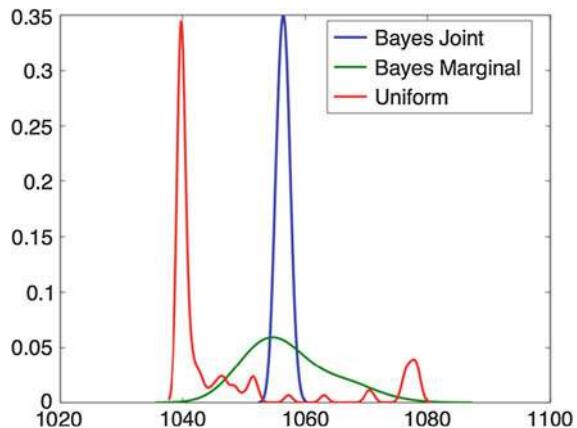

Joint distributions arise from analysis of the interdependency among parameters. The support of the joint distribution is represented as the solid green trapezoid in Fig. 48.4. Here, using experimental data, the relationship among the parameters is recognized. This results in a smaller probabilistic volume to sample from and should eliminate all code crashes due to unphysical parameter choices. It should be stressed that the assumption of parameter independence is essential for expert opinion-based parameter distributions because it is impossible, without detailed mathematical analysis of the experimental data, for an expert to intuit the relationship among parameters.

3.6.4 Effects of Different Types of Distributions

To illuminate the impact of these choices for parameter distribution function construction, an example is provided based on thermal hydraulic wall heat transfer. The uncertainty in a calculation of maximum fuel temperature is explained in terms of parameter distributions. The starting point was an expert opinion-based parameter distribution that was uniform between zero and twice the nominal value for each parameter. Random sampling of this uniform distribution resulted in many code crashes and a confusing distribution for maximum fuel temperature shown in red in Fig. 48.5. Then the expert opinion-based distribution was replaced by parameter distributions derived from Bayesian calibration of experimental data. Specifically, the Dittus-Boelter calibration results of Sect. 3.6.2 were used, noting the expert opinion-based distribution was selected as the parameter prior distribution.

In the first analysis using the Bayesian calibration results, each parameter was sampled from its marginal distribution, and assuming statistical independence, these

Fig. 48.5 Parameter distribution effects on uncertainty quantification

samples were combined across parameters to form a joint sample. The resulting distribution for maximum fuel temperature is shown in green in Fig. 48.5. A maximum fuel temperature distribution is seen that looks right skewed as also seen from expert opinion, but now unimodal due to much lower probability assigned to unphysical parameter settings. It is interesting to note that the range of the maximum fuel temperature distribution is not much different than the expert opinion-based distribution shown in red.

In the second analysis using the Bayesian calibration results, the maximum fuel temperature distribution was computed based on the joint parameter distribution. This is shown in blue in Fig. 48.5. A very tight distribution function is now seen with a nominally Gaussian shape. All sampled parameter settings in this case are probabilistically consistent with the experimental data.

It is important to note that a significant reduction in uncertainty, and a resulting larger margin, was accomplished simply through improved parameter distributions. The lower uncertainty resulting from the joint parameter distribution is easier to defend to a regulator than the larger expert opinion-based uniform distribution. As long as the expert opinion-based independent uniform parameter distribution is “larger” than the “real” parameter distribution based on experimental data, it will typically (under weak assumptions of code input-output behavior) result in a more conservative estimate of the output uncertainty.

3.7 User Effect

There is recognition in the nuclear power industry that there is a mode of uncertainty that comes from the code user called the user effect [12]. Based on the training of the code user and the level of code documentation for user guidelines and best practices, two different code users can get two different answers given the same simulation problem. This difference in answers is called the user effect.

To minimize user effect, one needs to eliminate, as much as possible, “tunable parameters.” Tunable parameters allow the code user to “dial in” whatever answer

they expect. They can force the simulation answer to behave the way the code user expects. This overriding of the code physics minimizes the work on code quality that provided the pedigree asserting the code physics was correct. If parameters are put into the input file for uncertainty quantification, a large number of tunable parameters can be created.

If ten people, given the same problem definition and the same software, get ten different answers, this typifies user effect. Code documentation that discusses best practices and user guidelines is the key to minimizing user effect. This can also be minimized by expanded input processing such as a graphical user interface (GUI). The GUI can have best practices and user guidelines built into the default values which reduce the number of parameters code users can change.

4 Modifications to PCMM

The PCMM process is evolving and can be modified to better suit the application. The following is a list of modifications, changes, and improvements to the PCMM process for this application:

1. Quantified Parameter Ranking Table (QPRT) – the QPRT augments the information from the PIRT and provides a more complete picture of the importance of physical models.
2. Validation Pyramid – a validation pyramid decomposes the QoI into its individual components.
3. Partitioning of Code and Application PCMM – PCMM applied to an application drives PCMM analysis of individual codes.

These will be discussed in the following subsections.

4.1 Quantified Parameter Ranking Table

The PIRT plays a key role in analyzing the predictability of software. The PIRT process consists of a team of experts defining which physical phenomena are important to correctly model for a given application and the set of QoIs. The experts list the important phenomena and then rank them in terms of each phenomenon's impact on each QoI (high, medium, or low) and then on available knowledge to model that phenomenon (high, medium, or low). Resources for modeling and simulation are then focused on phenomena that have high importance and low knowledge.

The challenge of a PIRT is that it is very subjective and there can be a large uncertainty in the PIRT process based on one's choice of experts. Therefore the PIRT process is augmented with a QPRT. The QPRT is a sensitivity analysis based on the parameters in the software. This is a quantitative process that is repeatable by different investigators (the expert bias has been removed). One can numerically

measure the impact of any given parameter on each QoI. These parameters can then be ranked ordinally from most important to least important. Given a working knowledge of the simulation code, each of these parameters can then be mapped back to a model of a physical phenomenon. In this way one can construct a list of phenomena that the “software” believes is important.

One is then left with the task of making the PIRT and QPRT agree. It is possible that an important physical phenomenon is ranked high in the PIRT but does not show up in the QPRT because a model for that phenomenon was not included in the code. This means that new models have to be added to the code. Sometimes the phenomena defined by the experts are not relevant to the simulation. For example, an expert may believe that interfacial friction is a key phenomenon; however, if the flow is single phase, then two-phase phenomena are not important.

There is another process that can be used to assess the quality of the PIRT and QPRT, and that is sensitivity experiments. In a sensitivity experiment, one makes small perturbations to the nominal experiment based on a physical phenomenon. One then experimentally confirms that perturbations in the phenomenon have a large or small effect on the QoI measured in the experiment.

If the PIRT, QPRT, and experimental sensitivity study all agree on what phenomena are important and are not important, then one can proceed with confidence that the important phenomena have been correctly identified. When the theoretical expert opinion-based PIRT and the mathematical and computer science-based QPRT agree with the experimental-based sensitivity studies, it is an easy process to convince a regulator that the important phenomena have been captured.

4.2 Validation Pyramid

The validation pyramid shown in Fig. 48.6 is constructed by starting with the QoI at the top and then decomposing the physics into its component parts. In the example given here, the QoI is the fuel temperature. The fuel temperature is computed based on the fuel code, the neutronic code which provides the heating, and the thermal hydraulic code which provides the cooling. In addition this process has a variety of code coupling parameters and some nonlinear feedback mechanisms. The heat source from the neutronics is a nonlinear function of the coolant density and the fuel temperature. The neutronics generates the heat which is passed into the fuel which then conducts it to the clad which is then removed by the fluid through convective heating and boiling. The validation pyramid pictorially describes all of the physical processes that need to be validated and all of the coupling and nonlinear feedback in the multi-physics code.

4.3 Partitioning of Code and Application PCMM

For a given application, one can divide the PCMM work between the top of the validation pyramid, which is specific to the application and the code coupling, and the bottom of the validation pyramid which is foundational and is independent of

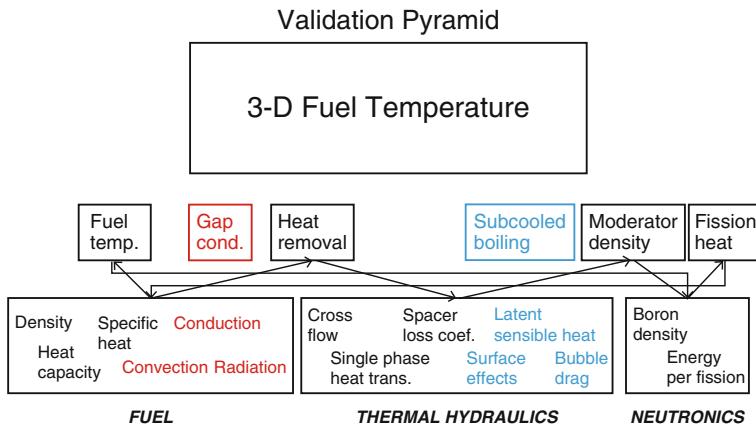

Fig. 48.6 Simplified validation pyramid

the application. This way one can partition PCMM work between the separate codes that make up the multi-physics application – in this case, fuels, thermal hydraulics, and neutronics – and the application itself which is computed from coupled codes. For a single QoI and a single application, this appears to be a somewhat arbitrary division. However, when one considers multiple QoIs and multiple applications, the value becomes more clear.

Each application and subsequent QoI clearly define a set of requirements of the individual codes. The validation pyramid precisely defines which physics are required by each separate code to construct the QoI for a given application. The individual codes can then build a foundational PCMM analysis that establishes the pedigree for the low-level capability required for the application. If there are multiple QoIs and multiple applications, then the code-level requirements are constructed from the union of all of the individual application and QoI requirements. This builds a set of application-independent requirements that have their maturity assessed by the code PCMM. The code PCMM is at a low level so validation is based on separate effects experiments.

Given a set of codes that have a PCMM pedigree for their application and QoI requirements, one is ready to then build the application and QoI PCMM pedigree. The pedigree of the coupled code utilized in the application is established. The verification and validation are now applied to the coupled application based on the solid foundation provided by the individual code PCMM. Validation at the application level is at a higher level and is therefore based on integral effects experiments.

This process provides a rapid way to move to new applications. The basic assumption is that the code PCMM will begin to saturate and all of the low-level requirements will be pedigreed by an earlier application. This way additional applications will focus mainly on integral effects experiments and coupled code applications due to the fact that the amount of work for code PCMM will diminish because of the redundancy in code-level requirements.

5 Sample Application

The sample application is for a single assembly with 17x17 fuel pins shown in Fig. 48.7. This is the simulation of a pressurized water reactor at hot full power. It includes thermal hydraulic feedback and is run at 100% of nominal power with a boron concentration of 1300 parts per million. More details of this study are presented in a technical report [8]. This test problem was chosen because it is small enough to do hundreds of runs easily, but complicated enough that it includes code coupling and key nuclear reactor phenomena. It should be noted that there are no validation data for this problem so the application validation effort will not be presented. The code validation effort was implemented with separate effects data used to calibrate some of the model parameters.

This is a steady-state problem at 100% of nominal power, implying single phase without subcooled boiling (the subcooled boiling occurs in the hot assemblies that are at higher than 100% nominal power). Due to this only a small fraction of the thermal hydraulic capability is utilized.

5.1 PIRT

The PIRT is presented in its entirety in Appendix B.2. The result of the PIRT is summarized in the following list of high-importance phenomena:

1. (H,M) Subcooled boiling (minimal effect due to void, possible effect due to improved heat transfer, but subcooled boiling occurs where the power is low)
2. (H,H) Single-phase heat transfer (Dittus-Boelter affects fuel temperature)

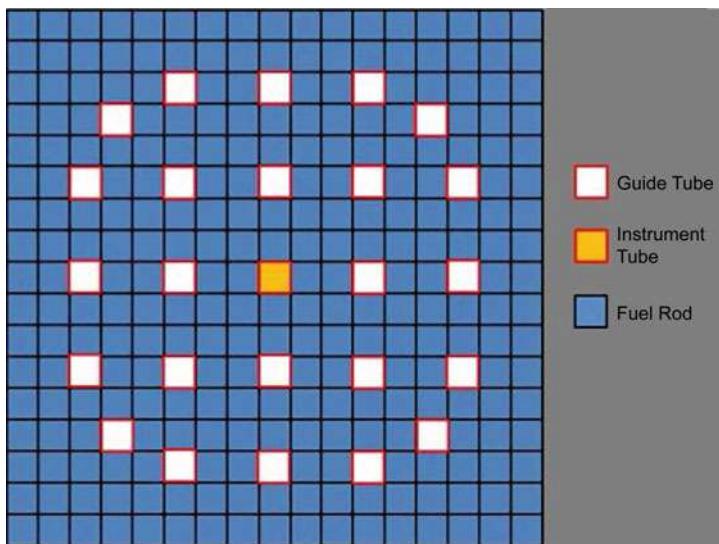

Fig. 48.7 Test problem

3. (H,L) Cross-flow models (important near guide tubes)
4. (H,M) Spacer grid loss coefficient
5. (H,M) Gap conduction model (pure He filled)
6. (H,H) Clad heat capacity
7. (H,H) Heat addition from neutronics
8. (H,H) Heat removal from thermal hydraulics
9. (H,H) Neutron cross sections
10. (H,H) Energy released per fission
11. (H,M) Boron density in the coolant
12. (H,H) Moderator density
13. (H,H) Fuel temperature (Doppler feedback)

It should be noted that some phenomena from the PIRT in this list have been collapsed into more general categories.

5.2 Numerical Uncertainty

Our first step is to use solution verification to estimate the numerical uncertainty for each of our three QoIs. The QoIs can sometimes be estimated by the stand-alone codes (CTF) and the coupled codes (VERA-CS). The verification results are presented in Table 48.1 which quantifies estimates of the numerical uncertainty.

5.3 QPRT

The code is used to estimate the important phenomena based on the software. Note that due to the complexity of the interrelationships among the cross sections, they were not simply “perturbed.” Instead, a set of 100 consistent cross-sectional libraries was constructed and each was run separately. For all other parameters, the multiplier of the nominal parameter value is listed as well as the resulting change in the QoI. It should be noted that some parameters received a larger perturbation due to the larger uncertainty in that parameter (gap conductivity and fuel conductivity in the fuel model are noted).

Table 48.2 provides sensitivities of the different parameters that represent the different phenomena in the code. The numerical uncertainty is presented in italics.

Table 48.1 Verification

Code	QoI	Numerical percent error estimate
VERA-CS	k-eff	0.002
VERA-CS	Maximum pin power	0.250
VERA-CS	Maximum fuel temperature	0.050
CTF	Maximum fuel temperature	0.015

Table 48.2 Reactivity

Variable description	Multiplier	Percent difference	Physics
Cross sections	NA	1.283	Neutronics
Cross sections	NA	-1.163	Neutronics
Gap conductivity	0.5	-0.422	Fuel
Gap conductivity	1.5	0.152	Fuel
Fuel temperature	0.95	0.081	Coupling
Fuel temperature	1.05	-0.080	Coupling
Fuel conductivity	0.9	-0.073	Fuel
Fission heat	1.05	-0.062	Coupling
Fission heat	0.95	0.061	Coupling
Fuel conductivity	1.1	0.059	Fuel
Moderator density	1.05	-0.035	Coupling
<i>Mesh spacing</i>	NA	0.020	Numerical
Moderator density	0.95	-0.017	Coupling
Wall heat transfer	0.95	-0.013	Thermal hydraulics
Moderator temperature	1.05	-0.010	Coupling
Moderator temperature	0.95	0.009	Coupling
Wall heat transfer	1.05	0.009	Thermal hydraulics

The numerical uncertainty sets the floor for future parameter work. Utilizing the concept of total uncertainty in Sect. 2.1, focus centers on the largest uncertainties among numerical, validation, and parameter. Since validation data are not available for this problem, only numerical and parameter uncertainties remain. Therefore interest in parameter uncertainties smaller than the numerical uncertainty is merely academic. As expected, the sensitivities associated with cross sections dominate the reactivity QoI. This is followed by fuel model phenomena and code coupling.

Table 48.3 provides the QPRT for the pin power QoI. As opposed to reactivity, which is a single global number, for this simulation pin power is different in every fuel pin and every axial level. As a local variable, it is a stronger function of the fuel temperature and the resulting feedback than the cross sections.

Table 48.4 provides the QPRT for the maximum fuel temperature QoI. This table is dominated by the fuel model which is expected for this QoI.

5.4 PIRT and QPRT Iteration

Table 48.5 compares the PIRT results with the QPRT results. The PIRT panel had a bias to members with a thermal hydraulic background. This resulted in thermal hydraulic phenomena being given a higher ranking. However, in the problem studied and for the QoIs selected, the neutronic and fuel models were more important than thermal hydraulics. It should also be noted that some entries in the PIRT were redundant since the lists were constructed separately for fuels, thermal hydraulics,

Table 48.3 Pin power

Variable description	Multiplier	Percent difference	Physics
Gap conductivity	0.5	-2.150	Fuel
Gap conductivity	1.5	0.905	Fuel
Cross sections	NA	0.815	Neutronics
Fuel conductivity	0.9	-0.493	Fuel
Fuel conductivity	1.1	0.411	Fuel
Fission heat	0.95	0.327	Coupling
Fission heat	1.05	-0.315	Coupling
Fuel temperature	0.95	0.280	Coupling
Fuel temperature	1.05	-0.260	Coupling
<i>Mesh spacing</i>	NA	0.250	<i>Numerical</i>
Cross sections	NA	-0.228	Neutronics
Moderator density	1.05	-0.073	Coupling
Wall heat transfer	0.95	-0.072	Thermal hydraulics
Wall heat transfer	1.05	0.053	Thermal hydraulics
Moderator density	0.95	0.052	Coupling
Moderator temperature	0.95	0.038	Coupling
Moderator temperature	1.05	-0.035	Coupling
Turbulent mixing of liquid mass	1.05	0.006	Thermal hydraulics
Turbulent mixing of liquid mass	0.95	0.005	Thermal hydraulics
Turbulent mixing of liquid momentum	1.05	0.002	Thermal hydraulics
Turbulent mixing of liquid energy	1.05	0.002	Thermal hydraulics
Turbulent mixing of liquid energy	0.95	0.001	Thermal hydraulics

and neutronics. The code coupling parameters (fission heat and fuel temperature) play a major role in this application.

5.5 Code PCMM

The next step in the process is to establish the initial PCMM scores for the separate codes. The expected PCMM values, referred to as “goals,” are also established. This first step provides an initial external assessment (outside of the code team) which identifies areas of improvement for the code team. It should be noted that the PCMM goals reflect the intended use of the application results. In this example, the application was simply a progression problem used to monitor code development progress. Since no important decisions are based on the results, the goal PCMM scores are low.

The second step is to come back later and remeasure the PCMM score relative to the goal. Once the software has achieved its PCMM goal, additional work is of lower priority.

Table 48.4 Maximum fuel temperature

Variable description	Multiplier	Percent difference	Physics
Gap conductivity	0.5	21.423	Fuel
Gap conductivity	1.5	-7.445	Fuel
Fuel conductivity	0.9	6.807	Fuel
Fuel conductivity	1.1	-5.405	Fuel
Fission heat	1.05	4.436	Coupling
Fission heat	0.95	-4.354	Coupling
Cross sections	NA	0.739	Neutronics
Wall heat transfer	0.95	0.610	Thermal hydraulics
Wall heat transfer	1.05	-0.495	Thermal hydraulics
Fuel temperature	0.95	0.254	Coupling
Fuel temperature	1.05	-0.236	Coupling
Cross sections	NA	-0.198	Neutronics
Moderator density	1.05	-0.106	Coupling
Moderator density	0.95	0.085	Coupling
<i>Mesh spacing</i>	NA	0.050	Numerical
Moderator temperature	0.95	0.034	Coupling
Moderator temperature	1.05	-0.032	Coupling
Turbulent mixing of liquid mass	0.95	0.005	Thermal hydraulics
Turbulent mixing of liquid momentum	1.05	0.002	Thermal hydraulics
Turbulent mixing of liquid mass	1.05	-0.001	Thermal hydraulics
Turbulent mixing of liquid energy	0.95	0.001	Thermal hydraulics

Table 48.5 Comparison of PIRT and QPRT

Phenomenon	PIRT	QPRT	Resolution
Subcooled boiling	High	No effect	No subcooled boiling occurred in the simulation studied
Dittus-Boelter	High	Low	Minor effect
Cross-flow models	High	Very low	Less than numerical uncertainty
Grid spacer loss coefficient	High	No effect	Minor impact on density
<i>Gap conduction model</i>	<i>High</i>	<i>High</i>	<i>Major contributor</i>
Clad heat capacity	High	Low	Overwhelmed by fuel heat capacity
<i>Fission heat</i>	<i>High</i>	<i>High</i>	<i>Major contributor</i>
Heat removal from thermal hydraulics	High	Low	Already accounted for by Dittus-Boelter
<i>Neutron cross sections</i>	<i>High</i>	<i>High</i>	<i>Major contributor</i>
Energy released from fission	High	High	Already accounted for by fission heat
Boron density	High	No effect	Boron density was held constant
Moderator density	High	Low	Minor impact
<i>Fuel temperature</i>	<i>High</i>	<i>High</i>	<i>Major contributor</i>

Table 48.6 Neutronic PCMM scores

Element\score	Goal	Initial	Current
Geometry (Geom)	1.0	0.0	1.5

Code verification (Code Ver.)	1.0	1.0	1.0
Solution verification (Sol. Ver.)	1.0	0.0	1.0
Validation (Val.)	1.0	0.5	1.5
Uncertainty quantification (UQ)	1.0	0.0	1.0

Fig. 48.8 Neutronic Kiviat diagram

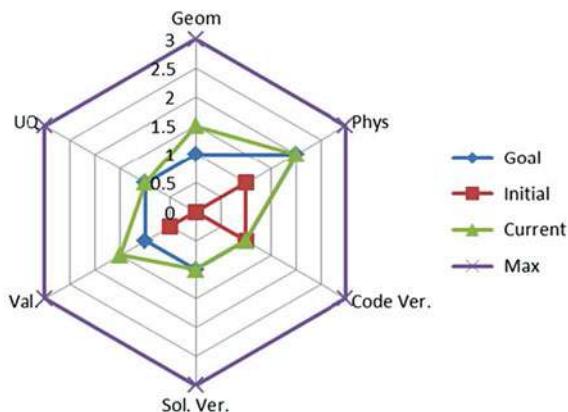

Table 48.7 Thermal hydraulic PCMM scores

Element\score	Goal	Initial	Current
Geometry (Geom)	2.0	2.0	2.0
Physics (Phys)	1.0	1.0	1.0
Code verification (Code Ver.)	2.0	1.0	1.25
Solution verification (Sol. Ver.)	1.5	1.5	1.5
Validation (Val.)	2.0	0.5	1.5
Uncertainty quantification (UQ)	1.0	0.0	1.0

5.5.1 Neutronics

Table 48.6 provides the initial PCMM scores, goals, and current scores for neutronics. In all cases, the current score exceeds or meets the goal. Note that during this study, it was decided that the neutronic code would be replaced. This resulted in relatively low goal PCMM values.

The results of Table 48.6 can be quickly summarized by the Kiviat diagram shown in Fig. 48.8. The Kiviat diagram provides a quick reference for where additional work is needed, if anywhere.

5.5.2 Thermal Hydraulics

Table 48.7 provides the PCMM scores for thermal hydraulics. In this case, the thermal hydraulic code was older and therefore was appropriately measured as more mature software.

Fig. 48.9 Thermal hydraulic Kiviat diagram

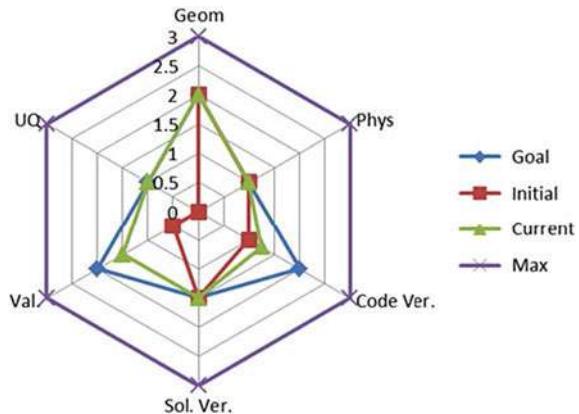

Table 48.8 Application PCMM scores

Element\score	Goal	Current
Geometry (Geom)	1.0	1.0
Physics (Phys)	1.0	1.0
Code verification (Code Ver.)	1.0	0.5
Solution verification (Sol. Ver.)	1.5	1.5
Validation (Val.)	0.0	0.0
Uncertainty quantification (UQ)	1.0	1.0

Figure 48.9 shows the pictorial summary of Table 48.7. This diagram shows that additional work is needed in code verification and validation. It should be noted that this work was completed after this study was conducted.

5.6 Application PCMM

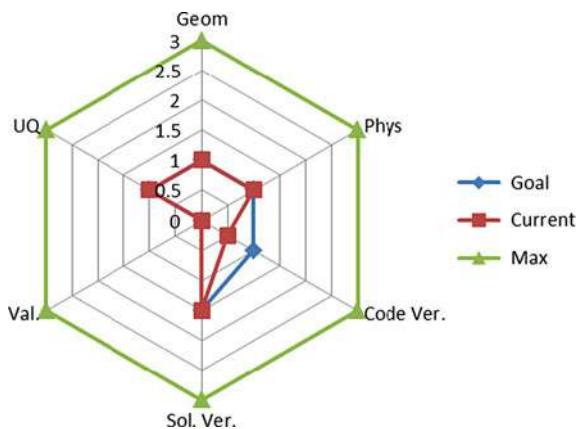

Table 48.8 provides the PCMM scores for the coupled code application. It is sometimes challenging to separate the code PCMM from the application PCMM since there is a certain amount of overlap. Note that since this application does not have any validation experimental data, the goal for validation is zero.

Figure 48.10 shows the summary of Table 48.8. It is seen that all the goal values have been met except for application code verification. It should be noted that whereas solution verification is easy for an application, code verification often requires additional software development (e.g., method of manufactured solutions).

5.7 Best Estimate Plus Uncertainty

Based on the parameter downselect from the sensitivity study, an uncertainty quantification study was conducted using a small subset of the code parameters focusing on the ones that had significant impact on the QoIs. These UQ studies

Fig. 48.10 Application Kiviat diagram

included a variety of approaches. For neutronics, all of the cross sections were represented as a single parameter having uncertainty captured by perturbed cross-sectional libraries. Some of the parameters had detailed parameter distributions constructed from Bayesian calibration of separate effects tests as described in Sect. 3.6.2. Some parameters used expert opinion which is always the fallback position. The result was the construction of a two-standard-deviation uncertainty range for each of the QoIs.

5.7.1 Reactivity

The reactivity uncertainty, although small on a percentage basis, was higher than expected. Future efforts will be applied to understand this large uncertainty and make attempts to reduce it:

$$\text{Reactivity (nondimensional)} = 1.16415 \pm 0.01242 \quad (48.4)$$

5.7.2 Maximum Rod Power

The uncertainty in the maximum rod power was small and would have little impact on the decision-making process:

$$\text{Power} \left(\frac{\text{Watts}}{\text{cm}^2} \right) = 269.445 \pm 4.60 \quad (48.5)$$

5.7.3 Maximum Fuel Temperature

The uncertainty in the maximum fuel temperature was the result of large uncertainty in the gap conductance model and the fuel conductivity model. Work is currently underway to employ a high-fidelity fuel performance code to reduce the uncertainty in the low-fidelity fuel model employed in this study:

$$\text{Temperature (C)} = 1991.859 \pm 338.0 \quad (48.6)$$

6 Presentation of the Evidence File

When the best estimate plus uncertainty results are being presented in a hostile environment where a regulator is reviewing the information, it is important they be presented in a logical fashion that is easy to follow. The “story” should be presented in a manner that demonstrates a high-level understanding of both the application physical phenomena and a deep understanding of the code results. The evidence files for each of the six PCMM elements should be available for a “deep dive” if details are needed to support conclusions. However, these details can be summarized quickly in a Kiviat diagram, and there is no need to “step through” all of the evidence.

It is important to recognize the major sources of uncertainty as numerical, model-form (validation), and parameter uncertainty. It is important to present a succinct summary that all important topics have been covered in a logical fashion. For parameter uncertainty, it is desirable to establish which parameters were studied and which parameters were not with a logical explanation of why parameters were excluded. When possible parameter distributions based on Bayesian calibration of separate effects tests should be employed, but expert opinion is always the fallback position.

The key to presenting uncertainty quantification results in a regulatory environment is to prepare as much as possible for whatever reasonable questions could be asked. If questions are answered quickly and concisely with backup evidence available, the regulators will quickly gain confidence in the presenter. Because of the high level of stress induced by a regulatory review, “thinking off the top of one’s head” can be dangerous. It is sometimes preferable to simply admit ignorance and ask for more time to study than to give an incorrect answer.

7 Conclusions

There is a strong pull to use “black box” uncertainty quantification methods. However, accurate application of these methods requires detailed understanding of both the UQ method and the simulation code being studied. In that sense there are really no “black box” methods that work for all codes all of the time. This is particularly true when presenting results in a regulatory environment:

1. One may be reviewed by a statistician who has a detailed knowledge of the UQ methods and their underlying assumptions.
2. One may be reviewed by a numerical method expert that clearly understands all of the shortcomings of the numerical approaches employed by the code.
3. One may be reviewed by an experimentalist having detailed understanding of the physics being modeled and the flaws in the physical models employed by the code.

4. Finally one may be reviewed by someone who has intimate knowledge of the simulation software and knows what model parameters are exposed for study and which model parameters are hidden in the code.

If the regulatory decision is important (e.g., related to nuclear reactor safety), one will most likely encounter experts in the review process from all four fields above. In a regulatory environment, black box approaches are only useful if the regulator does not know what is in the box.

It is important to understand all of the different sources of uncertainty and to address all of them clearly and logically. The PCMM process provides a structure that ensures that all important topics are accounted for. It is important for the regulator to be able to clearly understand the pedigree behind the best estimate value of the QoI and the quantified uncertainty in the QoI. It is not important to present all of the details, but it is important to have all of the details readily available when questions are asked. The PCMM Kiviat diagrams provide a very succinct summary of the work, and the PCMM evidence files provide the detailed information needed to answer specific questions.

Appendix

A.1 Analysis of Wilks Formula

In 1941 Wilks [15] introduced a nonparametric method for setting tolerance limits. This method assumes that the population cumulative distribution function $G(\cdot)$ of the QoI admits a density function $g(\cdot)$ with respect to Lebesgue measure, i.e., $\frac{d}{dy}G(y) = g(y)$. Calculation of Wilks tolerance limits requires the capability to randomly sample the distribution $G(\cdot)$. In the applications of interest here, the distribution $G(y)$ is defined as the probability of the set $\{\theta : f(\theta) \leq y\}$, where $f(\theta)$ denotes the results of a computational model evaluated at parameter setting θ . In this scenario, the random sampling requirement is met by (a) possessing an ability to sample θ from its correct distribution, even if this distribution is not available analytically (cf. Sect. 2.2.2), and (b) confirming that code crashes are independent of parameter values θ (cf. Sect. 2.2.1). The density $g(y)$ will not correctly represent the true output distribution, and therefore Wilks tolerance limits will be biased, if (a) the assumed parameter vector θ excludes additional inputs that if varied would induce changes in the QoI (cf. Sect. 2.2.3) or (b) $f(\theta)$ produces biased predictions of the QoI for θ values belonging to a set of positive probability (cf. Sect. 2.2.4).

Given an independent and identically distributed sample (Y_1, \dots, Y_n) from $g(\cdot)$, form the *order statistics* $(Y_{(1)}, \dots, Y_{(n)})$, where $Y_{(1)} \leq Y_{(2)} \leq \dots \leq Y_{(n)}$. Upper [lower] one-sided tolerance bounds of the form $(-\infty, U_t) = (-\infty, Y_{(t)})$ [$(L_t, \infty) = (Y_{(s)}, \infty)$] are considered and tolerance intervals of the form $(L_t, U_t) = (Y_{(s)}, Y_{(t)})$, $s < t$. Define the following random variables,

$$\begin{aligned} P_U &= 1 - G(Y_{(t)}) = \int_{Y_{(t)}}^{\infty} g(y) dy, \\ P_L &= G(Y_{(s)}) = \int_{-\infty}^{Y_{(s)}} g(y) dy, \text{ and} \\ P_C &= G(Y_{(t)}) - G(Y_{(s)}) = \int_{Y_{(s)}}^{Y_{(t)}} g(y) dy. \end{aligned}$$

The upper one-sided tolerance bound $(-\infty, Y_{(t)})$ has (random) coverage probability $1 - P_U$, the lower one-sided tolerance bound $(Y_{(s)}, \infty)$ has coverage probability $1 - P_L$, and the tolerance interval $(Y_{(s)}, Y_{(t)})$ has coverage probability P_C . Starting from the joint probability distribution of $(Y_{(s)}, Y_{(t)})$ (cf. [2]), these coverage probabilities each have beta distributions:

$$\begin{aligned} P_U &\sim \text{Beta}(n - t + 1, t), \\ P_L &\sim \text{Beta}(s, n - s + 1), \text{ and} \\ P_C &\sim \text{Beta}(t - s, n - t + s + 1). \end{aligned}$$

The cumulative distribution function of the beta(a, b) distribution evaluated at p is the regularized incomplete beta function denoted $I_p(a, b)$. The upper one-sided tolerance bound $(-\infty, Y_{(t)})$ is $(100 \times (1 - \alpha))/100 \times P\%$ if

$$\Pr[1 - P_U \geq P] \geq 1 - \alpha,$$

or equivalently $I_{1-P}(n - t + 1, t) \geq 1 - \alpha$. In similar fashion, the lower one-sided tolerance bound $(Y_{(s)}, \infty)$ is $(100 \times (1 - \alpha))/100 \times P\%$ if $I_{1-P}(s, n - s + 1) \geq 1 - \alpha$, and the tolerance interval $(Y_{(s)}, Y_{(t)})$ is $(100 \times (1 - \alpha))/100 \times P\%$ if $I_P(t - s, n - t + s + 1) \leq \alpha$. The Wilks method involves selecting the smallest sample size n for which the relevant condition involving the beta cumulative distribution function is satisfied, thus guaranteeing the corresponding tolerance bound/interval is $(100 \times (1 - \alpha))/100 \times P\%$. This method is nonparametric because no knowledge of $g(\cdot)$ is required other than its existence. This is advantageous in the many applications for which $g(\cdot)$ is unknown, although this approach can be highly inefficient for known $g(\cdot)$.

Often, the Wilks method is applied to a symmetric interval, obtained by taking $s = r$ for r a positive integer, and $t = n - r + 1$. Therefore, the upper one-sided tolerance bound $(-\infty, Y_{(n-r+1)})$, or the lower one-sided tolerance bound $(Y_{(r)}, \infty)$, are $(100 \times (1 - \alpha))/100 \times P\%$ by selecting the smallest n satisfying

$$I_{1-P}(r, n - r + 1) \geq 1 - \alpha.$$

Table 48.9 Minimum sample size n required for 95%/95% Wilks tolerance bounds/intervals

Tolerance bound		Tolerance interval	
r	n	r	n
1	59	1	93
2	93	2	153
3	124	3	208
4	153	4	260
5	181	5	311
6	208	6	361
7	234	7	410
8	260	8	458
9	286	9	506
10	311	10	554

For $r = 1$, this condition is equivalent to selecting the smallest n satisfying $P^n \leq \alpha$. The tolerance interval $(Y_{(r)}, Y_{(n-r+1)})$ is $(100 \times (1 - \alpha)\%) / (100 \times P\%)$ by selecting the smallest n satisfying

$$I_P(n - 2r + 1, 2r) \leq \alpha.$$

Table 48.9 provides the minimum sample sizes n required to obtain 95%/95% Wilks tolerance bounds/intervals for $r \in \{1, 2, \dots, 10\}$, calculated from the recipe of the previous paragraph. Note that increasing r corresponds to using more centrally located order statistics to define the tolerance bounds/intervals. It is seen that larger sample sizes n are required to guarantee that tolerance bounds/intervals using increasingly centralized order statistics will achieve the required 95% coverage of the distribution $G(\cdot)$ at the 95% confidence level.

B.2 PIRT

This simulation models a single assembly in a nuclear reactor with neutronic, thermal hydraulic, and a fuel model.

B.2.1 The Basic Physics

1. Compute a neutron flux that produces energy from fission (deposited in the fuel and the coolant).
2. Conduct the energy in the fuel radially out from the center, across the gap, and through the clad.
3. Remove the heat from the clad to the coolant and advect it out of the core.

B.2.2 Quantity of Interest

1. Reactivity (eigenvalue)
2. 3D pin power distribution
3. 3D fuel temperature

B.2.3 Phenomena

Phenomena are listed for each of the three physics areas. Phenomena will be ranked as an ordered pair (importance, knowledge) immediately after each phenomenon number.

Thermal Hydraulics

Here the fluid flow over the fueled portion of the pin is considered:

1. (H,M) Subcooled boiling (minimal effect due to void, possible effect due to improved heat transfer, but subcooled boiling occurs where the power is low).
2. (M,H) Water density (10% change over core, uncertainty in steam table ASME 1967 vs. ASME 1998).
3. (H,H) Single-phase heat transfer (Dittus-Boelter affects fuel temperature).
4. (L,M) Gamma heating (2% of total power directly into the coolant).
5. (L,L) Dimensional changes due to thermal expansion (may be smaller than other uncertainties in thermal hydraulics).
6. (M,M) Inlet mass flow rate (no feedback from loop so pressure drops sum to zero).
7. (M,M) Inlet temperature (no feedback from loop so changes in temperature sum to zero).
8. (M,H) Wall friction.
9. (H,H) Since the figure of merit is reactivity, power can be fixed for an eigenvalue search (cannot fix eigenvalue = fix reactivity and do a power search). Until transient capability is available, eigenvalue is the only logical search variable.
10. (H,L) Cross-flow models (important near guide tubes).
11. (H,M) Spacer grid model:
 - (a) (H,M) Loss coefficient is steady state.
 - (b) (M,M) Mixing term.
 - (c) (M,M) Enhanced heat transfer.

Fuel Model

Here the pellet, the gap, and the clad are considered. Energy is transferred from the fuel across the gap to the clad. The fuel model in CTF is currently being employed; later this will be replaced by Bison-CASL. Note that only fresh fuel is being considered so there are no burnup effects:

1. (M,M) Density of the fuel pellet
2. (M,M) Thermal conductivity of the fuel pellet
3. (M,M) Heat capacity of the fuel pellet
4. (H,M) Gap conduction model (pure He filled)
5. (L,L) Dimensional changes due to thermal expansion
6. (H,H) Clad density
7. (H,H) Clad thermal conductivity
8. (H,H) Clad heat capacity

9. (M,L) Model error due to assumptions in channel code
10. (H,H) Heat addition from neutronics
11. (H,H) Heat removal from thermal hydraulics

Neutronics

The challenge here is figuring out what to do with the large number of cross sections, which include fission, absorption, and scattering. The following list of materials pertain to this application:

1. U235
2. U238
3. U234
4. U236
5. Inconel
6. Zirconium
7. Oxygen
8. Hydrogen
9. Helium
10. Boron
11. Steel (nozzles and core plates)

There are 23 energy groups in the SPn calculation and 252 energy groups in the pin cell computations. It is important to note that the neutronic domain is larger than the thermal hydraulic domain. SCALE may provide uncertainty quantification information. It is necessary to conduct a literature search to look for cross-sectional prioritization work. The important phenomena for the QoIs (eigenvalue and 3D pin power directly or 3D fuel temperature is coupled through 3D power and cross-sectional feedback) are:

1. (H,H) Neutron fission (nuclear data would be the main component of this).
2. (H,H) Neutron/gamma absorption.
3. (H,H) Neutron/gamma scattering.
4. (H,H) Neutrons released per fission.
5. (M,H) Other neutron reactions ($n,2n$), ($n,3n$).
6. (H,H) Energy released per fission.
7. (L,H) Energy released per capture.
8. (L,M) Gamma energy deposition (in fuel, clad, and moderator).
9. (H,M) Boron density in the coolant.
10. (H,H) Moderator density.
11. (M,H) Moderator temperature.
12. (H,H) Fuel temperature (Doppler feedback).
13. (L,H) Clad temperature.
14. (M,M) Fuel density.
15. (L,L) Manufacturing uncertainties (mass and dimensions in fuel/clad/grids/structure).

16. (M,M) Neutron/gamma transport (includes things like SPn order, number of groups, homogenization, etc.).
17. (L,M) Bowing (only effects of thermal expansion since depletion is not included).
18. (L,M) Thermal expansion.
19. (L,L) What are the neutronic effects of layer of bubbles on fuel rod surface?

**Introduction to Software for Uncertainty
Quantification**

Dakota: Bridging Advanced Scalable Uncertainty Quantification Algorithms with Production Deployment

49

Laura P. Swiler, Michael S. Eldred, and Brian M. Adams

Abstract

This chapter highlights uncertainty quantification (UQ) methods in Sandia National Laboratories' Dakota software. The UQ methods primarily focus on forward propagation of uncertainty, but inverse propagation with Bayesian calibration is also discussed. The chapter begins with a brief Dakota history and mechanics of licensing, software and documentation acquisition, and getting started, including interfacing simulations to Dakota. Early sections are devoted to core sampling, stochastic expansion, reliability, and epistemic methods, while subsequent sections discuss more advanced capabilities such as mixed epistemic-aleatory UQ, multifidelity UQ, optimization under uncertainty, and Bayesian calibration. The chapter concludes with usage guidelines and a discussion of future directions.

Keywords

Dakota software • Open-source software • Black box • Parallel computing • Surrogate models • Sampling • Reliability • Polynomial chaos expansions • Stochastic collocation • Epistemic UQ • Interval estimation • Multifidelity • Stochastic design • Bayesian calibration • Adaptive methods • Sensitivity analysis • Optimization • Calibration • Importance sampling

1 Introduction

Sandia National Laboratories' Dakota software (available at <http://dakota.sandia.gov>) supports advanced exploration of computational models using a variety of algorithms, including uncertainty quantification methods. In general, Dakota manages and analyzes ensembles of simulations to provide broader and deeper perspective for analysts and decision makers. This enables them to enhance their understanding of risk, improve products, and assess simulation credibility. In its simplest mode, Dakota can automate parameter variation studies through a generic interface to a computational model. However, it also includes advanced parametric analysis techniques enabling global sensitivity analysis, design exploration, optimization, model calibration, risk analysis, and quantification of margins and uncertainty. These often support verification and validation activities. The Dakota project

includes significant algorithm research and development to make these analyses practical for complex science and engineering models.

1.1 History and Capabilities

Dakota was initiated as an internal R&D project at Sandia National Laboratories in 1994 and has continually evolved since then. Over 30 people, including external collaborators, have contributed over the years; see <http://dakota.sandia.gov/contributors.html>. Early development focused on design optimization, both unifying popular algorithmic approaches and developing new optimization methods to improve performance on computational engineering problems. This enabled designers to easily exercise parameter sweeps and various optimizers on a problem of interest.

Dakota grew to include many iterative analysis approaches which fit in the general workflow shown in Fig. 49.1, where Dakota iteratively executes a simulation code. Based on the characterization of input variables and method chosen, e.g., parameter study or uncertainty quantification, Dakota generates one or more parameter sets at which to evaluate the model. Here, each parameter set is a combination of simulation input values, also known as design points in optimization or sample points in UQ. For each parameter set, Dakota executes the computational simulation and any specified postprocessing and reads the resulting response metrics (derived quantities of interest). Dakota will repeat this process a number of times, depending on the method and the number of simulation evaluations it requires. Some methods, such as a design of experiments, may generate all the sample points in a single pass, while others such as optimization or adaptive UQ utilize feedback to generate new batches of parameter sets as they work to achieve their analysis goal. A key strength of the framework is the ability to easily switch among these different types of studies as a user explores different aspects of a computational model, from identifying influential parameters to calibrating them and from characterizing the effect of uncertainties to design optimization in their presence.

Over time, Dakota expanded to generate and perform these analyses on various types of multivariate surrogate models, e.g., polynomials, splines, neural networks, or Gaussian processes, to address computational cost and smoothness of parameter

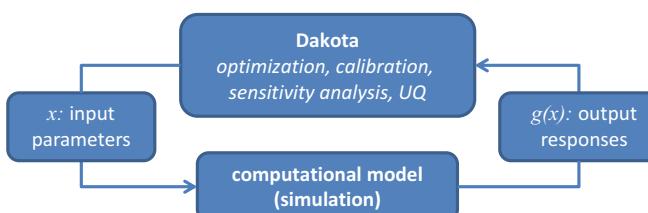

Fig. 49.1 Overall interaction between Dakota and a parameterized simulation

to response mappings. Uncertainty quantification methods evolved from Monte Carlo sampling through reliability and polynomial chaos to the plethora discussed in this chapter. Dakota can couple algorithms together in sequential or nested approaches, leading to such capabilities as hybrid optimization, surrogate-based optimization, optimization under uncertainty, reliability-based design optimization, and mixed epistemic-aleatory uncertainty analyses.

Throughout its existence, Dakota has supported parallel computing from the desktop to high-performance computers. It has an extensive set of multilevel parallel capabilities to handle parallel concurrency at the algorithm level and/or at the function evaluation level. These enable greater throughput of simulation runs in the course of iterative analyses.

A key goal of the Dakota project is to support development activities spanning from research to production, in support of Department of Energy (DOE) mission areas. The software is extensively used by analysts solving practical science and engineering optimization, sensitivity analysis, and uncertainty problems. These production users most commonly use well-established, tested methods such as gradient-based optimization or Monte Carlo sampling. However the development team strives to routinely deploy leading-edge research capabilities to address challenges analyzing expensive simulation codes. For example, recent work has focused on adaptive sparse grid methods to generate sample points for stochastic expansions such as in polynomial chaos and compressive sensing to optimally select bases used in such expansions. These methods help reduce the number of expensive simulations required to obtain a certain level of accuracy in an uncertainty estimate, for example, the estimate of the mean or 95th percentile of a stochastic response quantity.

1.2 Obtaining the Software

Dakota is open source and distributed under the GNU Lesser General Public License (LGPL): <http://dakota.sandia.gov/license.html>. The core source code is written in C++. Dakota distributions include required third-party libraries, written in C, C++, Fortran 77, and Fortran 90, with their own LGPL-compatible licenses. Given Dakota's research to development spectrum, release notes on the webpage indicate which capabilities are more recent and whether they are in a prototype stage.

More than 13,000 users worldwide have downloaded Dakota, and it has hundreds of users within the Department of Energy laboratory complex. It is supported on numerous Linux, Mac, and Windows operating system variants, including high-performance computing platforms. Software downloads (source and binary), system requirements, and installation information are available at <http://dakota.sandia.gov/download.html>. When feasible, users should download binary packages of Dakota. However, the website includes information on satisfying system prerequisites including compilers, MPI, Boost, and linear algebra libraries and compiling the source code with CMake.

1.3 Getting Started Resources

Extensive Dakota documentation is available at <http://dakota.sandia.gov/documentation.html>, including the following four primary manuals:

- **Users:** The Users Manual [1] addresses the various Dakota method categories such as parameter studies, design of experiments, optimization, and nonlinear least squares. Chapter 5 (Uncertainty Quantification Capabilities) addresses uncertainty quantification. This manual also covers surrogate and other types of models, how to define input variables and output responses, creating an interface between Dakota and the simulation code, and parallelism options.
- **Reference:** The Reference Manual [2] describes all valid keywords available to specify a Dakota study. For example, when using a genetic algorithm for optimization, one needs to define the population size, the mutation rate, the crossover rate, etc. This manual details the keywords and associated arguments that qualify them.
- **Theory:** The Theory Manual [3] supplements the Users Manual with advanced topics and more theoretical depth. For example, it covers surrogate-based optimization and optimization under uncertainty. In terms of uncertainty quantification, the Theory Manual has comprehensive descriptions of reliability methods, stochastic expansion methods, and evidence theory.
- **Developers:** The Developers Manual describes Dakota’s architecture, interfaces, development practices, and C++ class details.

To get started with Dakota, we recommend downloading and installing Dakota, reading Chapters 1 (Introduction) and 2 (Tutorial) of the Users Manual, and trying some of the examples (see the QuickStart page: <http://dakota.sandia.gov/quickstart.html>). The tutorial demonstrates Dakota use for a few simple studies, including a parameter study, an optimization study, and a Monte Carlo sampling study. After working through it, users will understand how to run Dakota, what inputs it expects, and what outputs it will produce.

The manuals are supplemented by examples included in the Dakota distribution in `examples/` and training materials from previous training sessions available at <http://dakota.sandia.gov/training/>. Dakota-related publications at <http://dakota.sandia.gov/publications.html> offer more in-depth discussion of many of the algorithmic approaches in Dakota.

1.4 Interfacing to Dakota

Dakota generally views the simulation model that it is interfaced to as a “black box.” In this mode, Dakota need not know details about nor have access to its internal state. Rather, when using the simulation in an optimization or uncertainty study, Dakota must be able to send input parameter values at which it would like

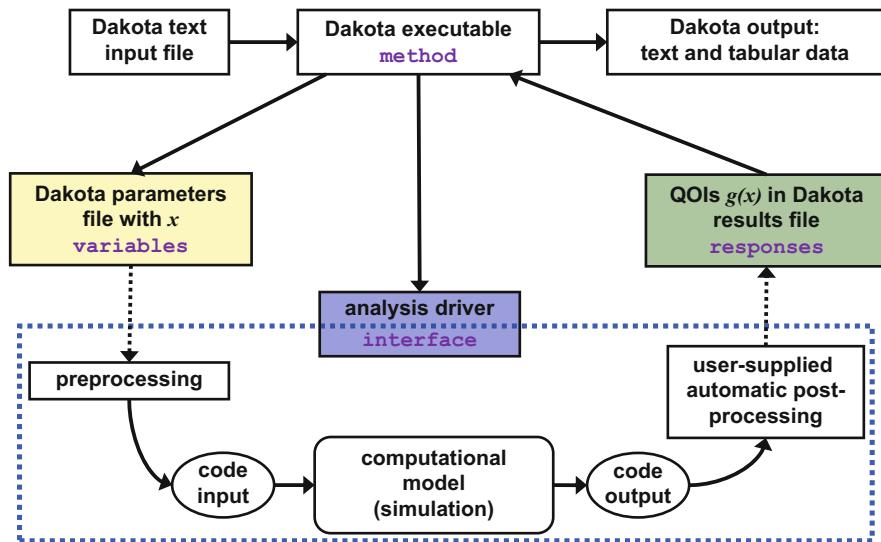

Fig. 49.2 Details of Dakota execution and information flow, including user-provided analysis driver

output responses, reliably execute the simulation in a non-interactive manner, and obtain the response data after the simulation has executed. While Dakota can be integrated into applications as a C++ library, it is most commonly used as separate executable, with an “analysis driver” script that manages the simulation workflow for each variable to response mapping. Dakota documentation and distributions include many examples of interfacing to simulations in this loosely coupled manner.

Figure 49.2 details an example of this information flow during Dakota execution. Dakota is invoked with a text-based input file, by running the command `dakota -i inputfile.in`, where `inputfile.in` is a text input file which can have any name. The input file tells Dakota what type of method will be executed and describes the variables, the responses, and the interface. Dakota then runs the user-specified method. For each model evaluation, Dakota generates a file containing parameter values and runs the analysis driver specified in the interface section of the input file. The analysis driver typically is a script that the user provides: it may be written in shell script, Python, Perl, or another language of the user’s choice. It can also be a program, such as a C++ executable program.

The analysis driver is required to accept a Dakota parameter file and preprocess as necessary to generate the proper parameterized input for the simulation code. Typically, this involves substituting the Dakota parameters into the simulation input file, which Dakota’s “dprepro” Perl-based preprocessor can help with. Once the simulation input is prepared for this sample point, the script runs the simulation and extracts the results of interest from the code output to send back to Dakota. This may be done by simple Unix commands such as searching and cutting particular

fields from an output file, or it may involve more significant manipulation of a binary output file. The script returns the responses to Dakota, and then Dakota starts another iteration of the simulation based on the method. At the end of all of the simulation evaluations, Dakota outputs the results both in text form and in a tabular data file.

Figure 49.3 provides an example of a basic Dakota input file. This example demonstrates an input file for sampling-based UQ. The method section indicates that the method is `sampling`, of type `lhs`, for Latin hypercube sampling (as opposed to pure Monte Carlo or importance sampling), and there will be 10 samples with a seed of 98765. The keyword `response_levels` indicates that Dakota should compute the cumulative distribution function (CDF) value at the specified response levels 0.1, 0.2, and 0.6, i.e., the probability that the simulation response is less than each of these values. Dakota will calculate sample statistics based on the ten samples; external postprocessing is not necessary.

In the variables section, there are two input variables x_1 and x_2 , characterized as uniformly distributed on the interval $[0, 1]$. The interface for this example is implemented in an analysis driver called “`text_book`,” an executable included with

Dakota that calculates the value of three algebraic “textbook” response_functions, polynomials that are a function of the input parameters x_1 and x_2 . Since this is a simple sampling study, gradients and Hessian information are not returned from the simulation to Dakota. The environment block at the top specifies output generation. For example, in this input file, the samples and the results are written to a tabular file called `textbook_uq_sampling.dat`. Another Dakota input block `model` is not shown in this example, implying the default single model. Models can be used for more complex variable to response mappings, including surrogate or nested models.

1.5 Characterizing Uncertain Variables

With the exception of deterministic moment matching and Bayesian calibration, which can characterize input variable uncertainty from data, Dakota largely focuses on forward uncertainty propagation. In doing so, it supports a number of characterizations of the uncertain input variables x .

Aleatory uncertain variable types include 11 standard distribution types: normal, log-normal, uniform, log-uniform, triangular, exponential, beta, gamma, Gumbel, Frechet, and Weibull, as well as an empirical continuous bin-based histogram. Five standard discrete distribution types are included: Poisson, binomial, negative binomial, geometric, and hypergeometric, as well as a point-wise histogram type supporting discrete integer-, string-, or real-valued variables. Correlations among these variable types can be specified as well. To characterize epistemic uncertainty, Dakota supports continuous and discrete interval types (e.g., to use in Dempster-Shafer theory of evidence approaches), as well as discrete sets of integer, string, and real values.

These various variable types will be used in subsequent sections which discuss the various Dakota uncertainty quantification methods.

2 Sampling Methods

A common method of propagating uncertainty through computational simulations is to assume particular distributions on the uncertain input variables, randomly sample from those distributions, run the model for each of the sampled inputs, and then assemble the set of output results to build up a distribution of the output values. This is Monte Carlo (MC) propagation of uncertainty. The output values can be analyzed to determine characteristics of the response, e.g., the maximum and minimum response values, the mean and the variance of the response, the probability of exceeding response thresholds, etc. For example, pure MC methods use a random number generator to draw samples from the specified distributions. The samples are unstructured; each “random draw” yields a realization unaware of its relation to samples drawn before or after it. Pure MC sampling produces unbiased estimates for the means, variances, and percentiles of the outputs.

In general, an advantage of random sampling is that the accuracy and computational burden is independent of the number of uncertain parameters, in contrast to many other methods in Dakota. It may be preferred when a sufficiently large number of samples are affordable. A disadvantage is that a large number of samples are required to accurately estimate the output statistics. The accuracy of the mean estimate obtained from a set of random samples exhibits $1/\sqrt{N}$ convergence, meaning that on average one needs to quadruple the number of sample points N to halve the error. To resolve small probabilities regarding predicted responses, hundreds of thousands of sample points may be required to obtain the desired accuracy.

A good alternative to pure random sampling is Latin hypercube sampling (LHS) [25, 34]. LHS is a stratified random sampling method where the distribution of each variable is divided into strata or bins. Each stratum is chosen to be equally probable, so that the strata are of equal length for uniform distributions but of unequal length for normal distributions (shorter strata near the center; longer strata near the tails). To create a total sample of size N using LHS, an individual sample value is chosen from each of the N equally probable strata for each input variable. This stratification approach forces better sampling across the entirety of each distribution, reducing clustering often seen in pure random sampling.

For multidimensional sampling, LHS also achieves good mixing of sample values from different input variables. For example, one would not want the sample in strata 1 from input A to be paired with the sample in strata 1 from input B. Instead, the pairing of the strata is performed in such a way [19] to generate multidimensional samples that are “well mixed” or randomized. These pairing algorithms allow the generation of independent inputs, but can also generate samples which honor a user-specified correlation structure. For example, one might want input C to have a correlation coefficient of 0.8 with input D.

Finally, LHS is more efficient than pure Monte Carlo; it requires fewer samples to achieve the same accuracy in statistics (e.g., standard error of the computed mean). LHS gives an estimator for a function mean that has lower variance than MC for any function having finite second moment [28, 31]. Further, the convergence behavior of LHS improves if the function is additively separable, meaning it can be decomposed into additive functions of the individual input parameters.

Dakota sampling techniques are selected using the `sampling` method selection. Currently, both traditional Monte Carlo (MC) and Latin hypercube sampling (LHS) are supported by specifying `sample_type` as `random` or `lhs`, respectively. The sampling method generates sets of samples according to the probability distributions of the uncertain variables and maps them into corresponding sets of response functions, where the number of samples is specified by the `samples` integer specification. The response function means, standard deviations, skewness, and kurtosis values are computed. The probability that a response is less than or greater than a particular value (cumulative distribution function, CDF or complementary cumulative distribution function, CCDF) may be computed for `response_levels` specifications. Similarly, the response levels may be computed by specifying either `probability_levels` or `reliability_levels`. The Dakota Reference Manual contains more information about the specification of these keywords.

Dakota's sampling implementation (MC and LHS) supports the full range of continuous and discrete distributions mentioned in the introduction. In addition, LHS accounts for correlations among the variables, which can be used to accommodate a user-supplied correlation matrix or to minimize correlation when a correlation matrix is not supplied.

2.1 Latin Hypercube Sampling Example

The input file previously shown in Fig. 49.3 demonstrates the use of Latin hypercube Monte Carlo sampling for assessing probability of failure as measured by specified response levels. The textbook example problem has two uniform variables on $[0, 1]$. The number of samples to perform is controlled with the `samples` specification, the type of sampling algorithm to use is controlled with the `sample_type` specification, the levels used for computing statistics on the response functions are specified with the `response_levels` input, and the `seed` specification controls the sequence of the pseudorandom numbers used by the sampling algorithms.

The response function statistics generated by Dakota when running this input file are shown in Fig. 49.4. The first two blocks of output specify the response sample moments and the confidence intervals for the mean and standard deviation.

Statistics based on 10 samples:

```

Fig. 49.4 Dakota response function statistics from UQ sampling example

The last section of the output defines CDF pairs (distribution cumulative was specified) for the response functions by presenting the probability levels corresponding to the specified response levels (response_levels were set and the default compute probabilities was used). Alternatively, Dakota could have provided CCDF pairings, reliability levels corresponding to prescribed response levels, or response levels corresponding to prescribed probability or reliability levels.

In addition to obtaining statistical summary information of the type shown in Fig. 49.4, the results of LHS sampling also include correlations. These can be helpful in understanding the influence of parameters on responses for ranking or screening. Four types of correlations are output: simple and partial “raw” correlations and simple and partial “rank” correlations. Raw correlations refer to correlations performed on the values of the input and output data. Rank correlations are instead computed on the ranks of the data. Ranks are obtained by replacing the data by their ranked (ascending) values. The simple correlation is calculated as Pearson’s correlation coefficient.

Figure 49.5 shows an example of the correlation output provided by Dakota for the input file in Fig. 49.3. Note that the simple correlations among the inputs are nearly zero. This is due to the default “restricted pairing” method in the LHS routine which forces near-zero correlation among uncorrelated inputs. In this particular example, the first response function is strongly negatively correlated with both input variables, meaning that the function decreases as the input values increase from lower to upper bounds. In contrast, the second response function is positively correlated with the first variable.

```

Fig. 49.5 Correlation results using LHS sampling

2.2 Importance Sampling

Importance sampling preferentially samples important regions in the parameter domain, e.g., in or near a failure region or other user-defined region of interest, and then appropriately weights the samples to obtain an unbiased estimate of the failure probability [30]. In this approach, samples are generated from an “importance density,” which differs from the original probability density of the input variables. To be accurate, the importance density should be centered near the region of interest. For black-box simulations such as those commonly interfaced with Dakota, it is difficult to specify the importance density *a priori*; the user often does not know where the failure region lies, especially in a high-dimensional space [33].

One Dakota importance sampling method is based on ideas from reliability modeling. An initial Latin hypercube sample is generated and evaluated. The initial samples are augmented with samples from an importance density as follows. The variables are transformed to standard normal space. In the transformed space, the importance density is a set of normal densities centered around points which are in the failure region. This is similar in spirit to reliability methods (discussed later), in which importance sampling is centered around a most probable point (MPP).

This method is specified with the keyword `importance_sampling` with options as follows. The keyword `import` centers a sampling density at one of the initial LHS samples identified in the failure region. It then generates the importance samples, weights them by their probability of occurrence given the original density, and calculates the required probability. The `adapt_import` option is similar, but is performed iteratively (adapts) until the failure probability estimate converges. Finally, `mm_adapt_import` takes all of the failure region samples to build a multimodal sampling density. First, it uses a small number of samples around each of the initial samples in the failure region. These samples are allocated to the different points based on their relative probabilities of occurrence: more probable points get more samples. This early part of the approach is done to search for “representative” points. Once these are located, the multimodal sampling density is set and the multimodal sampling proceeds until convergence.

3 Stochastic Expansion Methods

Stochastic expansion UQ methods approximate the functional dependence of the simulation response on uncertain model parameters by expansion in a polynomial basis. The polynomials used are tailored to the characterization of the uncertain variables. Dakota includes two stochastic expansion methods: polynomial chaos expansion (PCE) and stochastic collocation (SC). Polynomial chaos expansion is based on a multidimensional orthogonal polynomial approximation, while stochastic collocation is based on a multidimensional interpolation polynomial approximation, both formed in terms of standardized random variables. A distinguishing feature of these two expansion methods is that the final solution is expressed as a functional mapping, not merely as a set of statistics, as in many nondeterministic

methodologies. This makes expansion techniques particularly attractive in multi-physics applications.

One advantage of PCE methods is their convergence rate. For smooth functions (i.e., analytic, infinitely differentiable) in ℓ_2 (i.e., possessing finite variance), exponential convergence rates can be obtained under order refinement for integrated statistical quantities of interest such as mean, variance, and probability. Another advantage of stochastic expansion methods is that the moments of the expansion (e.g., mean or variance of the response) can be written analytically, along with analytic formulations of the derivatives of these moments with respect to the uncertain variables. This property can be exploited in design optimization under uncertainty or epistemic uncertainty problems [11]. A disadvantage of polynomial chaos, as for all global approximation-based methods, is that they may not scale well to high dimensions. Recent research in adaptive refinement and sparse recovery methods strives to address this limitation.

Variance-based decomposition, which explains how output variance relates to the variance of each input variable, may also be calculated analytically from a stochastic expansion. This is a powerful capability for global sensitivity analysis, where influential input parameters can be identified and rank ordered. In particular, Dakota can generate Sobol' indices for main, interaction, and total effects. A larger value of the sensitivity index, S_i , means that the uncertainty in the input variable i has a larger effect on the variance of the output. Analytic dependence on expansion coefficients makes computing Sobol' indices essentially free. In contrast, estimating Sobol' indices with LHS can be extremely expensive, since repeat multidimensional integrations must be performed.

Stochastic expansion methods also support automated refinement using uniform or adaptive approaches. Adaptive approaches currently include dimension-adaptive refinement or generalized sparse grid refinement. In the former, anisotropic dimension weightings for tensor or sparse grids are updated based on either the total Sobol' indices or the spectral coefficient decay rates computed for the current iteration. For generalized sparse grid refinement, a greedy approach is used in which candidate index sets are evaluated for their impact on the statistical quantities of interest (QoI), the most influential sets are selected and used to generate additional candidates, and the index set frontier of a sparse grid is evolved in an unstructured and goal-oriented manner. Since this approach evaluates fine-grained effects from individual index sets, precision in QoI increments (e.g., from hierarchical interpolation) becomes increasingly important.

3.1 Polynomial Chaos Expansion

In PCE, the output response is modeled as a function of the input random variables using a carefully chosen set of polynomials. For example, PCE employs Hermite polynomials to model Gaussian random variables, as originally employed by Wiener [39]. Dakota implements the generalized PCE approach using the Wiener-Askey scheme [40], in which Hermite, Legendre, Laguerre, Jacobi, and generalized

Laguerre orthogonal polynomials are used for modeling the effect of continuous random variables described by normal, uniform, exponential, beta, and gamma probability distributions, respectively. These orthogonal polynomial selections are optimal for these distribution types since the inner product weighting function corresponds to the probability density functions for these continuous distributions.

Dakota allows the selection of three types of basis functions for PCE: Wiener, Askey, and Extended. The Wiener option uses a Hermite orthogonal polynomial basis for all random variables. It employs the Nataf variable transformation to transform non-normal, correlated distributions to normal, independent distributions. The Askey option, however, employs an extended basis of Hermite, Legendre, Laguerre, Jacobi, and generalized Laguerre orthogonal polynomials. The Extended option avoids the use of any nonlinear variable transformations by augmenting the Askey approach with numerically generated orthogonal polynomials for non-Askey probability density functions (e.g., bounded normal, Weibull, histogram, etc.).

To propagate input uncertainty through a model using PCE, Dakota performs the following steps: (1) input uncertainties are transformed to a set of uncorrelated random variables, (2) a basis such as Hermite polynomials is selected, and (3) the parameters of the functional approximation are determined. The general polynomial chaos expansion for a response g has the form

$$g(\mathbf{x}) \approx \sum_{j=0}^P \alpha_j \Psi_j(\mathbf{x}) \quad (49.1)$$

where each multivariate basis polynomial $\Psi_j(\mathbf{x})$ involves products of univariate polynomials that are tailored to the individual random variables. If a total-order polynomial basis is used (e.g., a total order of 2 would involve terms whose exponents are less than or equal to 2, such as x_1^2 , x_2^2 , and x_1x_2 but not $x_1^2x_2^2$), the total number of terms N in a polynomial chaos expansion of arbitrary order p for a response function involving n uncertain input variables is given by $(n + p)!/n!p!$. If on the other hand, an isotropic tensor product expansion is used with order p in each dimension, the number of terms is $(p + 1)^n$. If the order p of the expansion captures the behavior of the true function, polynomial chaos methods will give very accurate results for the output statistics of the response.

In nonintrusive PCE, as in Dakota, simulations are used as black boxes and the calculation of the expansion coefficients α_j for response metrics of interest is based on a set of simulation response evaluations. To calculate these response PCE coefficients, two primary classes of approaches are used: spectral projection and regression. The spectral projection approach projects the response against each basis function $\Psi_j(\mathbf{x})$ using inner products and employs the polynomial orthogonality properties to extract each coefficient. Each inner product involves a multidimensional integral over the support range of the weighting function, which can be evaluated numerically using sampling, tensor product quadrature, Smolyak sparse grid [29], or cubature [32] approaches. The regression approach finds a set of PCE coefficients α_j which best match a set of response values obtained from either

a design of computer experiments (“point collocation” [38]) or from subsampling a set of tensor Gauss points (“probabilistic collocation” [36]). Various methods can be used to solve the resulting linear system, including least squares methods for overdetermined systems and compressed sensing methods for under-determined systems. Details of these methods are documented in the Linear Regression section of the Dakota Theory Manual [3].

3.2 Stochastic Collocation

Stochastic collocation (SC) is closely related to PCE, but replaces projection or regression of spectral coefficients with interpolation. An SC interpolant takes the form

$$g(\mathbf{x}) \approx \sum_{j=1}^{N_p} r_j L_j(x) \quad (49.2)$$

where N_p is the number of unique collocation points in the multidimensional grid and r_j is the response at those points. Since the expansion coefficients are just the response values at the sampled points, the core of the method is formation of the multidimensional interpolation polynomials used as the basis. This basis can be formulated to be nodal or hierarchical and either value based (Lagrange interpolation polynomials) or gradient enhanced (Hermite interpolation polynomials). Point sets are generally defined using either tensor or sparse grid constructions, where the latter lead to sparse interpolants formed from linear combinations of low-order tensor interpolants. Relative to PCE, SC can be a good selection when either local error estimates (formed from hierarchical surpluses) or explicit interpolation of derivatives (using Hermite interpolants) is important.

3.3 PCE Example

In the simplest case, if one wants to use a polynomial chaos expansion in Dakota with isotropic tensor product expansion and five quadrature points for each input variable, the method section of the Dakota input would look like the following:

```
method
  polynomial_chaos
  quadrature_order = 5
```

If there were two variables, this would involve $5 \times 5 = 25$ function evaluations. If instead, one wanted to use a sparse grid at level 1, the method section of the Dakota input would look like the following:

```
method
  polynomial_chaos
  sparse_grid_level = 1
```

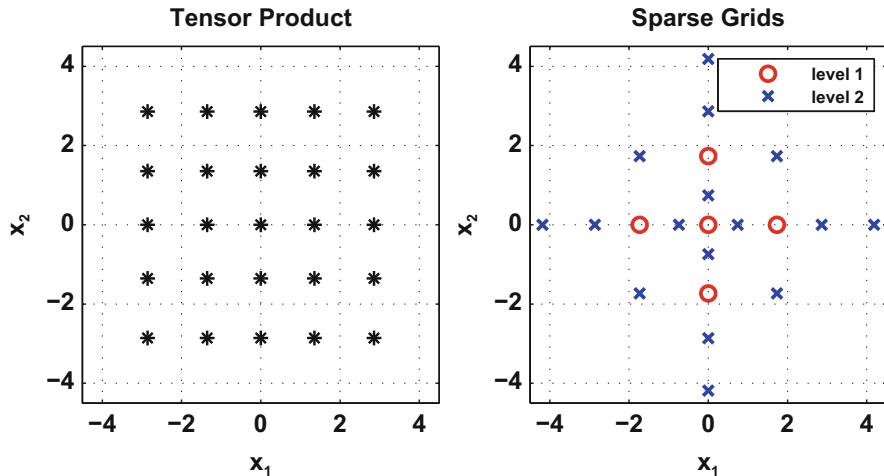

Fig. 49.6 Comparison of tensor product (*left*) and sparse grids (*right*) used in Dakota PCE construction

Figure 49.6 contrasts the resulting sample designs for two standard normal variables. The full tensor grid with quadrature order 5 is shown on the left. On the right, the level 1 sparse grid requires evaluation of the center point and three-point quadrature rules for each variable ($2n + 1$ total points for symmetric weakly-nested rules). The level 2 sparse grid requires 21 points, including those in the level 1 sparse grid due to the default use of nested rules (Genz-Keister for Hermite). The sparse grid points have a bigger range than the quadrature points in this particular example.

Using a PCE method in Dakota results in the moments of each response function, the covariance matrix for the response functions, and the local and global sensitivities, as shown in Fig. 49.7. The local sensitivities of each response function are calculated as the derivative of the response function evaluated at the means of the uncertain variables. The global sensitivities are calculated by variance-based decomposition, and the main, interaction, and total effects are reported. In this particular example, the responses are separable in the two inputs, so the interaction sensitivities are negligible. As with sampling, one may also request information about the probability density of the response functions in terms of histogram information and about the CDF values. This is shown in Fig. 49.8.

Dakota's stochastic expansions support many options. In lieu of listing them here, the reader is encouraged to explore the Dakota Reference Manual [2]. Table 49.1 summarizes key Dakota PCE features; similar options are available for SC.

4 Reliability Methods

Reliability UQ methods are a popular probabilistic approach which can be less computationally demanding than sampling, particularly when quantifying uncertainties with respect to a particular response or probability level. The prototypical

Fig. 49.7 Statistical output generated from a polynomial chaos expansion in Dakota

application of reliability methods is to estimate failure probabilities, i.e., the probability that an output response exceeds or falls below a threshold value. These approaches preferentially evaluate points around the area of interest, namely, the failure region, and may use successive approximations to refine failure estimates. Reliability methods can generally be used to compute response mean, response standard deviation, and CDF/CCDF values; however, their strength is they can be more efficient than Monte Carlo sampling when computing statistics in the tails of the response distributions (low probability events). The interested reader is encouraged to start with [15] for an excellent overview of local reliability methods.

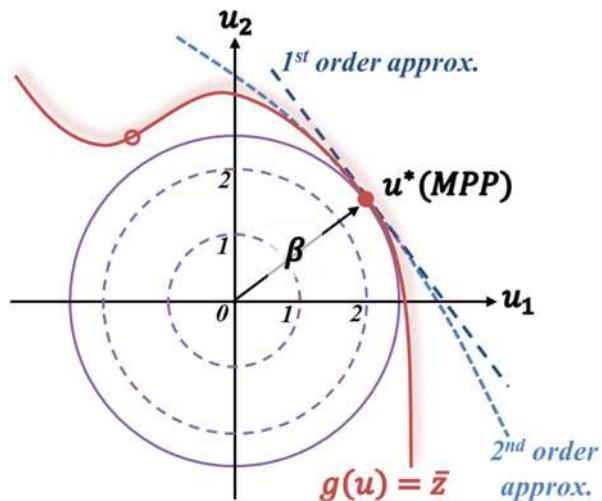

Fig. 49.8 PDF and CDF information from results of a polynomial chaos expansion in Dakota

Table 49.1 Major options available in Dakota's PCE capability

Capability	Option
Orthogonal polynomial basis	Askey, Wiener, or extended
Spectral projection approach to estimate PCE coefficients	Sampling, tensor product quadrature, Smolyak sparse grid, or cubature
Regression approach to estimate PCE coefficients	Least squares, basis pursuit, basis pursuit denoising, orthogonal matching pursuit (OMP), least absolute shrinkage (LASSO), least angle regression (LARS), and orthogonal least interpolation
Automated refinement	Uniform, anisotropic dimension adaptivity (Sobol, decay), or generalized sparse grid
Variance-based decomposition	Limit reported indices using interaction order and drop tolerance

More specifically, reliability methods address the fundamental question: “Given a set of uncertain input variables x with a probability density $\rho(x)$, and a scalar response function, $g(x)$, what is the probability that the response function is below (or above) a certain level, \bar{z} ? ” The former can be written as $P[g(x) \leq \bar{z}] = F_g(\bar{z})$ where $F_g(\bar{z})$ is the cumulative distribution function (CDF) of the uncertain response $g(x)$, evaluated at the target response level. The latter can be written as $P[g(x) > \bar{z}]$ and defines the complementary cumulative distribution function (CCDF). This is depicted in Fig. 49.9, where a contour of the response function corresponding to

Fig. 49.9 Reliability methods: failure boundary $g(u) = \bar{z}$ in uncorrelated standard normal probability space, with most probable point of failure indicated

the level of interest \bar{z} is shown in solid red. The probability calculation involves a probability-weighted multidimensional integral of the implicit simulation mapping $g(x)$ over the failure domain, for example, outside the red curve, as indicated by the shading.

Figure 49.9 depicts a standard normal probability space u , in which probability calculations can be more tractable. In Dakota, the Nataf transformation [24] can be used to automatically map the user-specified uncertain variables, x , with probability density function, $\rho(x_1, x_2)$, which can be nonnormal and correlated, to a space of independent Gaussian random variables, (u_1, u_2) , each with mean zero and unit variance. In this transformed space, probability contours are circular, instead of the rotated hyper-ellipses of correlated variables, or arbitrary level curves of a general joint probability density function.

In u -space, the multidimensional integrals that define the failure probability can be approximated by simple functions of a single parameter, β , called the reliability index. β is the minimum Euclidean distance from the origin in the transformed space to the failure boundary, also known as the limit state surface. This closest point is known as the most probable point (MPP) of failure. This nomenclature is due to the origin of these methods within the disciplines of structural safety and reliability; however, the methodology is equally applicable for computation of probabilities unrelated to failure.

Within the class of reliability methods, there are local and global algorithms. The most well-known are local methods, which locate a single MPP using a local, often gradient-based, optimization search method and then utilize an approximation centered around this point (see the notional linear and quadratic approximations in Fig. 49.9). In contrast, global methods generate approximations over the full random variable space and can find multiple MPPs if they exist, for example, the second most likely point, shown as an open red circle in Fig. 49.9. In both cases, a primary

strength of the methods lies in the fact that the computational expense is generally unrelated to the probability level; the cost of evaluating a probability in the far tails is no more than that of evaluating near the means.

4.1 Local Reliability Methods

The Dakota Theory Manual [3] provides the algorithmic details for the local reliability methods as well as references to related research activities. Local methods include first- and second-order versions of the mean value method (MVFOSM and MVSOSM) and a variety of most probable point (MPP) search methods, including the advanced mean value method (AMV and AMV²), the iterated advanced mean value method (AMV+ and AMV²+), the two-point adaptive nonlinearity approximation method (TANA-3), and the traditional first-order and second-order reliability methods (FORM and SORM) [15]. The MPP search methods may be used in forward (reliability index approach (RIA)) or inverse (performance measure approach (PMA)) modes, as dictated by the type of level mappings. Each of the MPP search techniques solve local optimization problems in order to locate the MPP, which is then used as the point about which approximate probabilities are integrated (using first- or second-order integrations in combination with refinements based on importance sampling).

Given variants of limit state approximation, approximation order, integration approach, and MPP search type, the number of algorithmic combinations is significant. Table 49.2 provides a succinct mapping for some of these combinations to common method names from the reliability literature.

4.2 Global Reliability Methods

Global reliability methods are designed to handle nonsmooth, multimodal, and highly nonlinear failure surfaces by creating global approximations and adaptively refining them in the vicinity of a particular response threshold. Three variants are available: EGRA, GPAIS, and POFDarts.

Table 49.2 Mapping from Dakota options to standard reliability methods

MPP search	Order of approximation and integration	
	First order	Second order
None	MVFOSM	MVSOSM

u_taylor_mpp	u-space AMV+	u-space AMV ² +
x_two_point	TANA	
u_two_point	u-space TANA	
no_approx	FORM	SORM

4.2.1 EGRA

As the name implies, efficient global reliability analysis (EGRA) [6] has its roots in efficient global optimization (EGO) [18, 21]. The main idea in EGO-type optimization methods is that a global approximation is made of the underlying function. This Gaussian process model approximation is used to guide the search by finding points which maximize the expected improvement function (EIF). The EIF is used to select the location at which a new training point should be added to the Gaussian process model by maximizing the amount of improvement in the objective function that can be expected by adding that point. A point could be expected to produce an improvement in the objective function if its predicted value is better than the current best solution, or if the uncertainty in its prediction is such that the probability of it producing a better solution is high. Because the uncertainty is higher in regions of the design space with fewer observations, this provides a balance between exploiting areas of the design space that predict good solutions and exploring areas where more information is needed.

In the case of reliability analysis, specified with `global_reliability`, the goal of optimizing an objective function is replaced with the goal of resolving the failure boundary. In this case, the Gaussian process model is adaptively refined to accurately resolve a particular contour of a response function using a variation of the EIF known as the expected feasibility function. Then, the failure probabilities are estimated on this adaptively refined Gaussian process model using multimodal adaptive importance sampling.

4.2.2 GPAIS

Gaussian process adaptive importance sampling (GPAIS) [7] starts with an initial set of LHS samples and adds samples one at a time, with the goal of adaptively improving the estimate of the ideal importance density during the process. The approach uses a mixture of component densities. An iterative process is used to construct the sequence of improving component densities. The GPs are not used to directly calculate the failure probability; they are only used to approximate the importance density. Thus, GPAIS overcomes limitations involving using a potentially inaccurate surrogate model directly in importance sampling calculations.

This method is specified with the keyword `gpaiss`. There are three main controls which govern the behavior of the algorithm. `samples` specifies the initial number of Latin hypercube samples which are used to create the initial Gaussian process surrogate. `emulator_samples` specifies the number of samples taken on the latest Gaussian process model each iteration of the algorithm. The third control is `max_iterations`, which controls the number of iterations of the algorithm after the initial LHS samples.

4.2.3 Adaptive Sampling with Dart Throwing

Probability of failure darts, specified in Dakota as `pof_darts`, estimates the probability of failure based on random sphere packing. Random spheres are sampled from the domain with the constraint that each new sphere center has to be outside prior disks [8]. The radius of each sphere is chosen such that the entire sphere lies

either in the failure or the non-failure region. This radius depends on the function evaluation at the disk center, the failure threshold, and an estimate of the function gradient at the disk center.

After exhausting the sampling budget specified by `samples`, which is the number of spheres per failure threshold, the domain is decomposed into two regions. These regions correspond to failure and non-failure, each represented by the union of the spheres of each type. After sphere construction, a surrogate model is built and extensively sampled to estimate the probability of failure for each threshold.

The surrogate model can either be a global surrogate or an ensemble of local surrogates. The local option leverages a piecewise surrogate model, called a Voronoi piecewise surrogate (VPS). The VPS model is used to construct high-dimensional surrogates fitting a few data points, allowing the user to estimate high-dimensional function values with cheap polynomial evaluations. The core idea in the VPS is to naturally decompose a high-dimensional domain into its Voronoi tessellation, with the few given data points as Voronoi seeds. Each Voronoi cell then builds its own surrogate. The surrogate used is a polynomial that passes through the cell's seed and optimally fits its local neighbors by minimizing their error in the least squares sense. Therefore, a function evaluation of a new point requires finding the closest seed and using its particular polynomial coefficients to find the function value estimate.

Fig. 49.11 Results of the mean value method on the textbook function

mean value first-order, second-moment, or MVFOSM method). It is specified with method keyword `local_reliability`. This method calculates the mean and variance of the response function based on information about the mean and variance of the inputs and gradient information at the mean of the inputs. The mean value method is very inexpensive (only five runs were required for the textbook function based on a central finite difference for two inputs), but can be quite inaccurate, especially for nonlinear problems and/or problems with uncertain inputs that are significantly non-normal. More detail on the mean value method can be found in the Local Reliability Methods section of the Dakota Theory Manual [3].

Example output from the mean value method is displayed in Fig. 49.11. The textbook objective function is given by $f = (x_1 - 1)^4 + (x_2 - 1)^4$. Since the mean of both inputs is 1, the mean value of the output for response 1 is zero. However, the mean values of the constraints, given by $c_1 = x_1^2 - \frac{x_2}{2} \leq 0$ and $c_2 = x_2^2 - \frac{x_1}{2} \leq 0$, are both 0.5. The mean value results indicate that variable x_1 is more important in constraint 1 while x_2 is more important in constraint 2.

5 Epistemic Methods

Uncertainty quantification is often used for assessing the risk, reliability, and safety of engineered systems. In these contexts, uncertainty is increasingly separated into two categories for analysis purposes: aleatory and epistemic uncertainty [16, 27]. Aleatory uncertainty is also referred to as variability, irreducible or inherent uncertainty, or uncertainty due to chance. Examples of aleatory uncertainty include the height of individuals in a population, or the temperature in a processing environment. Aleatory uncertainty is usually modeled with probability distributions. In contrast, epistemic uncertainty refers to lack of knowledge or lack of information

about a particular aspect of the simulation model, including the system and environment being modeled. An increase in knowledge or information relating to epistemic uncertainty will lead to a reduction in the predicted uncertainty of the system response or performance. Epistemic uncertainty is referred to as subjective, reducible, or lack of knowledge uncertainty. Examples of epistemic uncertainty include little or no experimental data for a fixed but unknown physical parameter, incomplete understanding of complex physical phenomena, uncertainty about the correct model form to use, etc.

There are many approaches which have been developed to model epistemic uncertainty, including fuzzy set theory, possibility theory, and evidence theory. There are three approaches to treat epistemic uncertainties in Dakota: interval analysis, evidence theory, and subjective probability. In the case of subjective probability, the same probabilistic methods for sampling, reliability, or stochastic expansion may be used, albeit with a different subjective interpretation of the statistical results. We describe the interval analysis and evidence theory capabilities in the following sections.

5.1 Interval Methods for Epistemic Analysis

In interval analysis, one assumes only that the value of each epistemic uncertain variable lies somewhere within a specified interval. It is not assumed that the value has a uniform probability over the interval. Instead, the interpretation is that any value within the interval is a possible value or a potential realization of that variable. In interval analysis, the uncertainty quantification problem translates to determining bounds on the output (defining the output interval), given interval bounds on the inputs. Again, any output response that falls within the output interval is a possible output with no frequency information assigned to it.

Dakota supports interval analysis using either global (`global_interval_est`) or local (`local_interval_est`) approaches. The global approach uses either optimization or sampling to estimate the bounds, with options for acceleration with surrogates. Specifying the keyword `lhs` performs Latin hypercube sampling and takes the minimum and maximum of the samples as the bounds (no optimization is performed), while optimization approaches are specified via `ego`, `sbo`, or `ea`. In the case of `ego`, the efficient global optimization method adaptively refines a Gaussian process surrogate to calculate bounds. The latter two (`sbo` for surrogate-based optimization and `ea` for evolutionary algorithm) support mixed-integer nonlinear programming (MINLP), enabling the inclusion of discrete epistemic parameters such as model form selections. If the problem is continuous and is not expected to contain multiple extrema, then one can use local gradient-based optimization methods (`sqp` for sequential quadratic programming or `nip` for a nonlinear interior point) to calculate epistemic bounds. Local methods may scale better with the number of epistemic variables, though care must be exercised when potentially working with a multimodal response.

5.2 Dempster-Shafer Theory of Evidence

Evidence theory, also referred to as Dempster-Shafer theory or the theory of random sets [27], has found favor at Sandia for modeling epistemic uncertainty, in part because evidence theory is a generalization of probability theory. In this framework, there are two complementary measures of uncertainty: belief and plausibility. Together, belief and plausibility can be thought of as defining lower and upper bounds, respectively, on probability values consistent with the evidence.

In Dempster-Shafer evidence theory, the uncertain input variables are modeled as sets of intervals. The user assigns a basic probability assignment (BPA) to each interval, indicating how likely it is that the uncertain input falls within the interval. The BPAs for a particular uncertain input variable must sum to one and may be overlapping, contiguous, or have gaps. In Dakota, an interval uncertain variable is specified as `interval_uncertain`. When one defines an interval type variable in Dakota, it is also necessary to specify the number of intervals defined for each variable with `num_intervals` as well the basic probability assignments per interval, `interval_probs`, and the associated bounds per each interval, `interval_bounds`.

Once the intervals, the BPAs, and the interval bounds are defined, the user can run an epistemic analysis by specifying the method as either `global_evidence` or `local_evidence` in the Dakota input file. Epistemic analysis is then performed using either global or local methods, using the same algorithm approaches described previously for interval analysis. The primary difference from interval analysis is the number of solves that must be performed, as each unique input BPA bound defines new cells requiring separate minimum and maximum response values. This ensemble of cell minima and maxima are used to define cumulative distribution functions on belief and plausibility.

6 Advanced Capabilities

The following sections describe advanced capabilities that build on the core foundation of sampling, stochastic expansion, reliability, and epistemic methods. Dakota allows for flexible combination of core components to create “meta-algorithms” which may use facilities for nesting, recasting, surrogate modeling, and multilevel parallel scheduling.

6.1 Mixed Aleatory-Epistemic UQ

Mixed UQ approaches employ Dakota nested models to embed one uncertainty quantification (UQ) within another, as depicted in Fig. 49.12. The outer level UQ is commonly linked to epistemic uncertainties and the inner UQ is commonly linked to aleatory uncertainties. The outer level generates sets of realizations of the epistemic

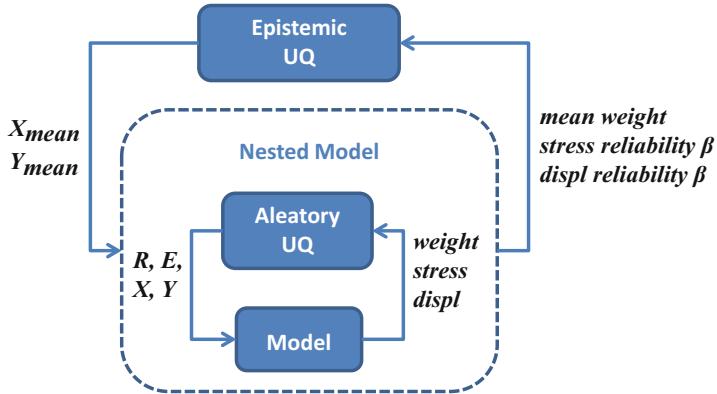

Fig. 49.12 Dakota nested model for mixed UQ analysis

parameters, and each set of these epistemic parameters is used within a separate inner loop probabilistic analysis over the aleatory random variables. In this manner, ensembles of aleatory statistics are generated, one set for each realization of the epistemic parameters. Each level may flexibly use any relevant Dakota UQ method.

Dakota supports three approaches for mixed UQ: interval-valued probability (IVP), Dempster-Shafer theory of evidence (DSTE), and second-order probability (SOP). These three approaches differ in how they treat the outer loop epistemic variables: they are treated as intervals in IVP, as belief structures in DSTE, and as subjective probability distributions in SOP. This yields a spectrum of assumed epistemic structure, from strongest assumptions in SOP to weakest in IVP. IVP (also known as probability bounds analysis [5, 12, 22]), employs an outer loop interval estimation in combination with an aleatory inner loop to generate bounds on aleatory statistics. Sampling-based outer loop approaches yield an ensemble of cumulative distribution functions or CCDFs, one CDF/CCDF result for each aleatory analysis. Plotting an entire ensemble of CDFs or CCDFs in a “horsetail” plot allows one to visualize the upper and lower bounds on the family of distributions (see Fig. 49.13). Given that the ensemble arises from realizations of the epistemic uncertain variables, the interpretation is that each CDF/CCDF instance has no relative probability of occurrence, only that each instance is possible. For prescribed response levels on the CDF/CCDF, an interval on the probability is computed based on the bounds of the ensemble at that level and vice versa for prescribed probability levels. For example, in Fig. 49.13, intervals on the response levels corresponding to probabilities of 0.05 and 0.95 are emphasized. Once again, this interval-valued statistic is interpreted simply as a possible range, where the statistic could take any of the possible values in the range.

The example input file shown in Fig. 49.14 is complex compared to previous examples, as one must specify two entire UQ problems, together with a nested model to coordinate them. The depiction in Fig. 49.12 should help considerably in understanding it. Here, the outer epistemic variables X_{mean} , Y_{mean} are characterized

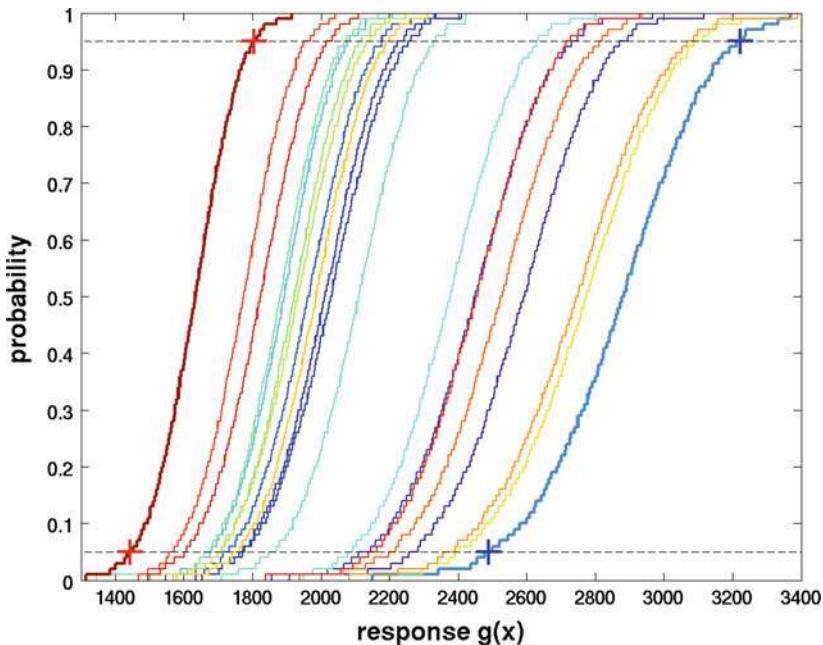

Fig. 49.13 Example CDF ensemble. Commonly referred to as a “horsetail” plot

as intervals. Each sample generated from these intervals will define the mean for uncertain variables X and Y employed in an entire inner level reliability analysis. The analysis problem studied is an algebraic model of a cantilevered beam, subject to loading. The inner reliability analysis holds the width w and thickness t fixed, while assessing the effect of uncertainty in residual stress R , Young’s modulus E , horizontal load X , and vertical load Y on responses weight, stress, and displacement.

Figure 49.15 shows excerpts from the resulting output. In this particular example, the outer loop generates 50 possible realizations of epistemic variables, each of which are communicated to the inner loop to calculate statistics such as the mean weight and cumulative distribution function for the stress and displacement reliability indices. Thus, the outer loop has 50 possible values for the mean weight but there is no distribution structure on these 50 samples. So, only the minimum and maximum values are reported. Similarly, the minimum and maximum values of the CCDF for the stress and displacement reliability indices are reported.

6.2 Multifidelity UQ

Multifidelity UQ approaches use a predictive low-fidelity model to reduce the number of high-fidelity model evaluations required to compute high-fidelity statistics

Fig. 49.15 Interval-valued statistics for cantilever beam reliability indices

to a specified precision. When a low-fidelity model captures useful trends of the high-fidelity model, the model discrepancy may have either lower complexity, lower variance, or greater sparsity, requiring less computational effort to resolve its functional form than that required for the original high-fidelity model [26]. In the case of multifidelity polynomial chaos expansions, this reduction in computational effort can often be linked to a more rapid decay in the coefficient spectrum of the model discrepancy relative to the decay of the high-fidelity coefficient spectrum.

Dakota capabilities for multifidelity UQ are currently implemented using stochastic expansion methods. To enable the goal of the low-fidelity model informing the high-fidelity statistics, an expansion is formed for the model discrepancy (the difference between high- and low-fidelity responses). An additive or multiplicative discrepancy may be used:

$$A(\mathbf{x}) = g_{hi}(\mathbf{x}) - g_{lo}(\mathbf{x}) \quad (49.3)$$

$$B(\mathbf{x}) = \frac{g_{hi}(\mathbf{x})}{g_{lo}(\mathbf{x})} \quad (49.4)$$

Approximating the high-fidelity response functions using approximations of these discrepancy functions then involves

$$\hat{g}_{hi_A}(\mathbf{x}) = g_{lo}(\mathbf{x}) + \hat{A}(\mathbf{x}) \quad (49.5)$$

$$\hat{g}_{hi_B}(\mathbf{x}) = g_{lo}(\mathbf{x}) \hat{B}(\mathbf{x}) \quad (49.6)$$

where $\hat{A}(\mathbf{x})$ and $\hat{B}(\mathbf{x})$ are stochastic expansion approximations to the exact correction functions:

$$A(\mathbf{x}) \approx \hat{A}(\mathbf{x}) = \sum_{j=0}^{P_{hi}} \alpha_j \Psi_j(\mathbf{x}) \quad \text{or} \quad \sum_{j=1}^{N_{hi}} a_j \mathbf{L}_j(\mathbf{x}) \quad (49.7)$$

$$B(\mathbf{x}) \approx \hat{B}(\mathbf{x}) = \sum_{j=0}^{P_{hi}} \beta_j \Psi_j(\mathbf{x}) \quad \text{or} \quad \sum_{j=1}^{N_{hi}} b_j \mathbf{L}_j(\mathbf{x}) \quad (49.8)$$

where α_j and β_j are the spectral coefficients for a polynomial chaos expansion and a_j and b_j are the interpolation coefficients for stochastic collocation.

In addition to the stochastic expansion model for the discrepancy term, Dakota also forms a stochastic expansion for the low-fidelity surrogate model, where the intent is for the level of stochastic resolution to be higher than that required to resolve the discrepancy ($P_{lo} \gg P_{hi}$ or $N_{lo} \gg N_{hi}$), such that the low-fidelity expansion accurately captures the primary trends of the response using less expensive simulations:

$$g_{lo}(\mathbf{x}) \approx \sum_{j=0}^{P_{lo}} \gamma_j \Psi_j(\mathbf{x}) \quad \text{or} \quad \sum_{j=1}^{N_{lo}} r_{lo,j} \mathbf{L}_j(\mathbf{x}) \quad (49.9)$$

This separation in resolution can be enforced statically through order/level selections or automatically through adaptive refinement. The use of adaptive refinement strategies is conceptually appealing: we wish to rely on the low-fidelity model for parameter ranges where it is predictive and focus effort on refining the discrepancy model in regions where the low-fidelity model starts to break down. A multifidelity generalized sparse grid algorithm has been developed for this purpose [26]. After both expansions are formed, the two expansions are combined (added or multiplied) into a new expansion that approximates the high-fidelity model, from which the final set of statistics are generated. For more detail on the corrections and multifidelity approaches in general, see the Dakota Theory Manual [3].

Figure 49.16 shows an example of the Dakota input specification for an additive correction approach. Note that the two sparse grid levels refer to the sparse grid level used to construct the discrepancy term (in this case, 1) and the level used to approximate the low-fidelity model (in this case, 3). The model is defined as a hierarchical surrogate model, with pointers to the low- and high-fidelity models. The

correction term is additive and the zeroth_order specification indicates that the high-fidelity approximation given by (49.5) interpolates the true high-fidelity values at each of the high-fidelity simulation points, but not higher-order derivative information.

6.3 Optimization Under Uncertainty (OUU)

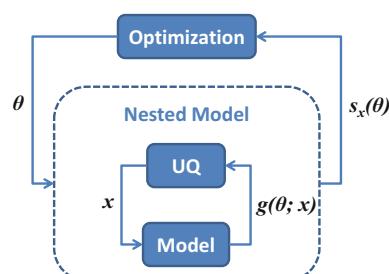

Another common hybrid method scenario is to nest uncertainty analysis within an optimization process to perform optimization under uncertainty (OUU). This allows design processes to account for the effect of input parameter uncertainties by seeking robust or reliable designs. In the former case, one might seek to minimize the variability of a critical performance metric in the presence of uncertainties, and in the latter case, one might constrain the probability of failure of a structure to be less than some allowable level, given uncertainty in applied loads and/or material properties of the structural components.

In OUU, a nondeterministic (UQ) method is used to evaluate the effect of uncertain variable distributions on response functions of interest. Statistics on these response functions are then included in the objective and constraint functions of a nonlinear optimization problem. Different UQ methods can have very different features from an optimization perspective, leading to the tailoring of optimization under uncertainty approaches to particular underlying UQ methodologies.

If the UQ method is sampling based, then three approaches are currently supported: nested OUU, surrogate-based OUU, and trust-region surrogate-based OUU. Within the nested OUU approach, the outer loop seeks to optimize a nondeterministic quantity (e.g., minimize probability of failure) over a set of design parameters, while the inner loop performs UQ to evaluate this nondeterministic quantity for a particular point in design space. Figure 49.17 depicts this case, where θ are the design variables, x are the uncertain variables characterized by probability distributions, $g(\theta, x)$ are the response functions from the simulation, and $s_x(\theta)$ are the statistics generated from the uncertainty quantification on these response functions. Surrogate-based OUU methods extend the nested approach by creating a surrogate over the design variables and/or the uncertain variables, and trust-region surrogate-based OUU manages the approximation models to ensure that the process converges to the optimum of the original problem. Additional details and computational results are provided in [9].

A second class of OUU algorithms is called reliability-based design optimization (RBDO). RBDO methods are used to perform design optimization accounting for reliability metrics. Dakota's reliability analysis capabilities provide a rich foundation for exploring a variety of RBDO formulations, and analytic sensitivities of

Fig. 49.17 Advanced capability example: nested optimization under uncertainty

reliability metrics can be used to accelerate gradient-based optimization algorithms. The simplest and most direct RBDO approach is the bi-level approach in which a full reliability analysis is performed for every optimization function evaluation, as in Fig. 49.17. An alternative RBDO approach is the sequential approach, in which additional efficiency is sought through breaking the nested relationship of the MPP and design searches through the use of local surrogate models (first- and second-order Taylor series approximations).

A third class of OUU algorithms performs OUU with stochastic expansions. Similar to RBDO, an advantage of using stochastic expansions for UQ is that analytic design sensitivities can be exploited, using either first-order expansions of response sensitivities or zeroth-order combined expansions over both design and uncertain parameter spaces [10]. Armed with analytic moments and their design sensitivities, a variety of bi-level, sequential, and multifidelity formulations can be explored; see the Dakota Theory Manual [3] for details.

Finally, when employing epistemic or mixed aleatory-epistemic UQ, the OUU formulation will involve optimizing metrics related to the epistemic interval (a worst case interval bound in the case of reliability and the width of the interval in the case of robustness). This enables the design process to directly account for lack of knowledge.

Configuring a Dakota study for any of these OUU approaches is similar to the earlier mixed UQ example. Figure 49.18 shows an outer gradient-based optimization method seeking values of width w and thickness t to minimize the mean weight of a cantilevered beam, subject to nonlinear inequality constraints that enforce stress and displacement reliability of at least 3.0. For each set of design variables selected by the optimizer, the nested model uses a polynomial chaos method to evaluate statistics on the weight, stress, and displacement responses; see Fig. 49.19. The nested model specification includes `primary_response_mapping` and `secondary_response_mapping`, which indicate which inner method statistics map to objectives and constraints, respectively.

6.4 Bayesian Methods

The UQ approaches presented thus far, e.g., sampling, reliability, stochastic expansions, and interval analysis, are *forward UQ* methods; they propagate information from uncertain input parameters through a computational model to inform response uncertainty. Dakota also includes *inverse UQ* methods for which the uncertainty in a response (typically given through physical observations or experiments) is propagated backward to obtain corresponding uncertainties on inputs consistent with the observed response uncertainty. Thus inverse UQ methods can be classified as parameter estimation or calibration methods that result in a richer characterization of input variables than point estimation.

Traditional optimization and least-squares calibration methods can be used for backward uncertainty propagation, when the input uncertainty characterizations are parameterized. For example, a log-normal distribution might be assumed, and the

Fig. 49.18 OUU: portion of Dakota input file showing outer gradient-based optimizer minimizing mean weight subject to reliability constraints

optimization procedure works to find the input mean and variance most consistent with the provided response data. A typical goal is to minimize the difference between statistics of the simulation response (as computed by forward UQ) and the experiment response, such as its mean, variance, and/or percentiles. This approach is sometimes called “moment matching” or “backward propagation of variance.” In Dakota, this would be expressed as nested OUU formulation, where a least squares objective over UQ statistics is defined on the outer loop [35].

Bayesian methods offer another means to characterize uncertainties on input distributions given observational data, and providing effective options in Dakota for this approach is a current point of emphasis. Bayesian calibration theory is well described elsewhere (e.g., [23]), so only a brief summary is provided in the following.

In Bayesian approaches, uncertain parameters are characterized by probability density functions. During the calibration process, a “prior distribution” (the probability density function that describes knowledge before the incorporation of data, $f_{\Theta}(\theta)$) is assumed for each input parameter. This prior is then iteratively updated through a Bayesian framework involving experimental data and a likelihood function. The likelihood function describes how well each parameter value is supported by the provided data. Bayes Theorem [20], shown in (49.10), is used for inference: to derive the plausible parameter values based on the prior probability density and the data y . The result is the posterior parameter density of the parameters $f_{\Theta|Y}(\theta|y)$. It is interpreted the same way as the prior, but includes the information derived from the data.

$$f_{\Theta|Y}(\theta|y) = \frac{f_{\Theta}(\theta) \mathcal{L}(\theta; y)}{f_Y(y)} \quad (49.10)$$

The likelihood function is used to describe how well a model's predictions are supported by the data. The likelihood function can be written generally as

$$\mathcal{L}(\theta; y) = f(g(\theta) - y) \quad (49.11)$$

where θ are the parameters of model g . The particular form for the function f can have significant influence on the results; Dakota employs likelihoods based on Gaussian probability density functions. These assume that the mismatch between the model (e.g., computer simulation) and the experimental observations (errors) is Gaussian:

$$y_i = g(\theta) + \epsilon_i, \quad (49.12)$$

where ϵ_i is a random variable that can encompass both measurement errors on y_i and modeling errors associated with the simulation $g(\theta)$. By further assuming that all n observations from experiments are independent, the probabilistic model defined by (49.12) results in a likelihood function for θ that is the product of n normal probability density functions:

$$\mathcal{L}(\theta; y) = \prod_{i=1}^n \frac{1}{\sigma \sqrt{2\pi}} \exp \left[-\frac{(y_i - g(\theta))^2}{2\sigma^2} \right]. \quad (49.13)$$

Markov Chain Monte Carlo (MCMC) is the standard method used to compute posterior parameter densities, given the observational data and the priors. There are many references that describe the basic Metropolis algorithm [13]. One variation used in Dakota is DRAM: Delayed Rejection and Adaptive Metropolis [14]. Note that MCMC algorithms typically take tens or hundreds of thousands of steps to converge. Since each iteration involves an evaluation of the model $g(\theta)$, surrogate models of the simulation response are typically employed, allowing the MCMC process to quickly generate thousands of samples on the emulator. One can specify a Gaussian process, a polynomial chaos expansion, or a stochastic collocation expansion as the emulator for the Bayesian calibration methods. The specification details for these are listed in the Reference Manual [2].

There are two implementations of Bayesian calibration in Dakota, specified with `bayes_calibration` followed by `queso` or `dream`. The QUESO method uses components from the QUESO library (Quantification of Uncertainty for Estimation, Simulation, and Optimization) developed at The University of Texas at Austin. DREAM is based on the DiffeRential Evolution Adaptive Metropolis approach which runs multiple different chains simultaneously for global exploration and automatically tunes the proposal covariance during the process by a self-adaptive randomized subspace sampling [37]. Dakota also has an experimental implementation of the Los Alamos National Laboratory-developed GPMSA (Gaussian Process Models for Simulation Analysis) approach [17]. It is currently being reimplemented in the QUESO framework for better integration with Dakota and is

Fig. 49.20 Sample Dakota input file for Bayesian calibration

not ready for general use as of this writing. For some detailed application examples with Dakota’s Bayesian capabilities, see [4].

One can also specify various configuration options for these different algorithm selections. For the QUESO MCMC, one can select the standard Metropolis-Hastings algorithm or an adaptive Metropolis in which the covariance of the proposal density is updated adaptively. There is also a setting to use delayed rejection. For the DREAM method, one can define the number of chains used, as well as the number of chains randomly selected to be used in crossover. There are also other settings governing the convergence and other features of DREAM. For more details about these parameters, see [37]. While DREAM is distributed and built with Dakota by default, the QUESO-based DRAM requires custom compilation at the user site.

Figure 49.20 shows a sample Dakota input file that gives a uniform prior distribution on parameters E (Young’s modulus) and w (width) of the cantilever beam. The QUESO Bayesian calibration method will use the cantilever beam simulation together with the ten user-provided experimental data points with corresponding measurement error to draw samples from the joint posterior distribution of E and w . The other parameters specified with `continuous_state` will be held fixed at their nominal values.

The choice of proposal covariance is important as it governs the size of the proposed steps in the MCMC chain. Dakota has a variety of options for the `proposal_covariance` keyword: one can specify the diagonals of the covariance matrix (i.e., the variance of the steps in each input parameter direction) or a full covariance matrix, one can use the prior to calculate a proposal covariance, or one can automatically use any available simulation derivative information to estimate it. The experimental data points in this example are provided in a file named `dakota_cantilever_queso.withsigma.dat`. The ten data points are provided along with estimates of their variance, as specified by the scalar variance type. Dakota supports several types of measurement error variances: constant measurement error for all of the data, a distinct scalar variance estimate per data point, and a full covariance matrix of measurement errors. These measurement errors are used in the calculation of the likelihood function.

To summarize, the DRAM and DREAM MCMC capabilities in Dakota can use data to generate posterior distributions on parameters. These capabilities have a number of method controls and can utilize Dakota's surrogate models so that the MCMC can be performed on an emulator in place of expensive simulations. Current research efforts in Dakota are adding new Bayesian capabilities and options. For example, analytic derivatives of emulator models such as PCE give rise to an inverse Hessian of the likelihood function to use as a proposal covariance, preconditioning the MCMC. Bayesian methods will support adaptive refinement of the posterior with emulator models and use various discrepancy functions δ to model the difference between the simulation and the observational data. Finally, recent capabilities allow Bayesian methods to handle field, or functional, data, where the output depends on independent coordinates such as time or space.

7 Usage Guidelines

The choice of uncertainty quantification method depends on how the input uncertainty is characterized, the computational budget, the nonlinearity and smoothness of the input/output mapping, and the desired output accuracy. Some recommendations for Dakota UQ methods are summarized in Table 49.3 and discussed in this section.

7.1 Sampling Methods

Sampling-based methods are the most robust uncertainty techniques available, are applicable to almost all simulations, and possess rigorous error bounds; consequently, they should be used whenever the function is relatively inexpensive to compute and adequate sampling can be performed. In the case of expensive computational simulations, however, the number of function evaluations required by traditional techniques such as Monte Carlo and Latin hypercube sampling (LHS)

Table 49.3 Guidelines for UQ method selection

Method classification	Desired problem characteristics	Applicable methods
Sampling	Nonsmooth, multimodal response functions; Larger sets of random variables; Response evaluations are relatively inexpensive	Sampling (Monte Carlo or LHS) Importance sampling
Local reliability	Smooth, unimodal response functions; Larger sets of random variables; Estimation of tail probabilities	Local reliability (MV, AMV/AMV ² , AMV+/AMV ²⁺ , TANA, FORM/SORM)
Global reliability	Smooth or limited nonsmooth response; Multimodal response; low dimensional; Estimation of tail probabilities	Global reliability, GPAIS, POFDarts
Stochastic expansions	Smooth or limited nonsmooth response; Multimodal response; low dimensional; Estimation of moments or moment-based metrics	Polynomial chaos, stochastic collocation
Epistemic	Uncertainties are poorly characterized	Interval: local/global interval estimation, sampling; BPA: local/global evidence
Mixed UQ	Some uncertainties are poorly characterized	Nested UQ (IVP, SOP, DSTE) with epistemic outer loop and aleatory inner loop, sampling
Bayesian calibration	Calibration of prior densities with data resulting in a posterior	Bayesian calibration with QUESO (DRAM), DREAM

quickly becomes prohibitive, especially if tail statistics are needed. Importance sampling is one goal-oriented approach that can reduce the number of samples needed.

7.2 Reliability Methods

Local reliability methods (e.g., MV, AMV/AMV², AMV+/AMV²⁺, TANA, and FORM/SORM) are more computationally efficient in general than sampling methods and are effective when applied to reasonably well-behaved response functions, i.e., functions that are smooth, unimodal, and only mildly nonlinear. When confronted with nonsmooth, multimodal, and/or highly nonlinear response functions, global reliability methods (efficient global reliability analysis (EGRA), Gaussian process adaptive importance sampling (GPAIS), and probability of failure darts (POFDarts)) should be used. These techniques employ adaptive point selection and refinement of surrogate models to accurately resolve the failure domain. For relatively low-dimensional problems (typically less than ten variables), global reliability methods display efficiency similar to local reliability methods, but with the accuracy of exhaustive sampling.

7.3 Stochastic Expansions Methods

Stochastic expansion methods (polynomial chaos and stochastic collocation) are general-purpose techniques provided that the response functions possess finite second-order moments. Further, these methods capture the underlying functional relationship between a key response metric and its random variables. The current challenge in the development of these methods, as for other global surrogate-based methods, is effective scaling for large numbers of random variables. Recent advances in adaptive collocation and sparsity detection methods address some of the scaling issues, with successful deployments approaching 100 random dimensions.

7.4 Epistemic Uncertainty Quantification Methods

Epistemic uncertainty methods in Dakota focus on uncertainties resulting from a lack of knowledge. In these problems, the assignment of input probability distributions when data is sparse can be somewhat suspect. One approach to handling epistemic uncertainties is interval analysis (`local_interval_est` and `global_interval_est`), where a set of intervals on inputs, one interval for each input variable, is mapped to a set of intervals on outputs. To perform this process efficiently, global or local optimization methods can be used. Another related technique is Dempster-Shafer theory of evidence (Dakota methods `local_evidence` and `global_evidence`), where multiple intervals per input variable (which can be overlapping, contiguous, or disjoint) are propagated, again potentially using optimization methods.

7.5 Mixed Aleatory-Epistemic UQ Methods

For problems with a mixture of epistemic and aleatoric uncertainties, it is desirable to separate the two uncertainty types within a nested analysis, segregating the reducible components of the uncertainty for purposes of clarifying the interpretation of the statistical results. In this nested approach, an outer epistemic level selects realizations of epistemic parameters, and for each epistemic realization, a probabilistic analysis is performed on the inner aleatory level. In the case where the outer loop involves propagation of subjective probability, the nested approach is known as second-order probability. In the case where the outer loop is an interval propagation, the nested approach is known as interval-valued probability. Between these two extremes lies the case where the outer loop is an evidence-based approach, for which belief and plausibility bounds are generated on aleatory statistics.

7.6 Bayesian Methods

Dakota has two MCMC approaches for calculating posterior distributions on model parameters using Bayesian calibration. These posterior distributions are based on

the prior parameter distributions and informed and updated with observational data. Currently, the MCMC approaches are based on DREAM or DRAM algorithms.

8 Conclusion

The freely available Dakota software delivers a suite of uncertainty quantification algorithms to address challenges associated with simulation-based science and engineering analyses. It allows the hybridization of UQ with optimization and the use of surrogates and multifidelity models with both analyses. Smart adaptive methods that can mitigate the curse of dimensionality for stochastic expansions and sampling are a current research emphasis. Bayesian calibration methods are also under active development, specifically focusing on surrogate modeling, discrepancy, postprocessing, and multi-model extensions.

Problem Solving Environment for Uncertainty Analysis and Design Exploration

50

Charles Tong

Abstract

This chapter gives an overview of the capabilities of the PSUADE (acronym for Problem Solving Environment for Uncertainty Analysis and Design Exploration) software package, which has been developed to support the many operations involved in a typical nonintrusive (i.e., simulation codes are to be treated as “black boxes”) uncertainty quantification (UQ) study, such as sample generation, ensemble simulations, and analysis of simulation results. Specifically, the software enables users to perform detailed UQ analysis such as uncertainty analysis (for computing statistical moments and probability distributions), sensitivity analysis (e.g., variance decomposition), parameter screening or down-selection, response surface analysis, statistical inferences, and optimization under uncertainty. In addition to a rich suite of UQ capabilities accessible via either batch or command line processing, PSUADE also provides many tools for data manipulation and visualization, which may be useful for more immersive data analysis. PSUADE is a public domain software that has been released under the LGPL license since 2007.

Keywords

Uncertainty quantification • Global sensitivity analysis • Bayesian inference • Response surface methodology • Dimension reduction • Numerical optimization • Optimization under uncertainty • Markov chain Monte Carlo • Discrepancy modeling • Cross validation • Aleatory-epistemic uncertainty

1 Introduction

UQ is defined as “the process of quantifying uncertainties associated with model calculations of true, physical quantities of interest, with the goals of accounting for all sources of uncertainty and quantifying the contributions of specific sources to the overall uncertainty” [1]. In this chapter a presentation will be given on how the different elements of this process can be performed using the mathematical, statistical, and computer science tools available from PSUADE.

At a glance, PSUADE contains a comprehensive suite of capabilities for UQ tasks such as:

1. Dimension reduction (parameter screening/down-selection)
2. Response surface (including adaptive) analysis
3. Basic uncertainty analysis (sampling- or response surface-based)
4. Mixed aleatory-epistemic uncertainty analysis
5. Global sensitivity analysis (sampling- or response surface-based)
6. Calibration/Bayesian inference with model form correction
7. Deterministic optimization and optimization under uncertainty

Each of these capabilities is equipped with many optional features (for expert users) and diagnostics (including Matlab-based graphics) for immersive analysis of simulation or UQ results.

The rest of this chapter is organized as follows: after giving a brief tutorial on PSUADE installation, a systematic exploration of PSUADE’s capabilities will be described via following the steps of a general process for performing UQ on a simulation model.

1.1 PSUADE Installation

PSUADE is a free software and its source code can be downloaded from

http://computation.llnl.gov/casc/uncertainty_quantification.

Successful build of PSUADE requires system tools such as C, C++, and Fortran compilers, as well as “ccmake” utilities. Installing PSUADE on Linux or Mac OS-based systems is straightforward by following the instructions below:

1. `tar xvfz PSUADE_vx.x.x.tar.gz`
2. `cd PSUADE_vx.x.x`
3. `mkdir build`
4. `cd build`
5. `ccmake ..`
 - Enter “c” to display the package information.
 - To install PSUADE other than locally in your home directory, set the “install directory.”
 - Check the default compilers and turn on/off other options as desired.
 - Enter “c” again to update the selection.
 - Finally, enter “g” to save and exit.
6. Now run `make` to create the “psuade” executable and the associated libraries in the “build/bin” and “build/lib” directories. Alternatively, run `make install` to build the “psuade” executable in your designated install directory.
7. To verify correct installation, run an example (on Linux) by:
 - `cd PSUADE_vx.x.x/Examples/Bungee`
 - `cc -o simulator simulator.c -lm`
 - `../../build/bin/psuade psuade.in`
 - If it runs successfully, some summary statistics (e.g., mean ≈18 and standard deviation ≈9) will be displayed.

Generally, this installation and testing procedure should take no more than a few minutes. Details of building and installing PSUADE on Windows-based platform can be found in the user manual that comes with the source code download.

1.2 A General UQ Process

Before embarking on a serious UQ study of complex simulation models, a UQ process (or plan) should be developed to guide the completion of the study. Without a well-thought-out plan, computational resources may be wasted and the results may not be defensible. A typical UQ process comprises the following steps (which may be refined depending on the needs of individual applications); for a given application (simulation model):

1. Define objectives of the UQ study.
2. Identify all relevant sources of uncertainties.
3. Characterize the identified sources of uncertainties.
4. Propagate the characterized uncertainties through computer simulations.
5. Analyze uncertainties of the model outputs of interest.

Each of these steps may take hours to months. In the following, a brief discussion of these steps is given to show how to set up PSUADE input files to capture these steps.

1.2.1 Defining UQ Objectives

This step entails a full description of the objectives of the UQ study as well as assumptions about the simulation models under study. In addition, it includes a full specification of all the essential components of the simulation model so that sufficient information are gathered to enable replication of the same UQ study at a later date. This is a crucial step in a UQ process, since conclusions drawn from the study are valid only under the assumptions made in this step.

Some of the UQ objectives are:

- (a) To quantify the prediction uncertainties of a given simulation model (uncertainty analysis)
- (b) To quantify contributions from major sources of uncertainty in the simulation model (sensitivity analysis)
- (c) To calibrate model parameters to match noisy data from physical experiments (parameter inference)

The objectives of the planned UQ study may affect which UQ methods are appropriate. For example, if the objective is to help prioritize research by assessing and comparing the impact of the various uncertain sources on the design, then sensitivity analysis will be valuable. Furthermore, if simulations are themselves computationally expensive, response surfaces can be used as inexpensive surrogates in place of ensemble model simulations in UQ analysis. PSUADE provides a spectrum of methods to achieve these UQ objectives.

1.2.2 Identification of Uncertainty Sources

A complex simulation model may contain hundreds of internal parameters that are tunable or uncertain. Due diligence should be exercised in compiling this comprehensive list of tunable parameters. If the parameter space (number of uncertain parameters) identified initially is too large (e.g., more than a few hundreds) for a comprehensive analysis, expert judgment may be needed to shorten the list. Other forms of simulation model uncertainty, such as model form uncertainties due to missing physics or model simplification, may also be identified at this stage. In addition, any available experimental data that may be helpful in reducing model prediction uncertainties should be included in this step.

1.2.3 Characterization of Uncertainty Sources

This step corresponds to compiling credible initial ranges and/or probability distributions for the uncertain parameters and is one of the most important and time-consuming tasks. Extreme caution should be taken in this step because the credibility of the final UQ results depends critically on the choice of ranges and

distributions. Therefore, every choice of ranges and distributions should be carefully made and justified.

Before performing the task of uncertainty characterization, it is useful to classify the identified sources of uncertainty. One such classification is based on the nature of uncertainty for which uncertainty is classified as either *aleatory* or *epistemic* (e.g., [12]). For all practical purposes, the definition of aleatory uncertainty can be confined to be uncertainty that can be characterized by a known probability distribution and the definition of epistemic uncertainty to be uncertainty that can be characterized by an interval (or a number of disjoint intervals) with unknown probability distribution. Furthermore, epistemic uncertainty includes systematic bias of model output caused by missing or simplified physics. This distinction clarifies the different approaches to quantifying uncertainties for the two types.

For uncertain variables (will be used interchangeably with uncertain parameters), other useful classifications are (1) continuous variables, (2) ordinal variables, and (3) categorical variables. Continuous variables can be set to any value within a given interval (or a set of intervals), and thus, they have infinite number of distinct settings. Discrete variables, on the other hand, can only take on a limited number values within their ranges. Finally, categorical variables do not have meaningful numerical values. They are used for the purpose of distinguishing different options, such as different material fracture models, that may have little functional relationship with each other.

After the uncertain sources have been classified, their ranges or probability distributions are to be prescribed. Information about reasonable ranges and distributions can be obtained from theory, literature, or local subject matter experts. In summary, the product of this step is a comprehensive list of relevant uncertain sources appended with their classifications and probability distributions (or intervals).

1.2.4 Propagation of Uncertainties

Uncertainties can be propagated via intrusive or nonintrusive approaches. Due to their practicality, PSUADE provides primarily nonintrusive methods. Propagation involves generating samples and running a possibly large number of simulations. A key element to uncertainty propagation is sampling strategy (also called design of computer experiments). Proper selection of sampling strategies depends on the UQ objectives as well as certain properties of the simulation models. For example, if simulation cost is high and response surfaces are desired, “space-filling” sampling strategies such as quasi-Monte Carlo or specialized Latin hypercube should be selected. Sampling strategies available in PSUADE will be given later. In summary, the execution of this step will yield a sample (consisting of a number of sample points drawn from the parameter probability distributions) as well as the corresponding simulation results. Propagation of uncertainties often involves large ensemble simulations that may benefit from compatible job schedulers on high-performance computer systems.

1.2.5 Analysis of Uncertainties

UQ objectives guide the selection of relevant sampling strategies and analysis methods. In the following, several analyses commonly performed during a UQ study are listed:

- (a) Quantify the means and standard deviations of selected model outputs.
- (b) Rank a large number of uncertain parameters in order of their importance in affecting the model outputs.
- (c) Construct response surfaces relating uncertain parameters to the model outputs.
- (d) Quantify the global sensitivities of uncertain parameters.
- (e) Compute the best parameter settings that match observational data.

1.3 PSUADE Basics

In this section an example is given on how to develop a simple UQ process and how to use PSUADE to help execute the steps. Specifically, given a simulation model called “simulator” which has 100 uncertain parameters, the UQ objective is to identify the 10 most sensitive parameters and quantify their individual contribution to the overall uncertainty of a certain simulation output of interest. In addition, suppose the simulator takes hours to run and little knowledge is provided on how the output of interest varies with the uncertain inputs (linearly or nonlinearly). With this initial specification, a possible UQ workflow is as follows:

1. Define clearly the UQ objective.
2. Identify and prescribe feasible ranges for the 100 uncertain parameters.
3. Perform parameter screening to identify the ten most sensitive parameters (this step is needed because the simulation cost is relatively expensive).
4. Build a response surface for the ten sensitive parameters.
5. Use the response surface to compute uncertainty and quantify individual contributions via global sensitivity analysis.

The user information required to perform Step (4) can be captured in the following PSUADE input file (the other steps can be set up and run in similar fashions).

```

PSUADE
INPUT
# There are 10 inputs with ranges in [-3,3].
# Probability information is not needed for
# response surface construction
dimension = 10
variable 1 X1 = -3.0 3.0
...
variable 10 X10 = -3.0 3.0
END

```

```
OUTPUT
# Output of interest
dimension = 1
variable 1 Y
END
METHOD
# Sampling design = randomized Latin hypercube
sampling = LH
num_samples = 100
random_seed = 129932931
END
APPLICATION
# The simulation code (executable) is 'simulator'
driver = ./simulator
max_parallel_jobs = 1
END
ANALYSIS
# analysis will be performed in command line mode
printlevel = 1
END
END
```

This file should have **PSUADE** as the first line, and it should normally contain five sections (but at the very least should have the **INPUT**, **OUTPUT**, and **METHOD** sections) followed by the keyword **END** in the last line.

1.3.1 The Input Section

The **INPUT** section allows users to specify the number of inputs, input names, input ranges, and input probability distributions, which are enclosed in an **INPUT** block. In this example, the number of inputs is ten with names X1, X2, and so on. Input probability distributions (PDF) are not needed at this stage (they are needed in the quantitative sensitivity analysis).

PSUADE currently supports primarily continuous uncertain variables. The available PDFs are the popular ones such as uniform, normal, lognormal, gamma, beta, exponential, triangle, and Weibull distributions. In addition, PSUADE also provides a distribution type called “S” (meaning user-provided distribution), which allows user to prescribe, via a user-provided sample, general non-parametrized PDFs or distributions for discrete variables.

1.3.2 The Output Section

The **OUTPUT** section is similar to but simpler than the **INPUT** section. Here only the output dimension and the names of the output variables are to be specified.

1.3.3 The Method Section

The **METHOD** section specifies the selected sampling method and additional information on sampling. In this example, the sampling method is Latin hypercube (LH) with sample size 100. Other available sampling methods will be given later. Also, the internal random number seed can also be provided. This is useful if repeatability is desired, as randomness is often introduced in various sampling strategies. Other advanced features include options in setting up uniform or adaptive sample refinements.

1.3.4 The Application Section

The **APPLICATION** section sets up the user-provided simulation executable and other runtime parameters. In this example, **driver** points to the simulation code **simulator**. The simulation code can be just a simple program or a complex superscript performing preprocessing, actual model evaluation, and postprocessing. The **driver** can also be a PSUADE data file, which is used internally within PSUADE to construct surrogate models.

max_parallel_jobs directs PSUADE to launch the desired number of jobs simultaneously. If it is set to larger than 1, the asynchronous job scheduling mode will be turned on using the Linux fork-join mechanism. Other available features include alternative methods for job control as well as support for fault detection and recovery.

1.3.5 The Analysis Section

The **ANALYSIS** section specifies the desired UQ analysis. For example, if the selected analysis method is **Moment**, PSUADE will run and sample and computes the first few statistical moments based on the sample design specified in the **METHOD** section. The **ANALYSIS** section also provides many options for fine-tuning the various statistical analysis (including numerical optimization) as well as setting diagnostics output levels (e.g., **printlevel** in the example PSUADE input file given above).

1.4 Running PSUADE

PSUADE can be run in either batch or command line mode. Batch mode is intended primarily for creating and running samples. Command line mode provides interactive tools for UQ analysis, sample data manipulation, and creation of plots for visualization. In the following, the two modes are discussed in detail.

1.4.1 PSUADE Batch Mode

In this mode the input file (say, **psuade.in**) described previously should be run via

```
[Linux prompt] psuade psuade.in
```

If the **driver** variable (pointing to the executable simulator code) is defined in the **METHOD** section, PSUADE will first generate the desired sample and then call the

driver code repeatedly, each with a different sample point, until all sample points have been evaluated. Batch mode is useful when simulation run time is relatively short. More often, when simulation time is long or when the simulation platform has its own job control system, it may be more preferable to have PSUADE generate the sample points only and let application users handle the ensemble simulation runs. This latter scenario can be facilitated by running PSUADE without defining driver. In this case PSUADE will create a sample file only. Users can take the sample points in this file and run the ensemble independently. Upon completion of all simulation runs, the results can be compiled into a PSUADE data file and analyzed in the command line mode.

1.4.2 PSUADE Command Line Mode

For PSUADE to run in command line mode, simply run “psuade” without any argument. A PSUADE prompt will be displayed and PSUADE is ready to accept user commands. A list of available command categories will be displayed by entering “help,” and details of how to use a specific command are available by issuing the command with “-h.” Command categories include reading/writing from/to files with different formats, uncertainty and sensitivity analyses, response surface fitting and validation, parameter estimation, sample data manipulation, and creation of Matlab graphics for visualization. A full list of commands can be found in the PSUADE reference manual released together with the source code.

2 UQ Methods and Tools in PSUADE

As discussed above, many different types of analysis may be needed during a UQ study. In this section details of these capabilities are given to show how to use them via the PSUADE batch or command line mode.

2.1 Uncertain Parameter Screening/Dimension Reduction

When the number of independent uncertain parameters is large (say, >100) and the outputs of interest exhibit nonlinear responses to parameter variation with possibly significant parameter interactions, it may not be feasible to tackle this high-dimensional problem directly (the notorious “curse of dimensionality”) when the objective is to accurately quantify uncertainties or sensitivities. Instead, it may be preferable to precede detailed quantitative analyses with a parameter screening step that seeks to qualitatively assess parameter importance via a relatively inexpensive “coarse” sampling of the parameter space. Parameter screening is also known as “variable selection” or “subset selection,” which is one of the most pervasive subject areas in statistical and machine learning applications. One basic assumption in applying screening methods is that most of the output variations are driven by a small subset of uncertain parameters (the so-called Pareto effect that has been

observed in many physical phenomena), and the goal is to identify this subset (hopefully with <20 independent parameters) for more detailed UQ analysis.

2.1.1 Parameter Screening Methods in PSUADE

In selecting screening methods, many practitioners resort to simple mathematical or statistical techniques that make major assumptions about linearity, smoothness, and interactions (e.g., derivative or gradient-based local sensitivity analysis and the classical correlation analysis). Violation of these assumptions, for example, as in many multi-physics simulation models, can impact the correctness of the analysis results. As such, it is pertinent that suitable “screening” methods should be used, based on prior knowledge about the simulation models. For example, known linearity and additivity (in the form of the function that maps uncertain parameters to the model output of interest) should make the computationally inexpensive linear sensitivity analysis method (or Plackett-Burman method [10]) adequate, while a general nonlinear input-output relationship may require more exotic methods such as the Morris method [8] or Bayesian screening [9].

In using coarse sampling strategy to reduce the overall computational cost for screening, errors may be made in identifying important parameters. There are two types of errors: (1) Type I error or when unimportant parameters are identified as important and (2) Type II error or when important parameters are identified as unimportant. Type I error is benign resulting only in higher computational cost for subsequent analysis. Type II is much more serious and safeguard against this error should be employed, for example, by using several methods (including expert judgment and visual inspection) to confirm the final selection.

Parameter screening can be conducted in PSUADE using one of the following methods:

- Local sensitivity method for linear models (“LSA”)
- Fractional factorial methods (“FFx” where $x = 4$ or 5)
- Morris method for general nonlinear models (“MOAT”)

Here “LSA” is the least expensive method requiring only $m + 1$ simulations (where m is the number of uncertain parameters), but they also have the least discriminating power, since their effectiveness hinges on the assumption that the model output is approximately a linear function of the uncertain inputs within their ranges. “FFx” also assumes linear models, but it accommodates an additional pairwise interaction. Finally, the “MOAT” method does not make assumptions about linearity or additivity. However, because of its coarse sampling nature, it is not effective in detecting small-scale changes (e.g., spikes in the parameter space) inside the parameter space.

There are other parameter screening methods in PSUADE that are less common. For example, if the number of parameters is not too large (say, <100) and a large random or quasi-random sample has already been generated and run, then the sample may be analyzed by the Delta test [4].

2.1.2 How to Perform Screening Methods in PSUADE

All screening methods in PSUADE are set up and performed in similar fashion; hence it suffices to simply show one of them. To perform MOAT screening, for example, the steps are as follows:

1. Create a PSUADE input file specifying the uncertain parameters, the sampling method to be MOAT with the appropriate sample size, and the executable simulation code (simulator). The simulation code reads a parameter file for the 20 input values (this example is available as one of PSUADE's test examples called **Morris20**), uses them in the simulation, and returns the simulation results in the output file). An example of PSUADE input file is (the number of sample points is $10(m + 1)$ where m is the number of inputs):

```

PSUADE
INPUT
# There are 20 inputs and with ranges in [0,1].
dimension = 20
variable 1 X1 = 0.0 1.0
...
variable 9 X9 = 0.0 1.0
variable 10 XA = 0.0 1.0
...
variable 20 XK = 0.0 1.0
END
OUTPUT
dimension = 1
variable 1 Y
END
METHOD
sampling = MOAT
num_samples = 210
END
APPLICATION
driver = simulator
END
END

```

2. Execute the input file to generate and run the sample as shown below, and then rename the sample output file from the default name **psuadeData** to, for example, **psdata**. (Alternatively, export the sample points to be run separately and compile the outputs in PSUADE data file format for analysis.)

```

[Linux prompt] psuade psuade.in
...
[Linux prompt] mv psuadeData psdata

```

3. Run screening analysis in command line mode (note: the text after `psuade>` are user inputs):

```
[Linux prompt] psuade
*****
*      Welcome to PSUADE (version 1.7.4)
*****
PSUADE - A Problem Solving environment for
          Uncertainty Analysis and Design
          Exploration (1.7.4)
(for help, enter <help>)
psuade> load psdata
psuade> moat
... results will be displayed ...
psuade> quit
[Linux prompt]
```

4. The screening results can also be inspected by visualizing an optionally generated Matlab file. An example is given in Fig. 50.1 for a 20-parameter problem where the first 10 parameters are important (screening results are generated using 210 simulations).
5. There are other diagnostics features in the MOAT screening methods for more immersive analysis, such as visualization tools for outlier identification and parameter interaction analysis.

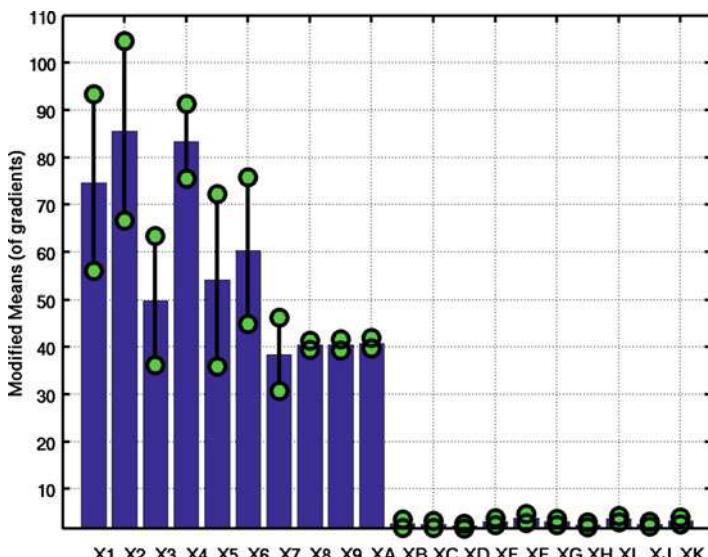

Fig. 50.1 MOAT screening plot for the 20-parameter model

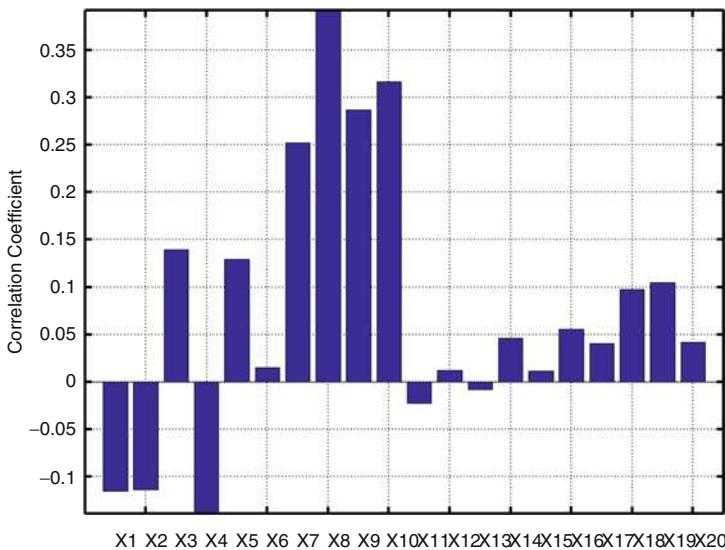

Fig. 50.2 Pearson screening plot for the 20-parameter model

6. To show the effectiveness of the MOAT method for nonlinear models, the same 20-parameter problem was analyzed with the Pearson correlation analysis on a Latin hypercube sample of size 500. Figure 50.2 shows the Pearson results, which do not reflect the correct ranking because the Pearson analysis is intended for near-linear models.

2.2 Response Surface Analysis

Response surface (also called surrogate models, emulators, meta-models, or reduced models) methods are a collection of statistical and mathematical techniques useful for reducing the computational cost in UQ analysis provided that the model output of interest is sufficiently smooth with respect to the uncertain parameters (so that the input-output relationship can be expressed by a “smooth” or piecewise “smooth” function). Response surface analysis should be performed on models with small to moderate number of parameters (up to 15–20). For models with large number of parameters, it is best to precede this step with parameter screening.

The construction of a response surface requires (1) a good set of “space-filling” sample points to best capture the model behavior in the parameter space, (2) a surface fitting method to construct a mathematical/statistical expression to fit the sample points, and (3) a mathematical technique to assess the “goodness-of-fit.”

2.2.1 Response Surface Methods in PSUADE

The response surface (RS) library in PSUADE provides a rich set of tools to facilitate the construction and validation of response surfaces. The library has four major components: (1) a collection of sampling designs and curve-fitting tools, (2) several methods for validating response surfaces, (3) a number of Matlab-based response surface visualization capabilities, and (4) software tools to create stand-alone response surface predictors (or interpolators) that can readily be used as surrogates in user codes.

To help capture dominant output behaviors in the parameter space, PSUADE provides many “space-filling” sampling methods for response surfaces. Some of them are:

- Monte Carlo sampling
- Quasi-Monte Carlo sampling (e.g., LP- τ)
- Latin hypercube sampling
- Orthogonal array sampling
- Orthogonal array-based Latin hypercube sampling
- Factorial and fractional factorial sampling methods
- Box-Behnken, Plackett-Burman, and central composite designs
- Sampling based on multidimensional domain decomposition
- Sparse grid sampling

Once generated, the sample points and their corresponding outputs (via simulation runs) are ready for “training” a response surface. The choice of response surface methods for a given simulation model depends on existing knowledge about the model itself. Response surface methods available in PSUADE are:

- MARS – multivariate regression splines by Friedman [5]
- MARS with bootstrapped aggregation
- Regression – linear, quadratic, cubic, Legendre polynomials
- Regression with user-provided kernel functions
- Derivative-based Legendre regression methods
- Support vector machine (SVM)
- Gaussian process model by MacKay ([6], to be downloaded separately)
- Universal Kriging method
- Radial basis function
- Sum-of-trees method
- K-nearest neighbor method
- 2- and 3-dimensional splines
- Sparse grids

Some of these methods may require special sampling method (e.g., splines require the use of the full factorial designs).

Since there is no one-size-fits-all approach to response surface analysis, the key is to select the best representation via rigorous validation. There are several RS validation methods available: (1) adjusted R-squared and resubstitution test

(error analysis on the training set), (2) hold-out sample test, and (3) K-fold cross validation. After rigorous validation, the final product should be a “good” response surface that can be used for further UQ analysis. A special feature in PSUADE is that users have the option to create a stand-alone code (in C and Python) that can be used to estimate the outputs of other locations in the parameter space (i.e., the code can be used as a surrogate for the simulation model). The quality of the response surface fit can also be examined visually by displaying the Matlab script created after response surface validation is completed.

2.2.2 How to Perform Response Surface Analysis in PSUADE

To illustrate how to build a response surface, the following Ishigami function is used:

$$Y = \sin(X_1) + 7 \sin^2(X_2) + 0.1X_3^4 \sin(X_1).$$

Once this function is implemented and compiled (into the executable “simulator”), the next steps are:

1. Create a PSUADE input file (e.g., psuadeRS.in) specifying the uncertain parameters, the sampling method (selected from the list above), and the sample size (should be chosen judiciously based on the available computing resources and the target curve fitting method). In the following example, the LP- τ quasi-random method is selected with an initial sample size of 100.

```

PSUADE
INPUT
    dimension = 3
    variable 1 X1    =    -3.1416    3.1416
    variable 2 X2    =    -3.1416    3.1416
    variable 3 X3    =    -3.1416    3.1416
END
OUTPUT
    dimension = 1
    variable 1 Y
END
METHOD
    sampling = LPTAU
    num_samples = 100
END
APPLICATION
    driver = simulator
END
END

```

2. Execute the input file to generate and run the sample as shown below and rename the sample output file from **psuadeData** to, for example, **psdata**. (If the simulation is expensive, this step can be replaced by exporting the sample points to be run separately and then re-assembling the simulation outputs in PSUADE data file format.)

```
[Linux prompt] psuade psuadeRS.in
...
[Linux prompt] mv psuadeData psdata
```

3. Perform response surface validation using **rscheck** in command line mode:

```
[Linux prompt] psuade
...
psuade> load psdata
load complete : nSamples = 100
            nInputs = 3
            nOutputs = 1
psuade> rscheck
# When prompted for RS type, choose MARS
...
Perform cross validation ? (y or n) y
Enter the number of groups to validate :
(2 - 100) 10
...
RSA: L 1:cross validation (CV) completed.
CV error file is RSFA_CV_err.m
psuade> quit
[Linux prompt]
```

In particular, after cross validation, summary statistics will be displayed on the screen. In addition, the cross-validation results can be visually inspected by running the Matlab file called **RSFA_CV_err.m**. An example is shown in Fig. 50.3 where the left plot displays the distribution of cross-validation errors and the right plot shows the one-to-one matching between the estimated and the actual sample outputs in cross validation. A perfect fit will give a “spike” at zero (error mean and standard deviations are both zero) on the left plot and all the “*” marks will be on the diagonal of the right plot. Observe from Fig. 50.3 that MARS does not give a good fit for a sample size of 100. In fact, for this sample size, none of the curve-fitting methods in PSUADE gives adequate results.

To improve the quality of the response surface, more sample points were added. Figure 50.4 shows the response surface validation results from using 500 sample points with Kriging, which gives a much better fit.

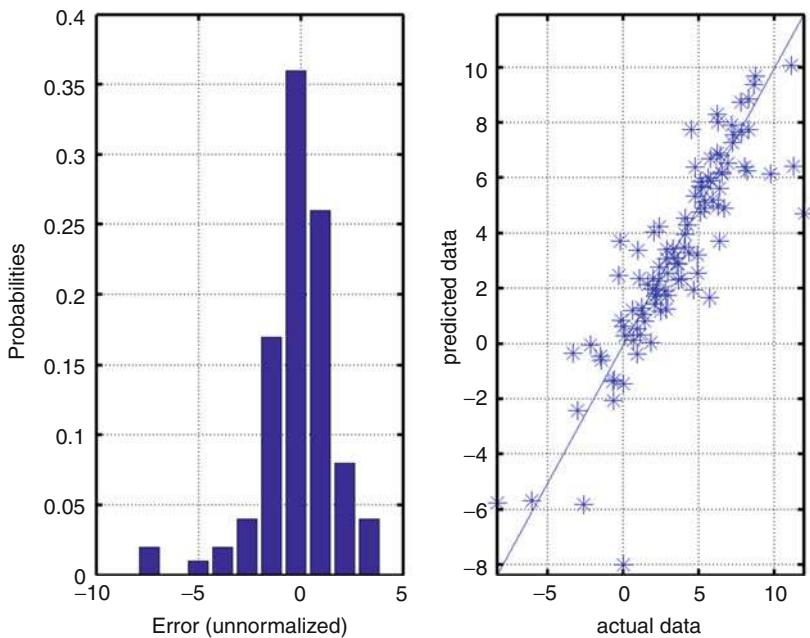

Fig. 50.3 MARS response surface validation for the Ishigami function

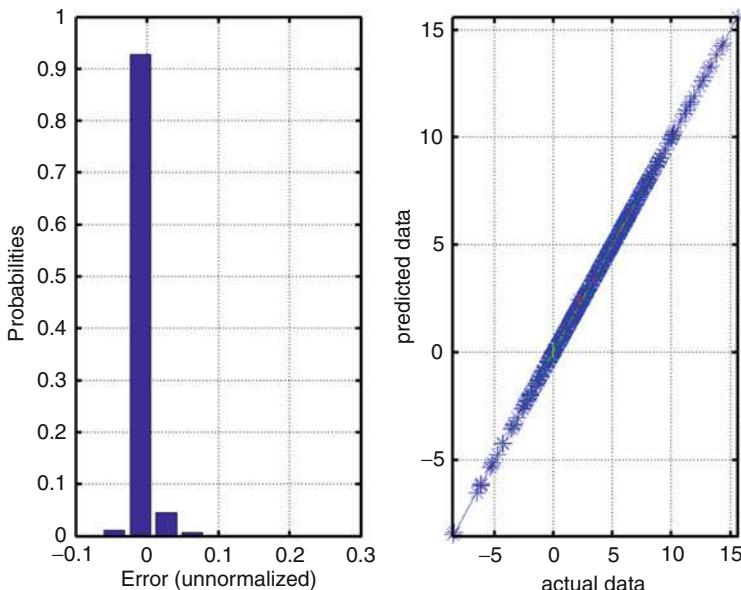

Fig. 50.4 Kriging response surface validation for the Ishigami function

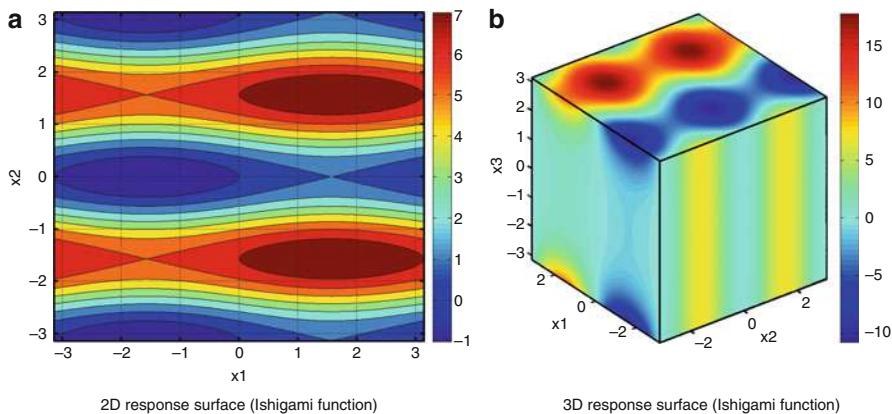

Fig. 50.5 Response surface visualization of the Ishigami function: 2D (*left*), 3D (*right*)

- Once the response surface validation has been completed, the response surface can be visualized with Matlab. For example, to generate a two-dimensional response surface plot using X_1 and X_2 in the Ishigami function, do:

```
[Linux prompt] psuade
...
psuade> load psdata
load complete : nSamples = 500
            nInputs = 3
            nOutputs = 1
psuade> rs2
Grid resolution ? (32 - 256) 256
# When prompted for the RS type, select kriging
...
matlabrs2.m is now available for response surface
and contour plots
```

Upon completion, `matlabrs2.m` can be run in Matlab for viewing the response surface. Three-dimensional plots can be generated in a similar manner using `rs3`. Examples of two- and three-dimensional plots are given in the Figure 50.5.

2.2.3 Adaptive Response Surface Analysis in PSUADE

PSUADE also provides computational tools for adaptive response surface analysis. Adaptive analysis can help reduce the simulation cost when “significant” variations in the simulation outputs are localized in some small regions in the parameter space. Adaptive analysis begins with the generation of a small (e.g., 50) initial space-filling sample. This sample is run on the simulation model and subsequently analyzed for

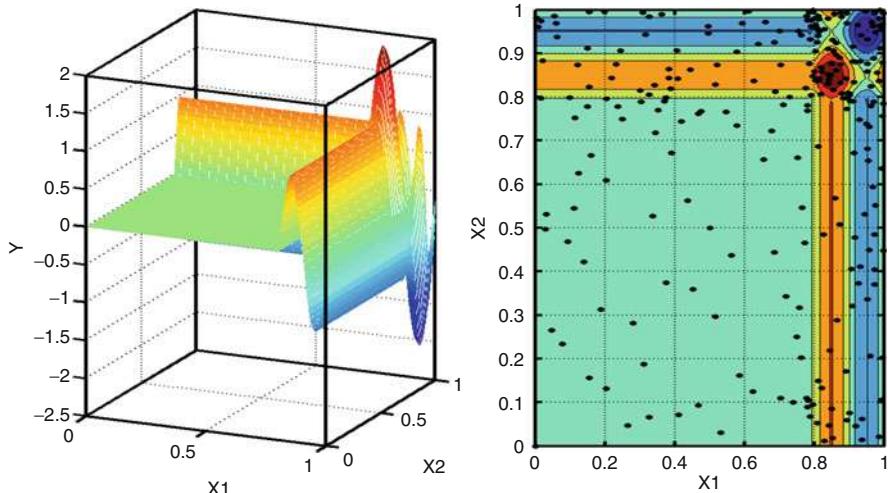

Fig. 50.6 An example of adaptive response surface analysis (dots denote sample points)

a good response surface fit. If more sample points are needed, adaptive sampling refinement can be performed using the `a_refine` command:

```
[Linux prompt] psuade
...
psuade> load <name of your sample file>
psuade> a_refine
...
How many sample points to add? <enter a number>
...
psuade> write <new sample file>
psuade> quit
[Linux prompt]
```

The steps above may be repeated multiple times to manually increment the sample size until the response surface errors are acceptable. This process can also be automated via PSUADE's batch processing mode (an example is provided in the software package). Figure 50.6 shows the result of applying adaptive response surface analysis to the following function (observe the higher density of sample points, represented by “*dots*,” in the highly oscillatory regions):

$$Y = \begin{cases} 0 & \text{if } X_1 \leq 0.8, X_2 \leq 0.8 \\ \sin(10\pi(X_1 - 0.8)) & \text{if } X_1 > 0.8, X_2 \leq 0.8 \\ \sin(10\pi(X_2 - 0.8)) & \text{if } X_1 \leq 0.8, X_2 > 0.8 \\ \sin(10\pi(X_1 - 0.8)) + \sin(10\pi(X_2 - 0.8)) & \text{otherwise} \end{cases}$$

In this case the initial sample size is 50 and 10 refinements are performed each with an additional 20 sample points, so the total number of sample points is 250. Subsequently, the MARS response surface is used to produce the response surface plot.

2.3 Uncertainty Analysis

The term “uncertainty analysis” is distinguished from “uncertainty quantification” in the sense that the former pertains narrowly to the estimation of the statistical moments and other metrics for characterizing model output uncertainties. For example, aleatory uncertainties can be described by basic statistics such as mean, standard deviation, skewness, and kurtosis. In addition, confidence of the calculated mean can be assessed by computing the standard error of mean. These quantities can then be used to certify or to quantify the uncertainty of a design under study. On the other hand, epistemic uncertainties should be quantified by lower and upper bounds. As for mixed uncertainty types, more complex mechanisms, such as probability bounds analysis, are more appropriate.

2.3.1 Uncertainty Analysis Methods in PSUADE

There are three types of uncertainty analysis in PSUADE:

1. Uncertainty analysis performed directly on large samples
2. Uncertainty analysis performed on response surfaces
3. Aleatory-epistemic uncertainty analysis performed on response surfaces

Since the accuracy of the estimated uncertainty metrics depends largely on the sample size (tens of thousands) and simulation costs are generally expensive, response surface-based uncertainty analysis is to be preferred in most cases. The first two types above are for uncertain parameters with known probability distribution functions. When there are also uncertain parameters that are epistemic – meaning that their probability distributions are not known – the third type is more suitable. In this mixed case, the epistemic parameters are described by their lower and upper bounds only, and ensemble uncertainty analysis is performed in a double inner-outer iterative loop. For each outer iteration, a sample point is drawn from the epistemic variables and uncertainty analysis is performed on the aleatory variables. The final results will be an ensemble of cumulative distribution functions (CDFs). The lower and upper bounds of these ensemble CDF plots provide useful information for, for example, probability bound analysis in the presence of epistemic uncertainty.

2.3.2 How to Perform Uncertainty Analysis in PSUADE

The steps to perform response surface-based uncertainty analysis using PSUADE are as follows:

1. Create a response surface for the simulation model by following the steps in the response surface analysis section. Upon completion, a sample file (say, `psdata`) and a suitable curve-fitting method will be available for the next step.
2. This step creates a large sample to be propagated through the response surface. Take the response surface created previously for the Ishigami function; first create a PSUADE input file (say, `psuadeRSUA.in`) as follows (note the absence of a driver since the objective is to create a sample only):

```

PSUADE
INPUT
    dimension = 3
    variable 1 X1   = -3.1416  3.1416
    variable 2 X2   = -3.1416  3.1416
    variable 3 X3   = -3.1416  3.1416
    PDF  1  N  0  0.6
    PDF  2  T  0  3.1416
    PDF  3  N  0  0.6
    COR  1  3  0.1
END
OUTPUT
    dimension = 1
    variable 1 Y
END
METHOD
    sampling = MC
    num_samples = 100000
END
END

```

The large sample will be drawn from a multivariate probability distribution function specified in the **INPUT** section where inputs 1 and 3 are normal distributions with zero means, standard deviations of 0.6, and a correlation of 0.1 (correlation is allowed only for normal distributions), and input 2 has a triangular probability distribution centered at 0 with a spread of π on each side. Other distribution types available in PSUADE are:

- (a) Lognormal parametrized by a $\log(\mu)$ and a standard deviation
- (b) Beta distribution parametrized by $\alpha > 0$ and $\beta > 0$
- (c) Weibull distribution parametrized by $\lambda > 0$ and $k > 0$
- (d) Gamma distribution parametrized by $\alpha > 0$ and $\beta > 0$
- (e) Exponential distribution parametrized by $\lambda > 0$
- (f) F distribution parametrized by $d_1 > 0$ and $d_2 > 0$
- (g) User-specified distribution provided in a sample file

3. Run this PSUADE input file to create a large sample in the file `sample`:

```
[Linux prompt] psuade psuadeRSUA.in
...
[Linux prompt] mv psuadeData sample
```

4. Perform uncertainty analysis using **rsua** or **rsuab** in command line mode:

```
[Linux prompt] psuade
...
psuade> load psdata
load complete : nSamples = 500
            nInputs = 3
            nOutputs = 1
psuade> rsua
Please enter your choice (response surface
type) : 18 <Kriging>
...
Output distribution plots are in matlabrsua.m.
psuade> quit
```

Upon completion, **matlabrsua.m** can be run in Matlab for viewing the probability distribution function. Alternately, one can use **rsuab** (**rsua** with bootstrapping) to also account for response surface uncertainties. An example Matlab plot is given in Fig. 50.7.

5. If the set of uncertain parameters contains both aleatory and epistemic parameters, a mixed uncertainty analysis can be performed using the **aeua** command. A PSUADE session to perform this analysis on the Ishigami function with X_2

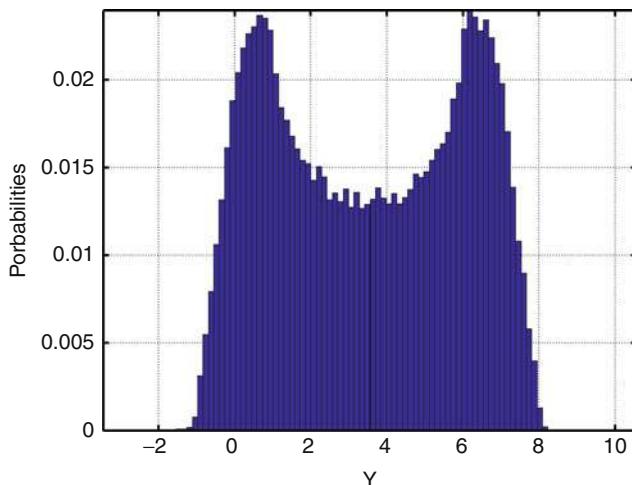

Fig. 50.7 Output probability distribution for the Ishigami function

as an epistemic variable is given below. In this analysis X_2 was re-ranged to $[-0.2, 0.2]$ and both X_1 and X_3 were given a normal distribution with zero mean and a standard deviation of 0.6. (Note: these re-ranged settings are to be provided in the sample file psdata. In addition, the response surface to be used in this analysis should also be set in this file.)

```
[Linux prompt] psuade
....
psuade> load psdata
load complete : nSamples = 500
            nInputs = 3
            nOutputs = 1
psuade> aeua
....
Step 1: select aleatory and epistemic parameters
Select epistemic parameters (1 - 3, 0 if
done) : 2
Select epistemic parameters (1 - 3, 0 if
done) : 0
....
Plot file for aleatory-epistemic analysis is now
in matlabaeua.m.
psuade> quit
```

Upon completion, `matlabaeua.m` can be run in Matlab for viewing the ensemble cumulative distribution function (CDF) plots. An example plot is given in Fig. 50.8:

2.4 Quantitative Sensitivity Analysis

Sensitivity analysis (SA) is the study of how the output variation of a model describing a certain static or dynamic process can be accounted for by variations in the model uncertain parameters. Only global sensitivity analysis, which studies the effects of the variations of uncertain parameters on the model outputs in the entire allowable ranges of the parameter space, is considered here. Saltelli et al. [13, 14] defines global methods by two properties:

1. The inclusion of influence of scales and shapes of the probability density functions for all inputs.
2. The sensitivity estimates of individual inputs are evaluated while varying all other inputs.

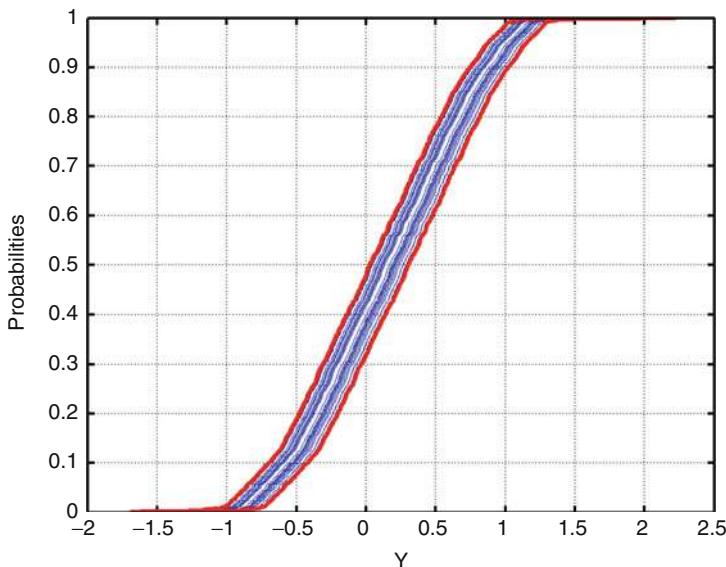

Fig. 50.8 Aleatory-epistemic CDF plot for the Ishigami function

One popular metric for quantitative sensitivity analysis is based on variance decomposition. This is a suitable metric if the objective is to quantify the contribution of each uncertain parameter toward the total output variance (i.e., metric that quantifies the percentages of the output variance from individual parameters).

2.4.1 Sensitivity Analysis Methods in PSUADE

There are three common types of variance-based sensitivity analysis:

- Main effects (first-order sensitivities: `rssobol1`, `rssobol1b`)
- Pairwise effects (second-order sensitivities: `rssobol2`, `rssobol2b`)
- Total order sensitivities (`rssoboltsi`, `rssoboltsib`)

where, for example, `rssobol1` is the PSUADE command for main effect analysis and `rssobol1b` is its bootstrapped version, which also provides uncertainty bounds for the sensitivity measures.

Since variance-based sensitivity analysis requires large samples to achieve sufficient accuracy, it is best performed on response surfaces that have been validated, although tools for computing sensitivity metrics directly from the samples are also available. Variance-based sensitivity analysis tools are available in both batch and command line modes. An example is given below for command line mode only.

The steps to perform uncertainty analysis using PSUADE are as follows:

1. Create a response surface for the simulation model by following the steps in the response surface analysis section. Upon completion, a sample file (say, `psdata`) and a suitable curve-fitting method will be available for the next step.
2. Launch and run PSUADE's command line interpreter as follows:

```
[Linux prompt] psuade
psuade> load psdata <This is a sample for the
Ishigami function)
...
psuade> rssobol1b
....
How many bootstrapped samples to use (10 - 300):10
...
Sobol1 Statistics (based on 10 replications):
Input 1: mean = 4.17199676e-01, std = 4.63387907e-02
Input 2: mean = 4.79228971e-04, std = 1.51545507e-03
Input 3: mean = 5.82298908e-01, std = 4.68131716e-02
rssobol1b plot file = matlabrssobol1b.m
...
psuade> quit
```

3. View parameter sensitivities by running `matlabrssobol1b.m` in Matlab. Figure 50.9 shows an example of both the first- and second-order (with first-order) sensitivity analysis results (second-order sensitivity analysis produces a Matlab file called `matlabrssobol2b.m`). Comparing the first- and second-order sensitivity plots, the second-order sensitivity (which includes first-order sensitivity) plot shows that there is some nontrivial interaction between X_1 and X_3 , which is clear from inspecting the Ishigami function. Similarly, total sensitivity analysis can be performed using the same procedure.

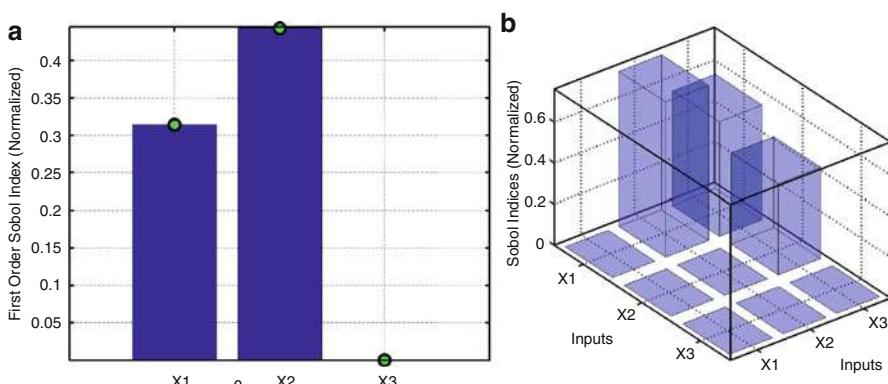

Fig. 50.9 Sensitivity analysis results. (a) First-order sensitivities. (b) First- and second-order sensitivities

Main effect analysis also supports the use of parameter distributions (which should be specified in the sample file, `psdata`). In addition, the `rssobolg` command enables group (dividing the parameter space into groups of parameters) sensitivity analysis.

2.5 Parameter Inference

A basic element of model validation is the comparison of data generated by a simulation model with experimental data. Due to the many uncertainties and unknowns in creating a simulation model, perfect match between simulation outputs and experimental data can rarely be achieved without some parameter tuning or model calibration. Calibration is essentially an optimization problem: given a set of parameters and their ranges, search for the parameter values that best match the data. Two optimization approaches can be used for model calibration, namely, deterministic numerical optimization and Bayesian optimization.

2.5.1 Deterministic Optimization Methods in PSUADE

In deterministic optimization, an objective function (e.g., sum-of-squares error) is first constructed from simulation model outputs and experimental data. In addition, the optimization (or design) parameters are to be specified with their initial guesses and their bounds. PSUADE currently only provides several derivative-free global optimization methods for bound-constrained problems: e.g.,

- `bobyqa`: a bound-constrained optimizer by Powell [11]
- `SCE`: a shuffled complex evolution method by Duan [2]
- `MM`: a two-level optimizer by Echeverria [3]

An example PSUADE input file (say, `psuadeBobyqa.in` to set up the optimization is given below.

```

PSUADE
INPUT
dimension = 5
variable 1 X1 = -2.0    2.0
variable 2 X2 = -2.0    2.0
variable 3 X3 = -2.0    2.0
variable 4 X4 = -2.0    2.0
variable 5 X5 = -2.0    2.0
END
OUTPUT
dimension = 1
variable 1 Y
END
METHOD

```

```

    sampling = MC
    num_samples = 1
END
APPLICATION
    opt_driver = simulator
END
ANALYSIS
    optimization method = bobyqa
    optimization tolerance = 1.000000e-06
END
END

```

This example has 5 optimization parameters with lower and upper bound -2 and 2 , respectively. The optimizer is **bobyqa** and the initial guess is a point drawn using a Monte Carlo sampling scheme (it is also possible to specify a user-generated initial guess).

Suppose the simulation model **simulator** is a 5-parameter Rosenbrock function compiled from:

```

#include <math.h>
#include <stdio.h>
main(int argc, char **argv) {
    int n, i;
    double X[5], Y=0.0;
    FILE *fileIn = fopen(argv[1], "r"), *fileOut;
    fscanf(fileIn, "%d", &n);
    for (i = 0; i < n; i++) fscanf(fileIn, "%lg", &X[i]);
    for (i = 0; i < n-1; i++)
        Y += (pow(1 - X[i], 2.0) + 100 * pow(X[i+1]
        - X[i]*X[i], 2.0));
    fileOut = fopen(argv[2], "w");
    fprintf(fileOut, "%24.16e\n", Y);
    fclose(fileIn); fclose(fOut);
}

```

The optimal solution will be obtained by launching PSUADE with

```

[Linux prompt] psuade psuadeBobyqa.in
....
PSUADE OPTIMIZATION : CURRENT GLOBAL MINIMUM -
    X      1 = 1.00000014e+00
    X      2 = 1.00000028e+00
    X      3 = 1.00000058e+00
    X      4 = 1.00000115e+00
    X      5 = 1.00000231e+00
                    Ymin = 1.80113178e-12

```

There are other optimization options and parameters that can be set to fine-tune the process (e.g., convergence tolerance and maximum number of function evaluations).

2.5.2 Bayesian Inference Methods in PSUADE

To describe the complex operations in inference, a more formal presentation is given below.

Let the simulation model be given by $Y = M(X, \theta)$ where X is some design parameter (assumed to be scalar for reason of simplification) and θ is an uncertain parameter that needs to be calibrated, and let $D(X^*)$ be the measurement data (also assumed scalar) at some design configuration X^* . The Bayes' formula relates the best θ values that match $D(X^*)$ via

$$\pi(\theta|D(X^*)) \propto p(D(X^*)|\theta)p(\theta)$$

where $p(\theta)$ (called the “prior” distribution) represents the initial knowledge of the likely values of θ ; $p(D(X^*)|\theta)$ is the likelihood function (probability that a specific setting of θ exactly produces $D(X^*)$ from the simulator; and $p(\theta|D(X^*))$ (called the “posterior”) represents the revised knowledge of the likely values of θ based on matching simulation results against measurements $D(X^*)$.

A popular likelihood function is the exponentiation of some error metric such as the weighted sum-of-squares errors:

$$p(D(X)|\theta) = C \exp\left(-0.5 \frac{(D(X^*) - M(X^*, \theta))^2}{\sigma_D^2}\right).$$

where σ_D is the standard deviation of $D(X^*)$ (measurement noise) and C is some normalization constant. A popular method for computing the posteriors is the Markov Chain Monte Carlo (MCMC) method using Gibbs or Metropolis-Hastings samplings.

Suppose an imperfect simulation model is given, which results in the presence of systematic errors between the model outputs and measurements. A set of measurement data $D(X_i^*)$, $i = 1, \dots, m_e$ is also given to mitigate the model imperfection. It has been shown [9] that accounting for systematic errors may have significant effect for robust calibration. One approach to model the systematic errors is to introduce a discrepancy model $\delta(X)$ built from the simulation outputs and measurement data:

$$\delta(X_i^*) = D(X_i^*) - M(X_i^*, \theta^*) \quad i = 1, \dots, m_e$$

where θ^* is a preselected set of values for the uncertain parameters (based on best prior knowledge about the calibration parameter). This preselection is needed to alleviate the “identifiability” problem). This discrepancy data set is used to construct the corresponding discrepancy function $\delta(X)$ using any regression technique

(but preferably global methods such as polynomial regression or Gaussian process). With this additional discrepancy model, the calibration process proceeds on the following modified simulation model

$$\tilde{M}(X, \theta) = M(X, \theta) + \delta(X)$$

in place of $M(X, \theta)$ in the Bayes' formulas.

2.5.3 An Example for Bayesian Inference Using PSUADE

To illustrate Bayesian inference with discrepancy modeling, consider the following simulation model:

$$Y = \theta X$$

where X and θ are the design and calibration parameters, respectively.

To perform Bayesian calibration, follow the steps below:

1. Create a response surface for the simulation model using the following PSUADE input file:

```
PSUADE
INPUT
    dimension = 2
    variable   1 X      = 0.2      4.0
    variable   2 B      = 0.35     0.75
END
OUTPUT
    dimension = 1
    variable 1 Y
END
METHOD
    sampling = LH
    num_samples = 50
END
APPLICATION
    driver = simulator
END
END
```

where `simulator` is compiled from

```
#include <stdio.h>
main(int argc, char **argv) {
    int i, n;
    double X[2], Y;
```

```

FILE *fileIn = fopen(argv[1], "r"),
*fileOut;
fscanf(fileIn, "%d", &n);
for (i = 0; i < n; i++) fscanf(fileIn, "%lg", &X[i]);
Y = X[0] * X[1];
fileOut = fopen(argv[2], "w");
fprintf(fileOut, "%24.16e\n", Y);
fclose(fileIn); fclose(fOut);
}

```

After running PSUADE on the above input file, rename the sample output file to **simdata**. To make sure that this sample set is adequate, perform a response surface validation using, for example, the quadratic regression method.

2. Prepare the experimental data for use in constructing the likelihood function. Suppose the true model (which is generally not known) is of the following form:

$$\delta(X) = \theta^* X / (1 + 0.05X)$$

where $\theta^* = 0.65$. This true model is run to produce the following set of experimental data:

```

PSUADE_BEGIN
11 1 1 1
1 2.00e-01 1.2871287128712872e-01 0.1
2 5.80e-01 3.6637512147716234e-01 0.1
3 9.60e-01 5.9541984732824427e-01 0.1
4 1.34e+00 8.1630740393627010e-01 0.1
5 1.72e+00 1.0294659300184161e+00 0.1
6 2.10e+00 1.2352941176470591e+00 0.1
7 2.48e+00 1.4341637010676156e+00 0.1
8 2.86e+00 1.6264216972878389e+00 0.1
9 3.24e+00 1.8123924268502585e+00 0.1
10 3.62e+00 1.9923793395427605e+00 0.1
11 4.00e+00 2.166666666666670e+00 0.1
PSUADE_END

```

This data set above has been put into a special format understood by PSUADE. Specifically, the first and last lines of this file contain the keywords **PSUADE_BEGIN** and **PSUADE_END**, respectively. The second line contains four integers in this example (but in general contains 3 or more integers) denoting the number of measurements (11), the number of outputs of interest (1), the number of design parameters (1), and the input parameter index of the design parameters (1 in this example). Subsequent lines contain measurement data, with each line having the experiment number, the design value(s), the data

mean(s), and the data standard deviation(s) for each output. This data set should be presented to PSUADE as a file, say, `expdata`.

3. Launch PSUADE in command line mode and run the `rsmcmc` command, which uses the response surfaces created from the sample file (`psdata`) and also `expdata` to compute the likelihood values. The MCMC implementation in PSUADE uses Gibbs sampling with multiple Markov chains and discrepancy modeling. An example PSUADE session for this analysis is as follows:

```
[Linux prompt] psuade
...
psuade> load psdata
psuade> ana_expert    # (optional) to turn on more
MCMC options
psuade> rsmcmc
...
# When prompted for a specification file, enter
'expdata'
# When prompted for model response surface,
answer 'quadratic'
# When prompted for discrepancy option, answer 'y'
# When prompted for discrepancy response surface,
answer 'Kriging'
# When prompted for posterior sample option,
answer 'y'
# When prompted for posterior plot, select input
2 for plot
# At the end, three files will have been created
# 1. a posterior sample file ('MCMCPostSample')
# 2. a Matlab file for plotting the posteriors
('matlabmcmc2.m')
# 3. a discrepancy sample file ('psDiscrepancyModel')
```

To generate the posterior plot, launch Matlab and run `matlabmcmc2.m`. The posterior plot for parameter 2 (θ) is given in Fig. 50.10. The value of θ with peak probability is at around $\theta = 0.55$, which has been set earlier in constructing the discrepancy model. A general posterior plot is given in Fig. 50.11. The histogram plots in the figure correspond to the posterior distributions of individual parameters, while the heatmap plot corresponds to joint posterior for the of parameters.

4. Examine the discrepancy model: if discrepancy modeling is activated (as in this example), a discrepancy sample file will have been created at the end of inference. This file is in the standard PSUADE data format, which can be loaded and analyzed as described above. Specifically, it can be verified via the `rscheck` command that Kriging is a suitable response surface. The corresponding Matlab plot is shown in Fig. 50.12.

Recall that the exact discrepancy function is

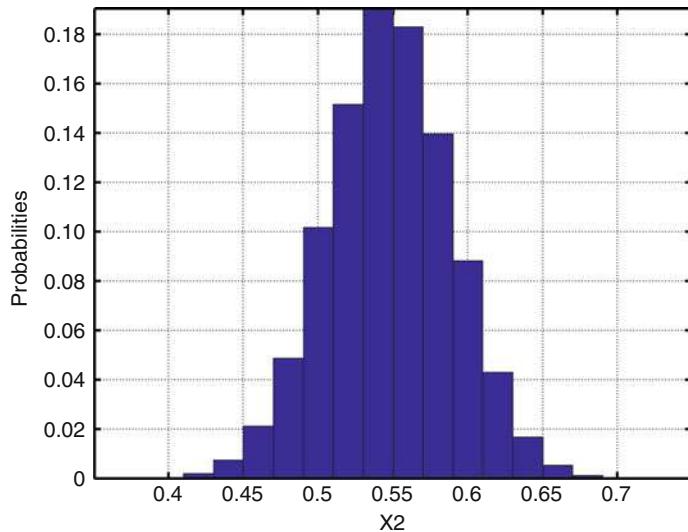

Fig. 50.10 The MCMC posterior distribution plot for this example

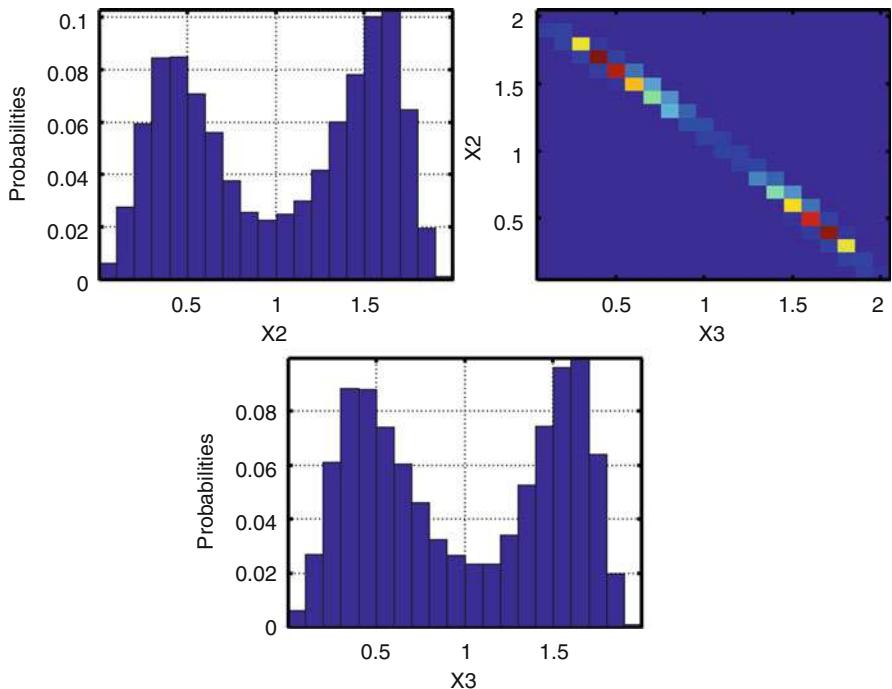

Fig. 50.11 Another example of MCMC posterior distribution plots

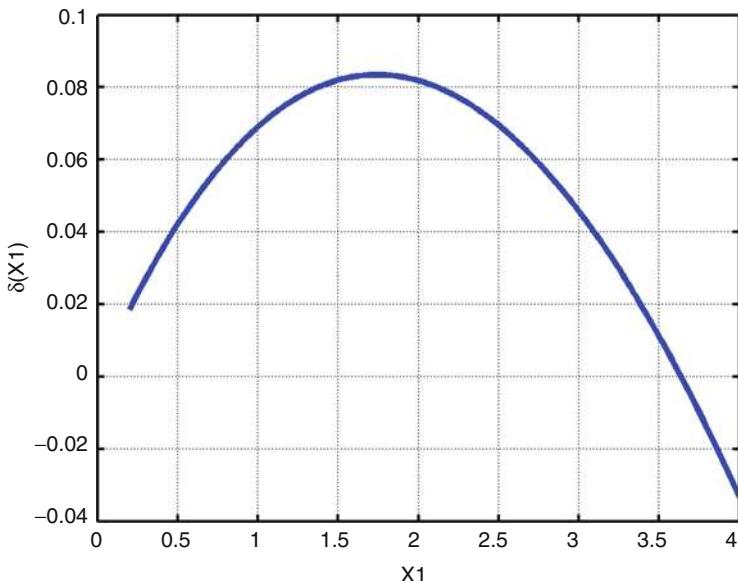

Fig. 50.12 Kriging response surface of the discrepancy model

$$\delta(X) = Y_e(X, \theta = 0.65) - Y(X, \theta = 0.55) = 0.65X/(1 + 0.05X) - 0.55 * X.$$

Observe that the discrepancy plot agrees well with this functional form.

5. Finally, the corrected model $Y^*(X, \theta) = Y(X, \theta) + \delta(X)$ can be used to predict other untested designs (other X 's). For example, to predict the model response at $X = 0.8$, do the following:

```
[Linux prompt] psuade
...
psuade> iread MCMCPostSample      # read the
          posterior sample
psuade> ireset                      # reset X = 0.8
...
psuade> write sample                # a sample around
          X = 0.8
psuade> load simdata               # load the
          simulation data
psuade> rsua                        # response surface
          -based analysis
# When prompted for discrepancy model, answer
# 'y', enter
# 'psDiscrepancyModel', and select Kriging.
# When prompted for the 'UA sample', enter
```

```

'sample'
# When prompted for model response surface, enter
'quadratic'
Output distribution plots are in matlabrsua.m.
psuade>

```

Upon completion, the prediction distribution at $X = 0.8$ can be visualized in Matlab, as given in Fig. 50.13. Observe that the prediction mean is around 0.5 consistent with the corrected model. (Note: calibration without the use of discrepancy modeling estimates the prediction mean to be 0.45) The prediction standard deviation is around 0.033, which has been induced by uncertainties in the posterior of θ .

2.6 Optimization Under Uncertainty

Consider again the simulation model $Y = M(X, \theta)$ where X is a design parameter and θ is an uncertain parameter. Suppose the objective is to minimize Y with respect to X . To include the effect of θ in the optimal solution, one approach is to minimize some functional Φ of Y with respect to θ (e.g., the mean of Y):

$$\min_X \Phi_\theta(M(X, \theta))$$

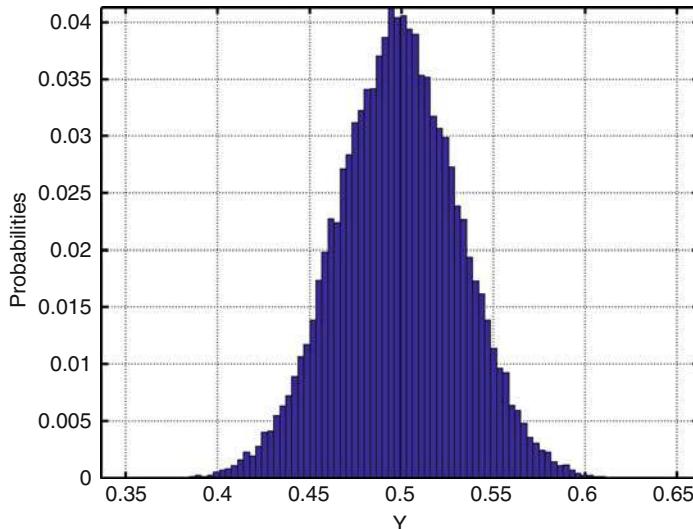

Fig. 50.13 Predicted distribution of the corrected model at $X = 0.8$

subject to some constraints on the inputs (e.g., bound, equality, or inequality constraints). A popular variant of this formulation (by computing the minimum value in the functional Φ on a discrete set of θ) is the scenario optimization problem:

$$\min_X \frac{1}{N} \sum_{i=1,\dots,N} M(X, \theta_i) p(\theta_i)$$

subject to some constraints on the inputs, where N is the number of scenarios drawn from θ and $p(\theta_i)$ is the probability of the i -th scenario.

Here N should be chosen to estimate the statistical quantities with sufficient accuracy. As such, a large sample may be needed. PSUADE provides the option to compute these estimates via response surfaces.

2.6.1 Performing Optimization Under Uncertainty in PSUADE

To solve the above problems in PSUADE, follow the steps below:

1. Create a PSUADE input file (sf psuadeOUU.in) specifying both the design (D_1, D_2) and uncertain parameters (W_1, W_2) in the INPUT section, set the optimization driver (opt_driver) to point to the simulation code ($M(X, \theta)$ or optdriver), and turn on the ouu optimization method. An example of this input file is

```

PSUADE
INPUT
    dimension = 4
    variable 1 D1 = -5      5
    variable 2 D2 = -5      5
    variable 3 W1 = -5      5
    variable 4 W2 = -5      5
END
OUTPUT
    dimension = 1
    variable 1 Y
END
METHOD
    sampling = MC
    num_samples = 1
END
APPLICATION
    opt_driver = optdriver
END
ANALYSIS
    optimization method = ouu
END
END

```

2. Run optimization in batch mode. Additional information will be requested in setting other options.

```
[Linux prompt] psuade psuadeOUU.in
# When prompted, enter the number of design and
# uncertain parameters
# When prompted, enter the sample file for the
# scenarios, or have PSUADE generate one for you
# Set other options
...
# Upon completion, the optimal values will be
# displayed.
```

PSUADE provides other more complex optimization under uncertainty solvers not covered in this chapter.

2.7 Other PSUADE Capabilities

There are other notable features in PSUADE that have been designed to assist users in improving the efficiency of certain computational analyses, diagnosing sample anomalies, and handling more complex data manipulations. Some of these features are:

1. Parallel analysis for
 - (a) The k-fold cross validation in response surface analysis
 - (b) The Kriging response surface method
 - (c) The bootstrapped quantitative sensitivity analysis methods
 - (d) The Bayesian inference using multiple chainsTo be able to use these parallel tools, PSUADE will have to be compiled with the MPI (message passing interface) library.
2. Support for a number of probability distributions such as multivariate Gaussian, lognormal, gamma, beta, Weibull, triangle, exponential, and nonanalytical distributions that are characterized by a user-provided sample (this last option is useful for the advanced hierarchical UQ analysis).
3. Read/write from/to files of different data formats
4. Sample data manipulation such as adding/deleting an input or output, input-output filtering, and sample splitting
5. Sample visualization such as input and output scatter plots (useful for detecting outliers)

In addition, a graphical user interface is currently under development to provide a more user-friendly environment for using these capabilities [7].

3 Conclusion

PSUADE comprises a rich set of mathematical and statistical tools for quantifying uncertainties and sensitivities. In addition to the analysis tools, it also provides many tools to generate Matlab files for visualizing response surfaces and uncertainties, automating the launching of ensemble simulations, as well as examining and manipulating sample data. This toolkit is suitable for quantifying uncertainties of both simple and complex simulation models.

Probabilistic Analysis Using NESSUS (Numerical Evaluation of Stochastic Structures Under Stress)

51

John M. McFarland and David S. Riha

Abstract

NESSUS is a general-purpose software program for probabilistic analysis with original development beginning in the 1980s as part of a 10-year NASA project focused on predicting risk and reliability of space shuttle main engine components. NESSUS now includes a streamlined graphical interface, 16 different reliability methods, interfaces to many third-party commercial analysis codes, and the ability to define custom interfaces to computational models. Recent developments have added powerful tools for global sensitivity analysis and have expanded the response surface methods to include Gaussian process modeling. This chapter highlights NESSUS's core capabilities and gives an overview of setting up and solving a probabilistic analysis problem using the software. A detailed tutorial is used to illustrate how to use NESSUS to perform a probabilistic analysis on a finite element model. A turbine blade case study is then presented to illustrate a practical solution strategy for assessing model uncertainties for computationally intensive models. The strategy demonstrates the use of response surface models and efficient probabilistic methods to make the best use of model evaluations to iteratively improve the uncertainty assessments.

1 Introduction

NESSUS (Numerical Evaluation of Stochastic Structures Under Stress) is a general-purpose software program for probabilistic analysis. It was originally created by a team led by Southwest Research Institute (SwRI) as part of a 10-year NASA project started in 1984 to develop a probabilistic design tool for the space shuttle main engine with a focus on probabilistic finite element analysis. The methods and capabilities in NESSUS were designed to support predicting the probabilistic response and/or probability of failure for computational intensive models. The input variations were modeled using probability density functions and propagated using traditional and newly developed probabilistic algorithms. In 1999, SwRI was contracted by Los Alamos National Laboratory to adapt NESSUS for application to extremely large and complex weapon reliability and uncertainty problems in support of its Stockpile Stewardship program. In 2002, SwRI was contracted by the NASA Glenn Research Center to further enhance NESSUS for application to large-scale aero-propulsion system problems. The end result of these large research programs was a completely redesigned software tool that includes a sophisticated graphical user interface (GUI), capabilities for performing design of experiments and sensitivity analysis, a probabilistic input database, a geometric uncertainty modeling tool for perturbing geometry in existing finite element models, and state-of-the-art interfaces to many third-party codes such as Abaqus, ANSYS, LS-DYNA, MSC.NASTRAN, and NASGRO.

NESSUS has seen continuous improvement and application since its beginnings in the late 1980s. Most recently, the CENTAUR (Collection of ENgineering Tools for Analyzing Uncertainty and Reliability) software library, which contains an array of methods for solving various types of problems with an emphasis on nondeterministic analysis, was developed to support NESSUS. CENTAUR provides methods for reliability analysis, distribution fitting, Bayesian uncertainty quantification, numerical optimization, and more. CENTAUR has been under active development since 2008 and provides several of the reliability analysis methods used by NESSUS.

NESSUS has been applied to a diverse range of problems to support decisions in such areas as aerospace structures, automotive structures, biomechanics, gas turbine engines, geomechanics, offshore structures, pipelines, pressure vessels, space

systems, and weapon systems. These probabilistic and uncertainty quantification analyses have supported decisions in design, failure analysis, and model verification and validation (V&V). The ability to quantify uncertainties in model predictions enables decisions to be made in light of known limitations in the models and data. Probabilistic approaches are also powerful for design analysis to evaluate the impact of variations in new processes, environments, and other uncertainties, especially early in the design process when material and process data are limited.

Uncertainty quantification is a key component of model V&V, which is a framework for collecting evidence and building credibility to substantiate that a model is adequate for its intended use. A successful V&V program includes assessments of the uncertainties in both experimental and simulation results, as well as sensitivity analysis to identify important variables. NESSUS provides a suite of uncertainty propagation methods to support V&V through quantification of uncertainty in the model output. In addition, NESSUS can be used to conduct various types of sensitivity studies, which may be used to guide model development and experimental activities, or to substantiate model assumptions/simplifications.

Commercial and academic licenses for NESSUS may be obtained directly from Southwest Research Institute. More information as well as demonstration licenses can be obtained through the website at www.nessus.swri.org. NESSUS is available for the Windows, Mac, and Linux platforms. NESSUS is installed by simply downloading and running the installer file, and the provided license key is then installed using the GUI.

This chapter gives an overview of the NESSUS software and its capabilities, followed by a description of the steps involved in setting up and executing a probabilistic analysis using NESSUS. Next, a detailed tutorial is presented that demonstrates a probabilistic analysis for a simple finite element model of a plate with a hole. Lastly, a case study involving a turbine blade is presented to illustrate a practical solution strategy to answer questions about the importance of potential uncertainties in the model. The strategy demonstrates the use of response surface models and efficient probabilistic methods to make the best use of model evaluations to iteratively improve the uncertainty assessments.

2 Capabilities Overview

NESSUS allows users to perform probabilistic analysis with analytical models, external computer programs such as commercial finite element codes, and general combinations of the two. NESSUS includes a graphical user interface that facilitates formulation of the problem and visualization of results.

While NESSUS was originally developed for reliability analysis by propagation of random variables through one or more performance models, it now contains a variety of related capabilities for working with models. These include generation of designs of experiments (including space-filling Latin hypercube designs), various methods for sensitivity analysis (including global sensitivity analysis, also known as variance decomposition), and sophisticated response surface modeling capabilities.

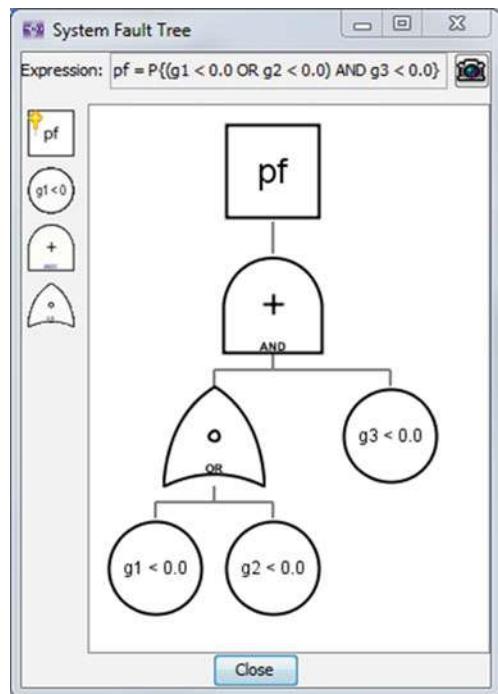

The core functionality of NESSUS is to compute the cumulative distribution function (CDF) of model responses using methods that can accurately and efficiently compute tail probabilities. The generated CDF is used to quantify the variability or uncertainty in the model predictions and to support probability of failure and reliability analyses. In NESSUS, a probabilistic analysis problem is formulated in terms of a series of equations that establish a performance function, g , which relates the input random variables, X , to the response variable, Z :

$$Z = g(\mathbf{X})$$

Next, the user may define one or more “specified performance values,” which NESSUS uses to compute probabilities. By convention, NESSUS computes the probability that the performance is less than each specified performance value. This is the traditional forward reliability analysis problem. NESSUS also allows the user to set up an inverse reliability analysis problem, in which case the user specifies the probabilities and NESSUS computes the corresponding performance levels.

NESSUS also allows users to define system-level reliability analysis problems using a graphical fault tree editor (Fig. 51.1). An individual limit-state equation is defined for each failure mode, and the system-level probability of failure is formulated in terms of these using any general combination of “AND” and “OR”

Fig. 51.1 NESSUS fault tree editor for system reliability analysis

gates. The probabilistic fault tree formulation in NESSUS correctly accounts for common variables in the failure events [1].

NESSUS includes a variety of capabilities for working with response surface models. The user may provide a set of training data and have NESSUS fit a response surface model using either polynomial or Gaussian process (GP) regression. The GP model supports several options for noise in the response data, including noise-free data (resulting in a response surface that exactly interpolates the training data), a user-defined noise level, or automatic estimation of the noise level (ideal when modeling data from physical experiments). NESSUS includes goodness-of-fit information based on leave-one-out cross-validation assessment [2] as part of the output. Response surface models created from user-provided training data can be interrogated using Monte Carlo simulation or any of the other deterministic or probabilistic analysis methods available in NESSUS.

In addition, NESSUS includes several tailored probabilistic methods that use response surface models internally. When using these methods, NESSUS automates several steps that the user would normally do, including generation of the DOE, analysis of the true performance model at each design point, creation of the response surface model, and finally random sampling using the response surface to compute a probability. The efficient global reliability analysis (EGRA) method uses an adaptive procedure designed to target response surface accuracy near the limit state to achieve an accurate and efficient probability estimate.

NESSUS has tailored capabilities for the design of computer experiments using Latin hypercube sampling. This includes the ability to search for optimal designs based on a minimum distance criterion, correlation reduction using the Iman-Conover algorithm [3], and the capability to augment designs while maintaining the Latin hypercube property.

NESSUS includes 16 different reliability methods, which include sampling methods, analytical methods, and response surface-based methods. These are listed in Table 51.1. All probabilistic methods support forward reliability analysis with a single limit state, but only a subset of the methods support inverse reliability analysis and system reliability analysis problems.

One of the original and most powerful reliability methods in NESSUS is the advanced mean value plus (AMV+) method [4]. The algorithm was developed to efficiently predict the probabilistic response for computationally intensive models. The algorithm iteratively replaces the actual model with a linear response surface to estimate the cumulative distribution function (CDF) over a range of response values. The algorithm is useful for incrementally improving CDF accuracy as the model runs are completed. AMV+ has been demonstrated to successfully identify multiple failure regions in the design space [4] and obtain solutions for noisy response functions [5], two issues that are problematic for most gradient-based probabilistic algorithms.

One of the newest methods in NESSUS is the efficient global reliability analysis (EGRA) method [6]. EGRA uses an algorithm that employs Gaussian process modeling to iteratively select points in the design space targeted at maximizing the

Table 51.1 Probabilistic analysis methods in NESSUS

Probabilistic method	Inverse analysis	System analysis
Monte Carlo sampling	X	X
Latin hypercube sampling	X	
First-order reliability method (FORM)	X

Efficient global reliability analysis (EGRA)	X	
Response surface method	X	
Gaussian process response surface method	X	

accuracy in the vicinity of the limit state. This targeting produces a locally accurate model sufficient for reliability analysis with fewer points than would be required to construct a globally accurate model.

Each of the reliability methods in NESSUS computes probabilistic sensitivity results, which can be used to identify important random variables. These include derivatives of the probability of failure, p , with respect to input random variable distribution parameters, μ and σ :

$$\frac{\partial p}{\partial \mu_i} \frac{\sigma_i}{p} \text{ and } \frac{\partial p}{\partial \sigma_i} \frac{\sigma_i}{p}$$

In addition, methods that employ the most probable point (MPP) concept also compute the associated importance factors associated with the random variables.

Recent work has been devoted to expanding NESSUS's sensitivity analysis capabilities to include methods for global sensitivity analysis using variance decomposition. NESSUS supports variance decomposition using "structured" Monte Carlo sampling, Fourier amplitude sensitivity test (FAST), and analytical solution using a Gaussian process response surface. The structured Monte Carlo sampling method uses an efficient scheme to compute both main and total effects using a single Monte Carlo loop [7]. Options for the use of low-discrepancy Sobol sequences, as well as random Monte Carlo or Latin hypercube sampling, are provided.

3 Problem Formulation and Solution

The process of setting up and solving a probabilistic or uncertainty analysis problem in NESSUS is broken into the following steps:

1. Declaration of variables and equations
2. Definition of basic random variables
3. Definition of numerical models
4. Probabilistic analysis type and method selection
5. Analysis and results visualization

3.1 Problem Statement Definition

The first step when setting up a new problem in NESSUS is to declare the variables and their basic relationships using the “Define Problem Statement” window. This window provides a text field for entry of one or more equations using a simple algebraic syntax. Multiple hierarchical equations can be defined on separate lines and are evaluated from the bottom to the top. For example in Fig. 51.2, first the value of “stress” is computed, and then this result is used in a subsequent equation to compute the value of “life.” For the purpose of probabilistic analysis, the response variable on the left-hand side of the top equation is treated as the overall response variable for the model (i.e., “life” in this example).

For models that have simple algebraic form, the NESSUS problem statement editor may be sufficient to completely define the functional relationships among the variables. For more complex models, the problem statement allows the use of a function notation syntax, which creates placeholders for numerical models to be defined separately. Any combination of numerical and analytical models may be used in the problem statement.

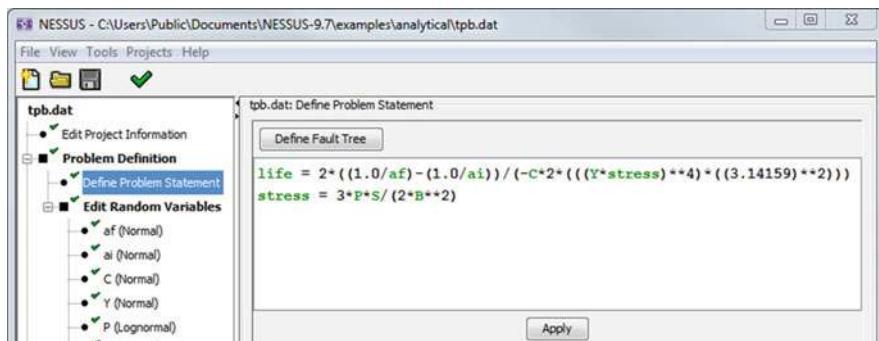

Fig. 51.2 NESSUS problem statement

3.2 Random Variable Input

Once the problem statement is successfully defined, NESSUS automatically identifies the independent variables and the computed variables. The next step for the user is to assign probability distributions to the independent variables. As shown in Fig. 51.3, NESSUS provides a graphical editor for defining the random variables. NESSUS supports 16 different continuous probability distribution models, including the beta distribution, truncated normal and Weibull distributions, and three-parameter generalized extreme value distributions. Where applicable, NESSUS allows for definition of distribution parameters using either natural parameters or mean and standard deviation. Linear (Pearson) correlations between variables are supported for many of the distribution types. In addition, independent variables in the problem statement may also be assigned fixed values and treated as deterministic variables.

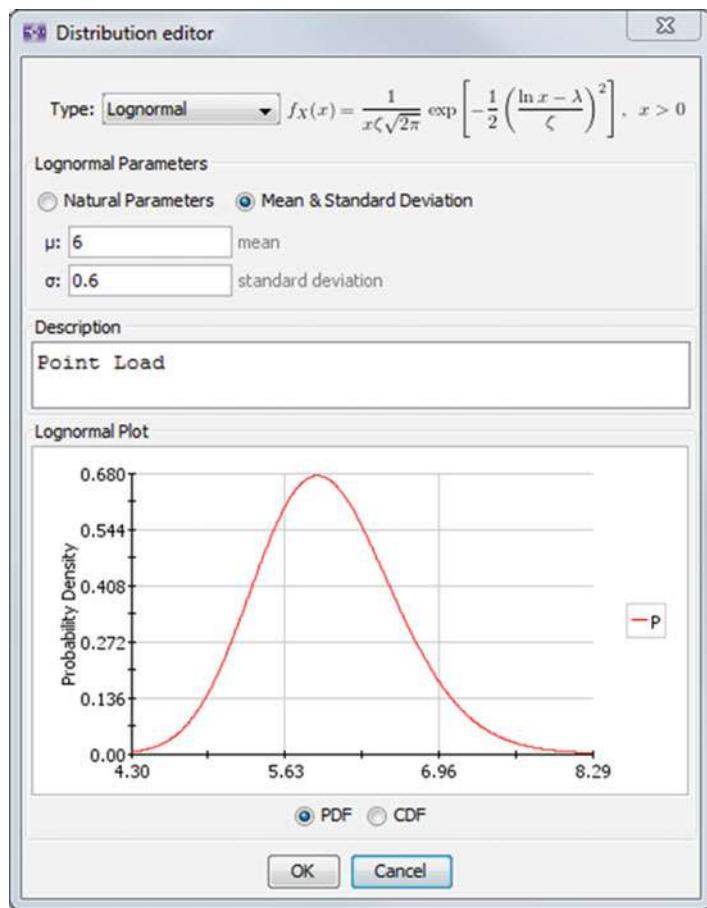

Fig. 51.3 NESSUS probability distribution editor

3.3 Response Model Definition

The next step is to define any response models that have been included in the problem statement using function notation. NESSUS provides several options for how these models may be defined, including “numerical,” “regression,” and “dynamically linked” model types. Numerical models involve the execution of external programs such as commercial finite element codes or scripts created by the user. The regression (response surface) model option includes a Gaussian process model as well as first- or second-order polynomial models. Dynamically linked models allow the user to write C, C++, or Fortran functions for model evaluation and compile the code into a shared library such as a Windows DLL, which is loaded by NESSUS at runtime.

When the “numerical” model type is selected, the “application” menu is used to define the numerical model interface. This menu provides 12 options, which include various commercial codes as well as a “user-defined” option. With the exception of the MATLAB interface, which involves the use of the shared MATLAB runtime libraries, all of the numerical model interfaces involve the use of system calls to external programs. Input and output data are passed between NESSUS and the external programs using file i/o. Input files are typically text-based files with numerical fields that NESSUS can modify. The mechanism for specifying output data is application dependent (e.g., for Abaqus, NESSUS reads directly from the binary ODB results database). The user-defined application uses plain text files for output data. Using these capabilities, it is possible for NESSUS to interface with virtually any computational model.

NESSUS provides two external model execution options: interactive and batch. For interactive operation, NESSUS will wait for each simulation to complete before starting the next analysis. This option works well for relatively fast-running models. In batch mode, NESSUS will create the analysis code input files (e.g., input files for 100 Monte Carlo samples or the initial steps in an iterative method such as AMV+) as well as a script with the execution commands for each required model analysis. However, in batch mode, the analyses are not executed. This provides the user greater flexibility in managing multiple analyses and can be used to run jobs in parallel or distribute jobs to multiple computers.

The NESSUS graphical interface facilitates the process of defining how input variables are mapped into numerical model input files. The process is very flexible and allows each model input variable to be mapped into one or more locations in one or more input files. Two mapping types are supported: “replace” and “vector scaling.” The “replace” mapping simply instructs NESSUS to overwrite a specified section of the input file with the current value of a variable. The “vector scaling” mapping can be used to control multiple fields based on the value of a single variable. For example, vector scaling can be used to define how nodal coordinates need to change based on the value of a geometric variable. This facility can be used to “parameterize” certain parts of a model, such as tabular material property definitions or geometric variables [8]. Figure 51.4 shows an example of the NESSUS editor for visually selecting fields within a numerical model input file.

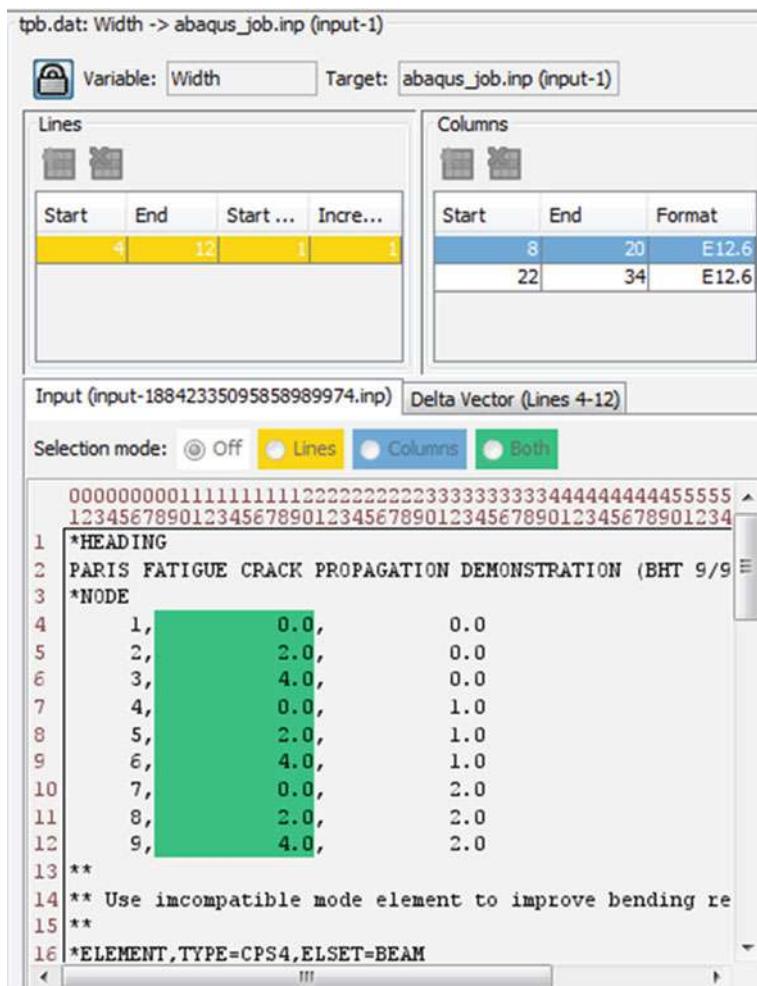

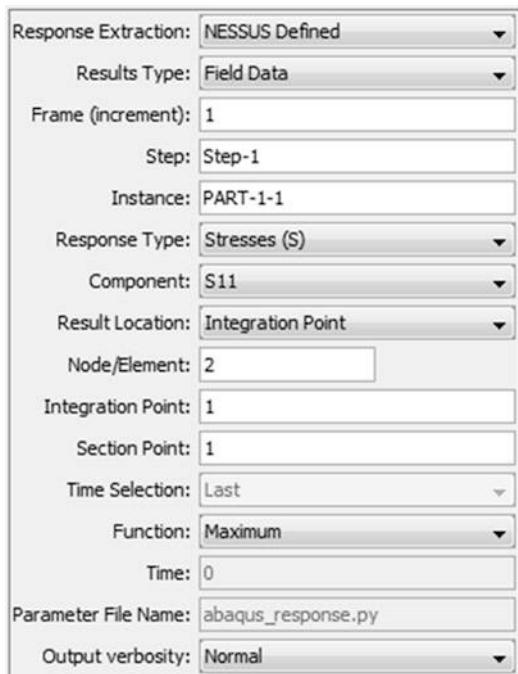

Fig. 51.4 NESSUS visual editor for definition of vector scaling mapping in numerical model input file

The options for defining the model output depend on the particular application. Customized dialogs are available for several of the commercial code interfaces. Figure 51.5 shows the menu for Abaqus, which includes options for response type and location, as well as functions for retrieving the maximum or minimum response over a specified set of nodes or elements.

When working with external analysis codes, NESSUS maintains a directory structure for each individual model run, including all input and output files, which facilitates debugging and verification of individual analysis cases. NESSUS also maintains a restart database, so that existing results are used when possible, as opposed to rerunning potentially time-consuming model evaluations.

Fig. 51.5 Definition of output variable for Abaqus response model

3.4 Deterministic Parameter Variation

The deterministic analysis section in NESSUS allows the user to exercise the models in the problem statement using a specified set of values for the variables. These values may be user defined (either manually entered into the table or imported from a file) or automatically generated based on built-in designs. The deterministic analysis capability can be used to manage or automate a series of external numerical models (e.g., finite element analyses), perform simple sensitivity studies (e.g., by perturbing each of the input variables one at a time), verify the NESSUS problem setup and model behavior (e.g., to verify that increasing the applied load results in a corresponding increase in stress), and more.

3.5 Probabilistic Analysis Definition

In NESSUS, the probabilistic analysis section defines four categories, referred to as “analysis types”:

- Specified probability levels
- Specified performance levels
- Full cumulative distribution
- Global sensitivity

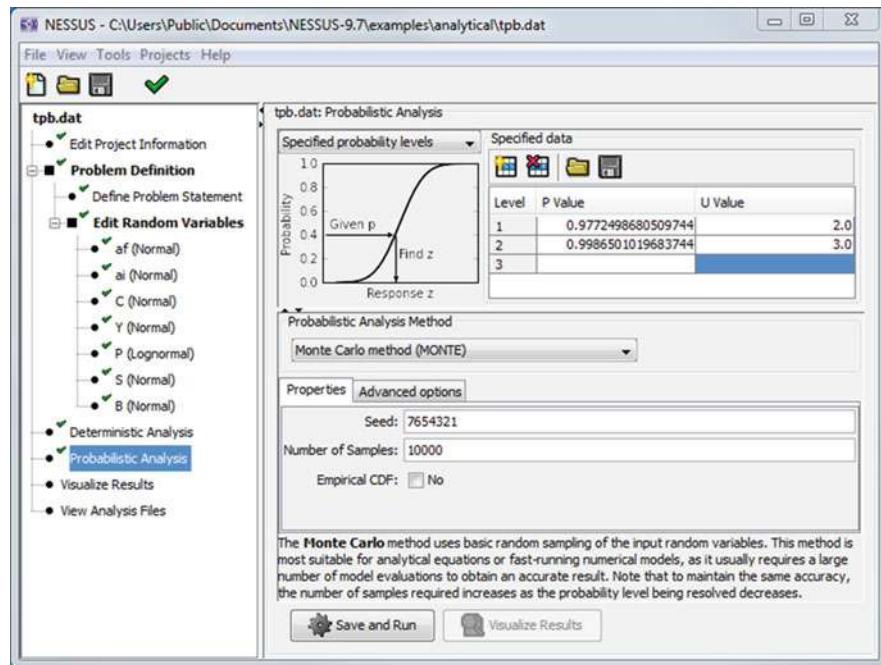

Fig. 51.6 NESSUS probabilistic analysis type and method selections

The specified probability levels and specified performance levels analysis types correspond to forward and inverse reliability analysis. In each case, the user may specify one or more “levels” at which to perform the analysis. For the full cumulative distribution analysis type, NESSUS automatically chooses a range of probability levels and performs an inverse reliability analysis at each one, in order to construct the CDF of the response variable. Global sensitivity analysis is provided as a separate analysis type, in which the objective is to compute the main and total effect indices associated with the basic random variables.

Lastly, the user selects the desired probabilistic method and configures the method-specific options, such as sample size (Fig. 51.6).

3.6 Results Visualization

The NESSUS graphical interface provides capabilities for visualizing results, which include:

- Deterministic response curves for one-variable-at-a-time studies
- Cumulative distribution function
- Derivative-based probabilistic sensitivities as a function of response level

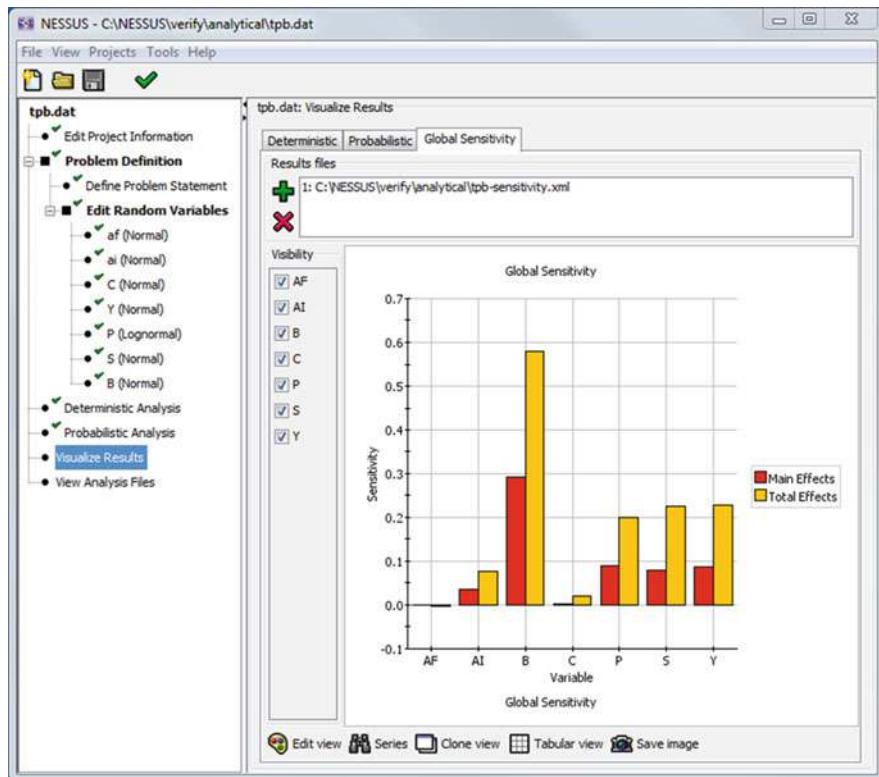

Fig. 51.7 Visualization of global sensitivity analysis results

- Probabilistic importance factors as a function of response level
- Bar charts for main and total effects from global sensitivity analysis
- Comparison of multiple results from separate analyses on the same plot

An example of the results visualization screen for global sensitivity analysis results is shown in Fig. 51.7. The graph shows the main and total effect sensitivity indices for each of the random variables defined in the problem statement.

4 Tutorial

The NESSUS problem formulation, analysis, and results visualization are demonstrated in this tutorial using a finite element model of a plate with a hole. The model predicts the stress concentration at a hole in a long plate of finite width due to end plate loads. The plate geometry and finite element model are shown in Fig. 51.8. The random variables are defined in Table 51.2. The far-field applied point force P is applied as an edge pressure to more accurately model the long plate condition.

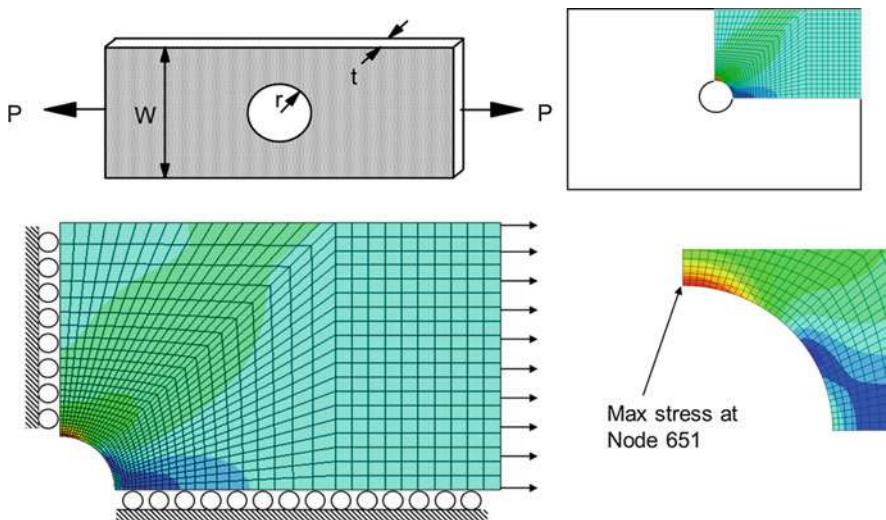

Fig. 51.8 Geometry and variables of a plate with a hole under uniform loading

Table 51.2 Random variable definitions for the plate with a hole probabilistic study

Variable	Description	Type	Mean	Standard deviation	Distribution
t	Thickness (in.)	Geometry	0.1	0.005	Lognormal
w_full	Width (in.)	Geometry	5.0	0.25	Lognormal
r	Radius (in.)	Geometry	0.5	0.025	Lognormal
P	Applied force (lbs)	Loading	7000	700	Normal
sigy	Yield stress (psi)	Material	80,000	4000	Normal

The model uses a linear elastic material definition ($E = 300,000$ psi, $\nu = 0.3$). An Abaqus CAE parametric model was developed that can create plate models for different values of the random variables. The geometry parameters in the Abaqus CAE model are used in the point and line definitions to create the plate geometry. A portion of the CAE script is shown in (Fig. 51.9) where the radius variable r is used in point definitions to create an arc for the hole in the plate. The script also shows the conversion of the applied force to edge pressure used for the loading.

For this example, NESSUS will be used to predict the variability in peak stress caused by the random variables defined in Table 51.2 and the probability of failure caused by exceeding the material's yield strength. Once the deterministic Abaqus CAE model has been developed, the first step is to define the problem statement in NESSUS, as shown in Fig. 51.10. In this example, the problem statement specifies the relationship between the response quantity (stress) and the basic random variables (plate geometry and loading). In this case, two equations are used, which are evaluated from the bottom to the top. The first equation divides the full width of the plate (w_{full}) by 2 to account for the use of symmetry in the finite element model. This second equation declares a function called "fe," which accepts the plate

```

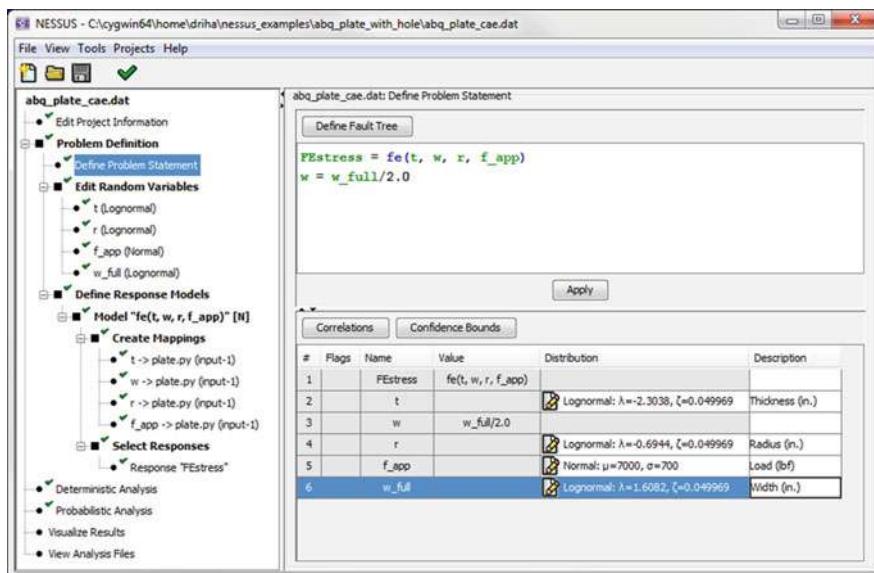

Fig. 51.10 NESSUS problem statement for the plate with a hole probabilistic study

half-width (w) as well as three additional inputs as arguments. Any name for the function can be chosen by the user, with the exception of the intrinsic functions such as \sin , \cos , and \exp . After clicking the Apply button, NESSUS recognizes the user-defined function and creates an entry for it in the outline for later definition.

Probability density functions are defined for the independent variables either in the Problem Statement section (Fig. 51.10) or in the Edit Random Variables section (Fig. 51.11) of the GUI. To edit a random variable directly from either of these screens, double-click on the pen icon under the “Distribution” column

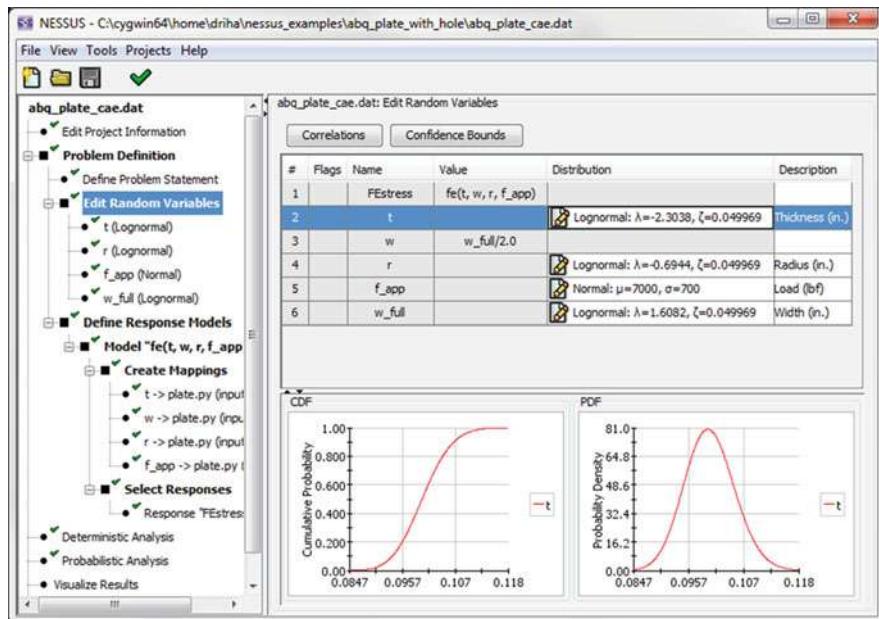

Fig. 51.11 Random variable definitions for the plate with a hole probabilistic study

in the table. This brings up an editor, as shown in Fig. 51.3. Using the editor, select the probability distribution type (e.g., normal, lognormal, etc.) and define the distribution parameters. Most probability distributions in NESSUS can be defined using either the mean and standard deviation or the natural parameters (e.g., shape and scale for a Weibull distribution). Each random variable is assigned its own probability distribution function. Correlations between any of the random variables may also be defined by clicking on the “Correlations” button.

Next, the function fe is assigned to the Abaqus numerical model interface capability in NESSUS as shown in Fig. 51.12. This screen defines the required input and output files and how to execute Abaqus. The deterministic Abaqus CAE script is defined in the Input files section under Source. NESSUS will modify this file based on variable mapping definitions (described in the next step) and write the modified file to the Destination file in a unique directory. NESSUS will then execute the commands in the Execution command window. The execution command for this problem requires two steps. First, Abaqus CAE is used to create the finite element model followed by executing the finite element analysis using Abaqus standard. Note that consistency is required between the execution commands and the Destination file and Output file names. For this problem, the destination filename plate.py is used in the first command. When run by Abaqus CAE, the plate.py script creates the abaqus_job.inp file that is used in the second command to run the finite element analysis. This analysis creates the abaqus_job.odb results file from which NESSUS will read the stress results.

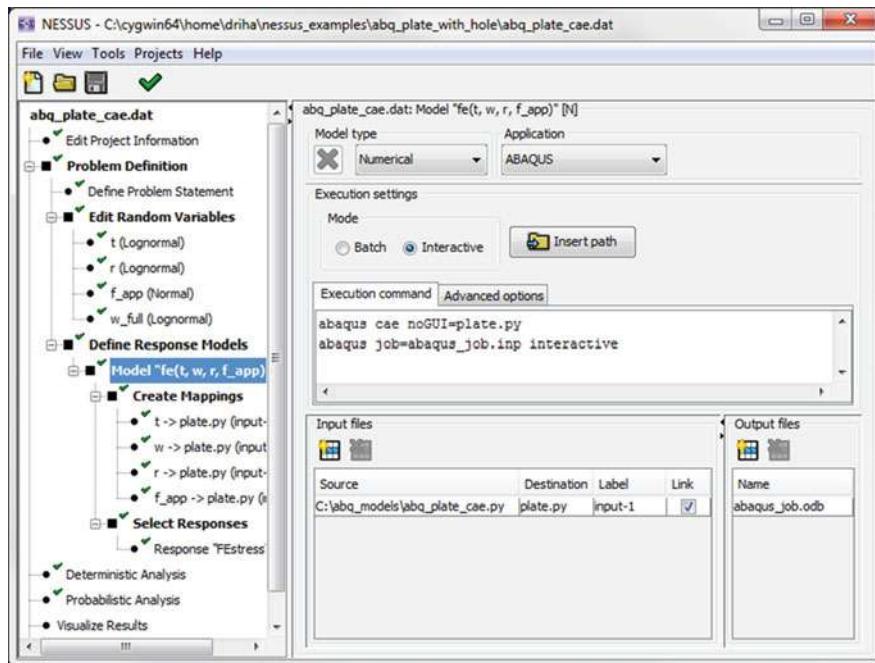

Fig. 51.12 Abaqus model definition for function fe

The next step is to map the variables defined in the fe function argument list to the Abaqus CAE script. Mappings are defined in the Create Mappings section under the Model fe (Fig. 51.13). The file and type of mapping for each variable are defined under Actions in this section of the GUI. Variables can be mapped multiple times into multiple files providing flexibility in relating random variables to model inputs. The “replace” type mapping is used for each variable in this model since the geometry has been parameterized in the Abaqus CAE script in terms of the random variables. NESSUS provides a graphical capability to map the variables to lines and columns in the source file. The mapping for the thickness variable t is shown in Fig. 51.14. The lines and columns in the tables are automatically populated when the lines and columns are graphically selected in the source file. These line and column numbers can also be inserted manually. Replace mappings can be applied to multiple lines and columns. Additional line blocks and columns can be added as needed. Line blocks are used to map to different line sections within the same file and mapping.

It is also necessary to define the numerical format to be used by NESSUS when writing values into the input file. This must be consistent with available field width in the input file, and the user must take care to provide sufficient precision so that changes made to the value of the variable by the NESSUS probabilistic analysis algorithms are correctly reflected in the numerical model input file. In this example,

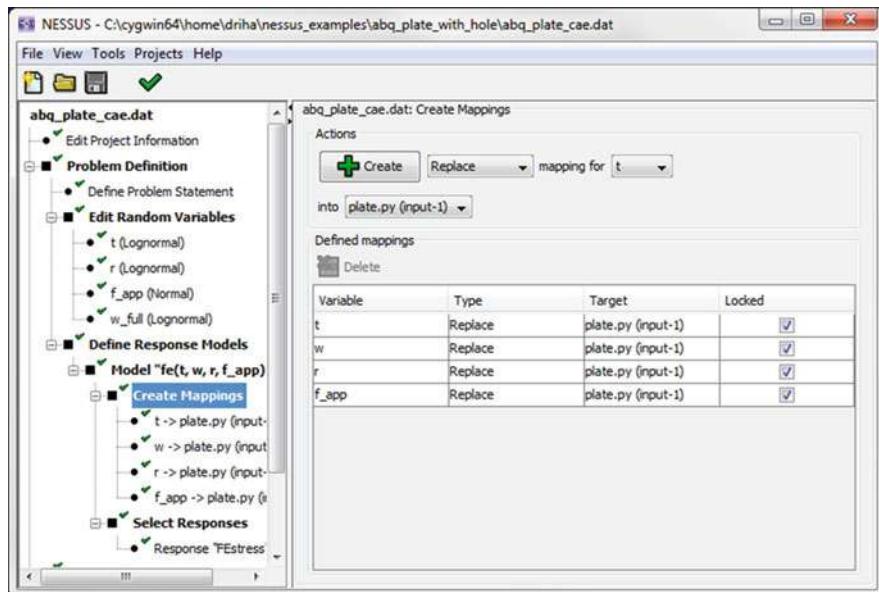

Fig. 51.13 Variable mapping definition

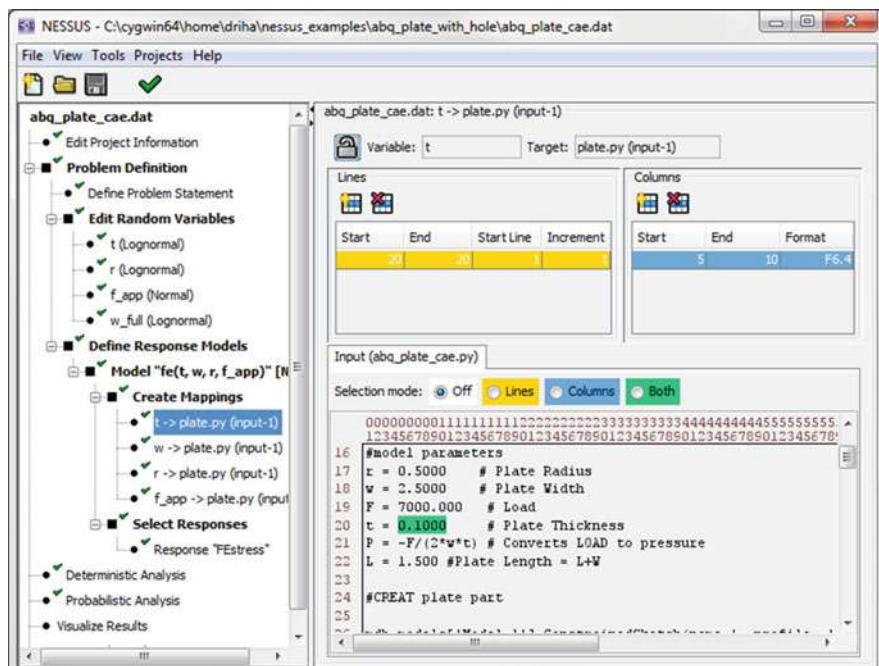

Fig. 51.14 Graphical mapping of the thickness variable to the Abaqus CAE input file.

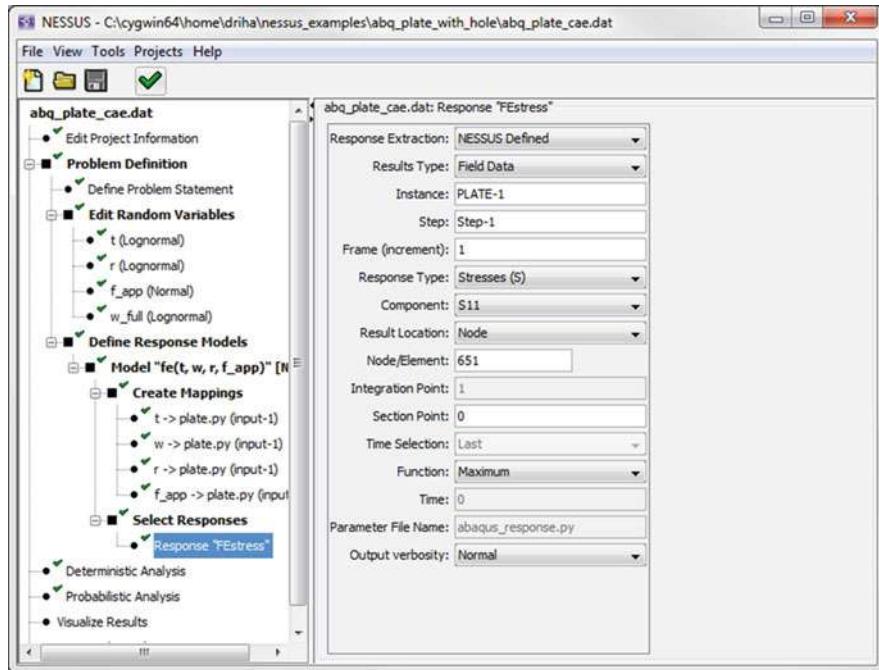

Fig. 51.15 Abaqus finite element response definition screen

the format specifies a field width of six characters, with four digits after the decimal place. This means changes to the thickness variable occurring beyond the fourth decimal place will not be captured in the numerical model input file. This can be an important consideration when using methods that make use of finite difference approximations.

The final step to define the model is to assign the computed variable FESTress in the problem statement. This definition is found in Select Responses under the model definition in the outline. The response selection screen is unique for the results and analysis capabilities for each predefined external analysis code interface in NESSUS. NESSUS is able to extract many responses of interest to engineering analysis from the Abaqus results file (Fig. 51.15). Results from both implicit and explicit analyses are supported for many nodal and element results of interest. Responses are identified at nodal or element locations for specified instances and load steps/increments. Several useful capabilities include extracting the maximum or minimum response for a list of nodes or elements and identifying responses in time series such as the last time or maximum or minimum over time. NESSUS also provides a mechanism for the user to define their own Abaqus CAE script to extract responses not supported by NESSUS.

The problem statement in NESSUS provides a concise and visual representation of the relationships between the models, variables, computed variables, and the

numerical model inputs (Figs. 51.10 and 51.14). These capabilities have evolved as means to better communicate the relationships between the variables and models and to reduce error in the problem definition. The model definition and mapping capabilities are flexible to non-intrusively define random variables in simple and complex numerical analysis models, execute the analyses, and extract results.

Once the model and variables are defined, any of the deterministic and probabilistic methods in NESSUS can be used. Continuing the tutorial, NESSUS is first used to predict the variation in the peak stress in the plate using the AMV+ method to compute the CDF. The AMV+ method is based on locating the MPP using successive linear approximations to the response function and then estimating the probability using FORM. The AMV+ method is useful to iteratively compute an increasingly accurate CDF for computationally intensive models. The first step in the AMV+ method is the MV solution, which is based on replacing the actual model with a first-order Taylor series expansion. The derivatives are approximated by finite difference using only $n+1$ model evaluations where n is the number of random variables. The MV method definition and step size for the finite difference are shown in Fig. 51.16. Additional step sizes for each variable can be added to the table for the MV, AMV, and AMV+ methods, which allows for a linear regression approximation to the derivative. For example, central difference or larger/smaller step sizes may provide a better representation of the derivative for highly nonlinear or noisy responses [5].

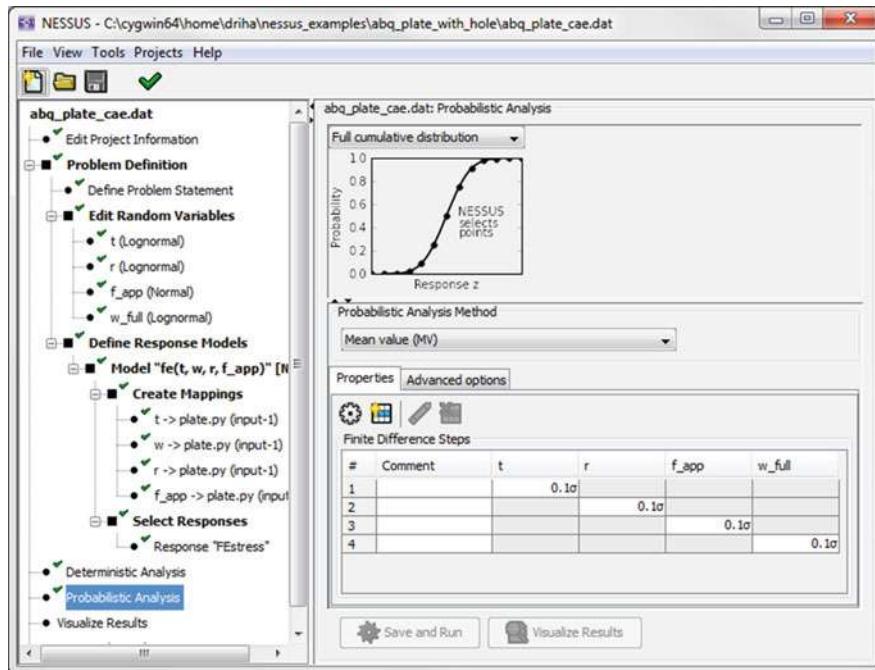

Fig. 51.16 Mean value probabilistic analysis method definition

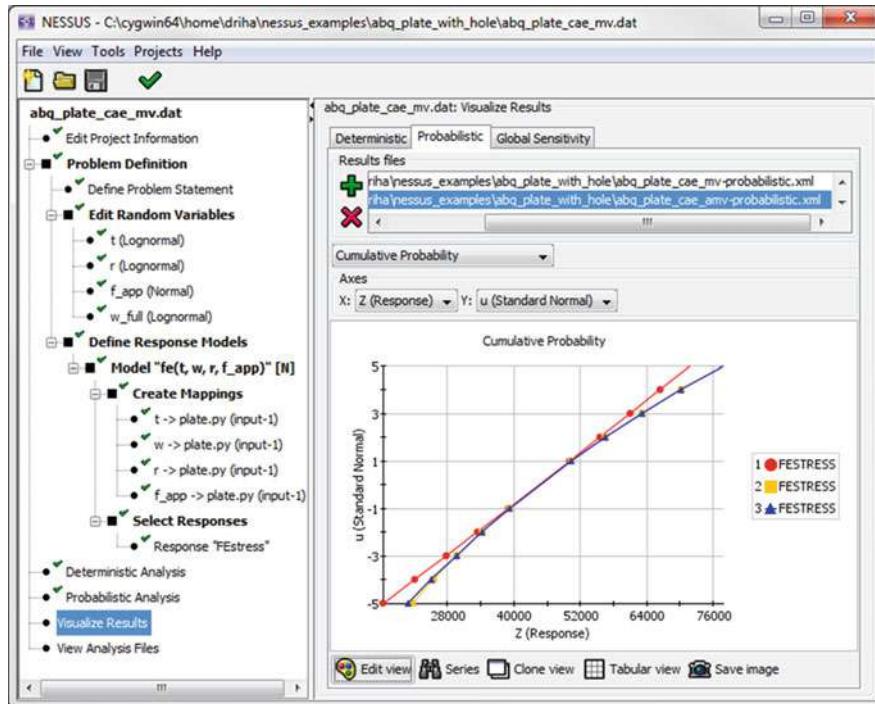

Fig. 51.17 CDF of peak stress using the MV, AMV, and AMV+ methods

The MV solution is shown by the red line in Fig. 51.17 and required four finite element solutions to estimate the full range of the CDF. The AMV solution (yellow line) requires one additional finite element analysis for each point on the CDF (10 for this analysis). The AMV+ method (blue line) iteratively recreates the Taylor series expansion at each MPP until a user specified convergence tolerance on the response value is reached. A 10% tolerance was used for this example, which required one additional Taylor series expansion for the two points defining the left tail of the CDF. The AMV solution met the defined tolerance for all other points in the CDF, without requiring additional iterations. The restart capability in NESSUS makes this solution approach very efficient. NESSUS identifies the finite element solutions already computed in each previous analysis step so no finite element solution is ever repeated for any previously computed set of variable values. For example, the AMV analysis reuses the existing results obtained from the MV analysis, without needing to repeat the finite element solutions.

Next, a reliability problem is formulated to compute the probability that the stress in the plate exceeds the material yield strength. The probability of failure, p_f , is defined as

$$p_f = P[\text{sigy} < \text{FEstress}] = P[\text{sigy} - \text{FEstress} < 0] = P\left[\frac{\text{sigy}}{\text{FEstress}} - 1 < 0\right]$$

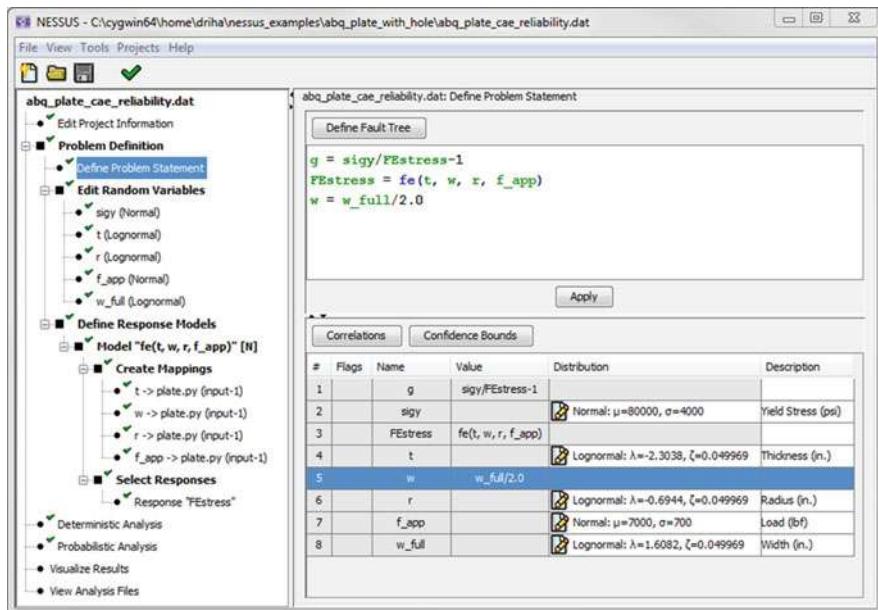

Fig. 51.18 NESSUS problem statement for reliability analysis

Each of these probabilities is equivalent. The last formulation normalizes the stress values and improves the convergence for the AMV+ method. This limit-state formulation is defined by g in the NESSUS problem statement (Fig. 51.18) and corresponds to the left side of the inequality in the probability definition. The analysis type is set to specified performance levels, and the performance level is set to zero based on the right side of the inequality, as shown in Fig. 51.19. The AMV+ solution required a total of 12 finite element analyses to determine a $pf = 0.000002$ using a FORM approximation to the limit state. The probabilistic importance levels are shown in Fig. 51.20 for this probability of failure. These give an indication of the relative importance of the contribution of each random variable to the probability of failure.

5 Solution Strategy Example

NESSUS was used to support a model verification and validation effort for a large-scale multi-physics system where full-scale testing was not practical. A solution strategy was developed to support model V&V and answer questions about the importance of potential uncertainties in the model. The model was expected to run for 16–18 h, and decisions using the model predictions were needed within a relatively short time frame. Therefore, efficient probabilistic methods and solution

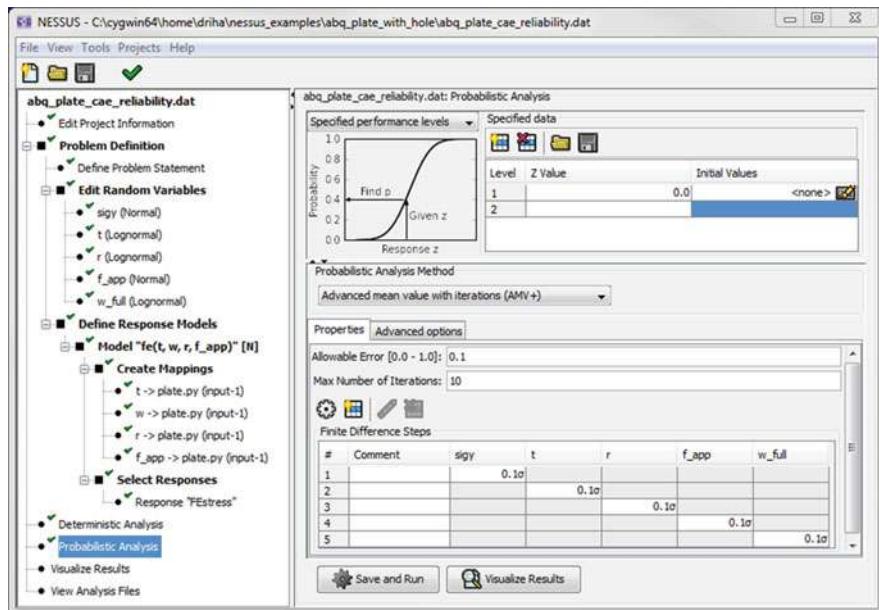

Fig. 51.19 NESSUS analysis type and probabilistic method for reliability analysis example

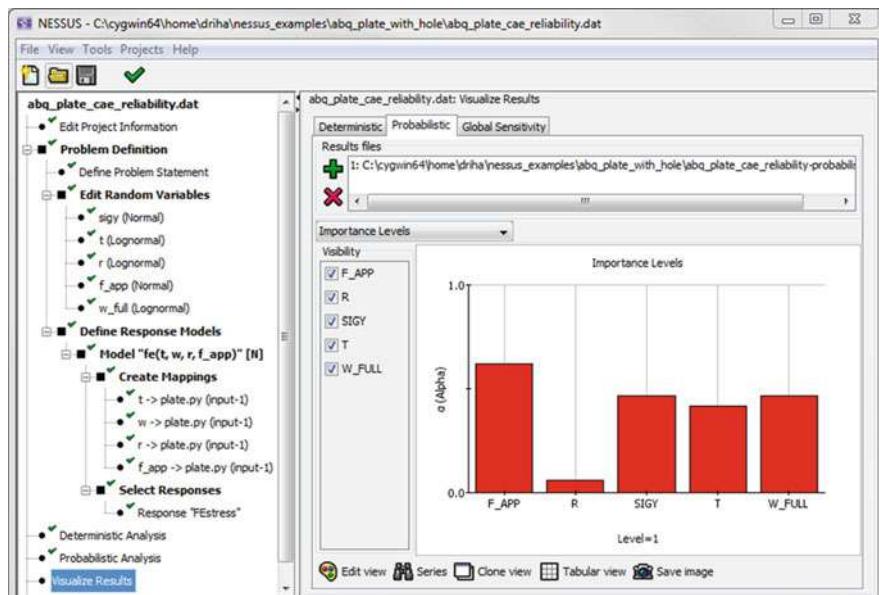

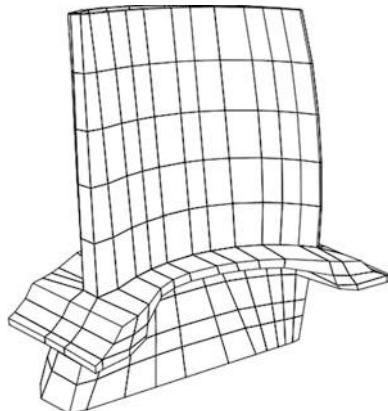

Fig. 51.20 Probabilistic importance levels for plate reliability analysis

Fig. 51.21 Space shuttle main engine turbopump turbine blade finite element model

strategies that could provide initial assessments for uncertainty and support for verification early in the process were required. Due to the sensitive nature and complexity of the actual model, a simplified model in terms of the number of variables and runtimes is used to demonstrate the developed strategy and how NESSUS can be used to perform these studies.

The demonstration uses a hypothetical design of a turbine blade used in NASA's Space Shuttle main engine turbopumps, which is represented by the finite element model shown in Fig. 51.21 [9]. A key characteristic of this approximately 2-inch blade is that it uses a directionally solidified single-crystal metal, which results in direction-dependent material properties. This anisotropic material is defined by material orientation angles relative to the model coordinate system. An actual blade in service would experience large centrifugal loads, vibrations, and extreme and varying temperatures and pressures. For this example study, uncertainties and variations in strain under a constant centrifugal load are computed using finite element analysis for a hypothetical comparison to a relatively simple laboratory experiment. Several questions are posed about the model and inputs that can be assessed using NESSUS:

- Does the model predict correct strains and trends?
- How important are variations in material properties to predicting strain?
- Are variations in material orientation important for strain?
- Are correlations in material properties important?

Uncertainties and variations are defined using normally distributed random variables based on engineering judgment as listed in Table 51.3.

The solution strategy was developed to answer specific questions about uncertainties in the model using a limited number of model evaluations. Deterministic and probabilistic assessments were selected to make the best use of the model runs to improve the solutions incrementally to increase understanding and correct models and data through the analysis process. Table 51.4 lists the analyses,

Table 51.3 Random variable definitions for turbine blade model

Variable	Description	Mean	Standard Deviation
rpm1	Angular velocity	3000 revolutions/min	150 revolutions/min

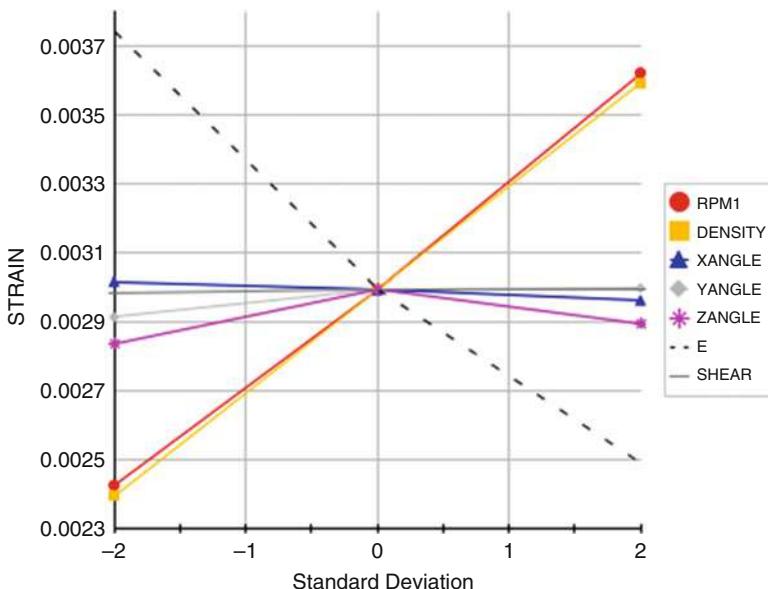

Fig. 51.22 Deterministic parameter variation study to verify correct trends of the turbine blade model

number of model runs, results, and assessments to be made in each step. The first analysis step is used as part of the model verification and to check for correct trends and importance. The deterministic parameter variation capability is used to perform a central difference sensitivity study. Each parameter is perturbed by 2 standard deviations below and above the mean. Figure 51.22 shows the plot from NESSUS for the central difference sensitivity study. Correct trends are observed such as increased strain with increasing rotational speed (RPM1) and material density.

The next step was to start the 100-run LHS analysis to provide a simulation-based CDF using the exact model and create additional training data for more accurate response surface models. While these LHS runs were in process, an initial assessment of prediction uncertainty and important parameters was made using a linear response surface trained with the model evaluations from the deterministic sensitivity study. Figure 51.23 shows the CDF and global sensitivities using the linear response surface. These studies are intended to provide initial information about important parameters and prediction uncertainty.

The results from the LHS study were used in addition to the central difference results to train a GP model to improve the accuracy of the CDF and global sensitivities. An accurate model fit is demonstrated by the cross-validation R-squared value of 0.99997, which is reported by NESSUS along with other goodness-of-fit information. A comparison of the CDF using the linear response surface, LHS with the exact model, and Monte Carlo simulation with the GP model are

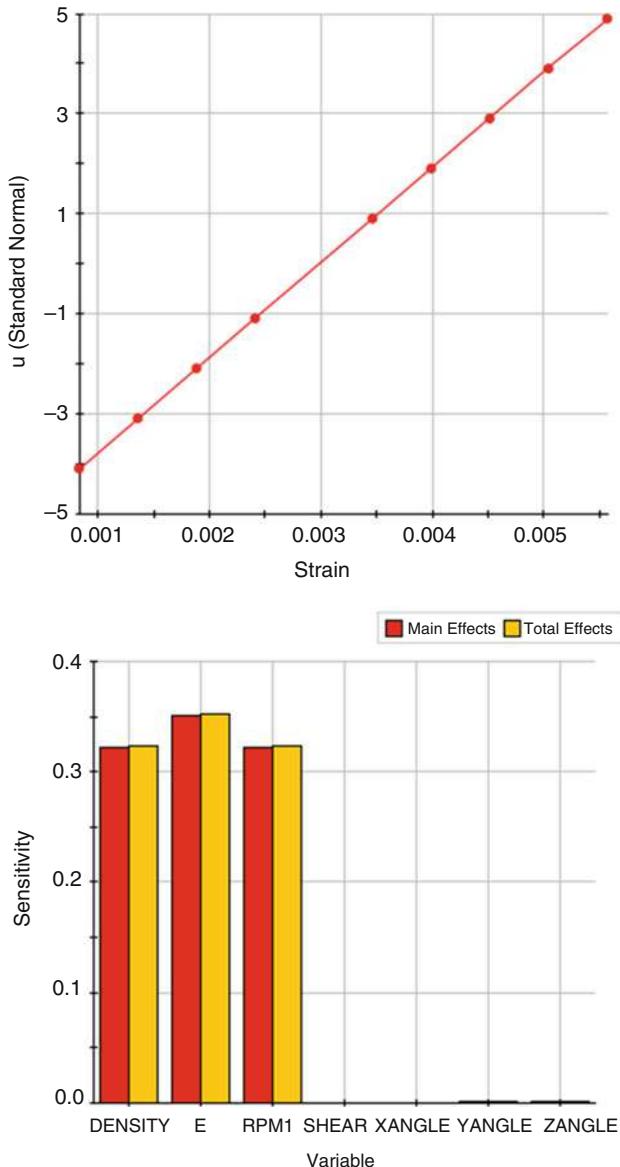

Fig. 51.23 CDF and global sensitivities using a linear response surface used to estimate prediction uncertainty and important parameters

shown in Fig. 51.24 along with global sensitivities using the GP model. The LHS solution was used as a partial verification for the accuracy of the GP model. The global sensitivities identify four variables that contribute very little to the

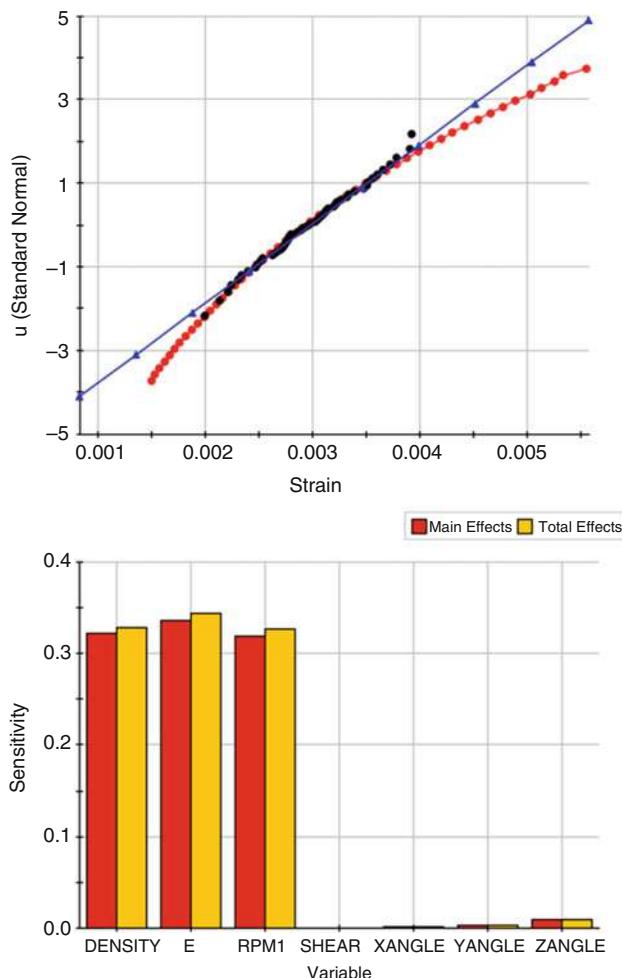

Fig. 51.24 CDF using the linear response surface (blue), LHS with exact model (black), and Monte Carlo simulation with the GP model (red) and the global sensitivities

predicted strain uncertainty: the three material angles and the shear modulus. These are candidate for removal in future uncertainty assessments for strain at this location.

Additional uncertainty studies can be quickly performed using the GP model. For example, sufficient experimental data are often not available to determine distribution types or correlations between different parameters. NESSUS can be used to study the impact of different distributions (such as normal or lognormal) on the predicted uncertainty by simply changing the distribution type. To demonstrate

the process for studying the uncertainty in correlations for this model, two additional NESSUS analyses were performed using Monte Carlo simulation with the GP model for correlation coefficients of -0.8 and 0.8 between the material stiffness and density. Correlations between these parameters influence the model uncertainty predictions as shown in Fig. 51.25. These results provide valuable information for allocating resources to either gather additional data/information to better quantify the correlation or to include this uncertainty when using the model.

Based on the global sensitivities, only important variables are retained to more efficiently predict the full distribution of strain using the exact model to refine the uncertainty assessment. The AMV+ method is used with the finite element model after removing the unimportant variables to predict the CDF. The NESSUS problem statement and CDF for the reduced variable set is compared to the LHS solution using the exact model and full variable set in Fig. 51.26. The AMV+ solution required 32 finite element analysis runs to predict the full range of the CDF.

This example shows some of the capabilities for performing uncertainty quantification in NESSUS. The combination of response surface models and efficient probabilistic methods allows for quick and informative studies to understand and communicate the model uncertainties. More large-scale problems solved using NESSUS can be found in Ref. [10].

6 Conclusions

The NESSUS probabilistic analysis software is designed to simplify and streamline the process of setting up and executing reliability analysis, uncertainty quantification, and sensitivity analysis studies. The software has been applied to a wide array of problems in a variety of engineering disciplines, but its development has been largely motivated by the need for practical tools that can be used for large-scale engineering applications and complex models with long runtimes. NESSUS was created in the 1980s with the goal of developing new technology for probabilistic design and analysis of space shuttle main engine components. Since then, the capabilities have continued to expand to include advanced response surface and sensitivity analysis methods.

NESSUS includes a variety of flexible and powerful capabilities for interfacing with deterministic performance models. These range from a simple algebraic equation syntax to sophisticated interfaces with external third party or user-defined codes, including a graphical interface for defining variable mappings. With the ability to set up user-defined interfaces based on either file input/output or direct calls into user-created shared libraries, it is possible to configure NESSUS to interface with virtually any numerical model.

NESSUS includes 16 probabilistic analysis methods, the majority of which were developed specifically for working with long-running performance models. These include the advanced mean value plus (AMV+) method as well as several methods based on Gaussian process response surface modeling, such as the efficient global reliability analysis (EGRA) method. NESSUS includes traditional probabilistic sensitivity results for all forward and inverse reliability analysis methods, and the software has recently been expanded to include variance-based global sensitivity analysis.

Abstract

Stokhos (Phipps, Stokhos embedded uncertainty quantification methods. <http://trilinos.org/packages/stokhos/>, 2015) is a package within Trilinos (Heroux et al., ACM Trans Math Softw 31(3), 2005; Michael et al., Sci Program 20(2):83–88, 2012) that enables embedded or intrusive uncertainty quantification capabilities to C++ codes. It provides tools for implementing stochastic Galerkin methods and embedded sample propagation through the use of template-based generic programming (Pawlowski et al., Sci Program 20:197–219, 2012; Roger et al., Sci Program 20:327–345, 2012) which allows deterministic simulation codes to be easily modified for embedded uncertainty quantification. It provides tools for forming and solving the resulting linear and nonlinear equations these methods generate, leveraging the large-scale linear and nonlinear solver capabilities provided by Trilinos. Furthermore, Stokhos is integrated with the emerging many-core architecture capabilities provided by the Kokkos (Edwards et al., Sci Program 20(2):89–114, 2012; Edwards et al., J Parallel Distrib Comput 74(12):3202–3216, 2014) and Tpetra packages (Baker and Heroux, Sci Program 20(2):115–128, 2012; Hoemmen et al., Tpetra: next-generation distributed linear algebra. <http://trilinos.org/packages/tpetra>, 2015) within Trilinos, allowing these embedded uncertainty quantification capabilities to be applied in both shared and distributed memory parallel computational environments. Finally, the Stokhos tools have been incorporated into the Albany simulation code (Pawlowski et al., Sci Program 20:327–345, 2012; Salinger et al., Albany multiphysics simulation code. <https://github.com/gahansen/Albany>, 2015) enabling embedded uncertainty quantification of a wide variety of large-scale PDE-based simulations.

1 Introduction

Stokhos [27] is a package for implementing *embedded* uncertainty quantification methods in C++ codes that is part of the Trilinos framework [16, 17]. Here the term embedded refers to methods that require substantial modification of the simulation source code to implement (also called intrusive). Stokhos itself does not provide any uncertainty quantification capabilities; rather it provides a set of tools for building those capabilities in general C++ simulation codes. There are two general classes of methods it enables: stochastic Galerkin methods based on a (generalized) polynomial chaos discretization and embedded sample propagation for any kind of sampling-based method. In both cases, Stokhos provides tools to support propagation of uncertainty information at the lowest levels of a simulation code via a technique called template-based generic programming [25, 26] as well as tools for forming and solving any resulting linear and nonlinear equations. It is geared toward uncertainty propagation in partial differential equations (explicit or implicit), but will work with any type of deterministic simulation code. In the sections that follow, stochastic Galerkin methods and their implementation with Stokhos are described, followed by a simpler discussion of embedded sample propagation. Next, use of these tools and techniques for exposing fine-grained parallelism on emerging multi-core and many-core architectures is described, followed by several examples describing the use of Stokhos for uncertainty propagation in C++ codes. The paper concludes with an example of applying these techniques to an uncertain fluid flow problem implemented through the Albany simulation code [26, 35]. More details on Stokhos and in particular its application in the emerging computer architecture context can be found here [30, 31].

2 Background

To describe the software tools for implementing embedded uncertainty quantification methods with Stokhos and to fix notation, a brief review of stochastic Galerkin methods is provided. Following [31], only steady-state problems are considered for simplicity, as the extension of the software to transient problems is straightforward. Let $(\Omega, \mathcal{B}, \mu)$ be a complete probability space where Ω is the set of outcomes, \mathcal{B} is the σ -algebra of measurable events, and $\mu : \Omega \rightarrow [0, 1]$ is the probability measure. Assume the problem depends on a finite set of M independent random variables $\xi_i : \Omega \rightarrow \Gamma_i \subset \mathbb{R}$, $i = 1, \dots, M$, representing uncertain input data with corresponding density function $\rho_i(y_i)$, $i = 1, \dots, M$. Let $\xi = [\xi_1, \dots, \xi_M]$, $\Gamma = \Gamma_1 \times \dots \times \Gamma_M$ and $\rho(y) = \rho_1(y_1) \dots \rho_M(y_M)$ be the density of ξ for $y = (y_1, \dots, y_M) \in \Gamma$. Finally, assume the problem of interest can be modeled by the discrete nonlinear system

$$f(x; \xi(\omega)) = 0, \quad (52.1)$$

where $x \in \mathbb{R}^n$ is the corresponding discrete unknown solution vector and $f : \mathbb{R}^{n+M} \rightarrow \mathbb{R}^n$. By the Doob-Dynkin Lemma [23], the solution x can be parameterized by the same random vector ξ : $x(\omega) = x(\xi(\omega))$. As described previously in this volume, this mapping can be approximated through the use of global polynomials $\{\Psi^i\}$ orthogonal with respect to the joint density function ρ [11, 12, 39, 40]:

$$\langle \Psi^j \Psi^k \rangle \equiv \int_{\Gamma} \Psi^j(y) \Psi^k(y) \rho(y) dy = \langle (\Psi^j)^2 \rangle \delta_{jk}, \quad j, k = 0, 1, 2, \dots \quad (52.2)$$

These polynomials are constructed in Stokhos in the traditional manner by tensorization of one-dimensional orthogonal polynomials. For each $i = 1, \dots, M$, let $\{\psi_i^j\}$ be a family of polynomials orthonormal with respect to the measure ρ_i :

$$\langle \psi_i^j \psi_i^k \rangle_i \equiv \int_{\Gamma_i} \psi_i^j(y_i) \psi_i^k(y_i) \rho_i(y_i) dy_i = \langle (\psi_i^j)^2 \rangle_i \delta_{jk}, \quad j, k = 0, 1, 2, \dots \quad (52.3)$$

ordered in such a way that the degree of polynomial ψ_i^j is j . For a given multi-index $\alpha = (\alpha_1, \dots, \alpha_M)$, define

$$\Psi^\alpha(y) = \psi_1^{\alpha_1}(y_1) \dots \psi_M^{\alpha_M}(y_M), \quad y = (y_1, \dots, y_M) \in \Gamma. \quad (52.4)$$

Then for a given $N \geq 0$, denote by $\mathcal{L}_{M,N}$ the complete polynomial space of total order at most N ,

$$\mathcal{L}_{M,N} = \text{span}\{\Psi^\alpha : |\alpha| \equiv \alpha_1 + \dots + \alpha_M \leq N\} \subset L_\rho^2(\Gamma), \quad (52.5)$$

and define $P + 1 \equiv \dim \mathcal{L}_{M,N} = \frac{(M+N)!}{M!N!}$. The solution $x(\xi)$ is then approximated in $\mathcal{L}_{M,N}$ as

$$x(\xi) \approx \hat{x}(\xi) \equiv \sum_{i=0}^P x^i \Psi^i(\xi). \quad (52.6)$$

The stochastic Galerkin method approximates the unknown coefficients x^i through orthogonal projection of the residual f into $\mathcal{L}_{M,N}$:

$$f^i = \frac{\langle f \Psi^i \rangle}{\langle (\Psi^i)^2 \rangle} = \frac{1}{\langle (\Psi^i)^2 \rangle} \int_{\Gamma} f(\hat{x}(y); y) \Psi^i(y) \rho(y) dy = 0, \quad i = 0, \dots, P. \quad (52.7)$$

Define

$$X = \begin{bmatrix} x^0 \\ \vdots \\ x^P \end{bmatrix} = \sum_{k=0}^P e^k \otimes x^k, \quad F = \begin{bmatrix} f^0 \\ \vdots \\ f^P \end{bmatrix} = \sum_{k=0}^P e^k \otimes f^k \quad (52.8)$$

where e_k is the k th column of the $(P+1) \times (P+1)$ identity matrix, $k = 0, \dots, P$. This defines a fully-coupled (spatial-stochastic) nonlinear system

$$F(X) = 0 \quad (52.9)$$

of $n(P+1)$ equations in $n(P+1)$ unknowns.

3 Stochastic Galerkin Methods with Stokhos

Stokhos provides a set of software tools for forming and solving the stochastic Galerkin nonlinear system (52.9) using Newton-type nonlinear solver schemes:

$$\frac{\partial F}{\partial X} \Delta X_l = -F(X_l), \quad X_{l+1} = X_l + \Delta X_l, \quad l = 0, 1, \dots \quad (52.10)$$

This involves several challenges, the first of which is evaluating the stochastic Galerkin residual and Jacobian matrix. Note that from the definition of F , the components f^i of F are just the polynomial chaos coefficients of $f(\hat{x}(\xi); \xi)$. Furthermore for $i, j = 0, \dots, P$,

$$\frac{\partial f^i}{\partial x^j} = \frac{1}{\langle (\Psi^i)^2 \rangle} \int_{\Gamma} \frac{\partial f}{\partial x}(\hat{x}(y); y) \Psi^i(y) \Psi^j(y) \rho(y) dy \approx \sum_{k=0}^P A^k \frac{\langle \Psi^i \Psi^j \Psi^k \rangle}{\langle (\Psi^i)^2 \rangle} \quad (52.11)$$

where

$$\begin{aligned} \frac{\partial f}{\partial x}(\hat{x}(\xi); \xi) &\approx \sum_{k=0}^P A^k \Psi^k(\xi), \\ A^k &= \frac{1}{\langle (\Psi^i)^2 \rangle} \int_{\Gamma} \frac{\partial f}{\partial x}(\hat{x}(y); y) \Psi^k(y) \rho(y) dy, \quad k = 0, \dots, P \end{aligned} \quad (52.12)$$

is the truncated polynomial chaos approximation to the Jacobian operator $\partial f / \partial x$. Given C++ computer code to evaluate f and $\partial f / \partial x$ for given values of x and y , Stokhos generates computer code to evaluate $\{f^i\}$ and $\{A^i\}$ using a technique called template-based generic programming [25, 26] based on the ideas of automatic differentiation (see, e.g., [13] and the references contained within). In brief, the code to evaluate f and $\partial f / \partial x$ is decomposed into a sequence of elementary operations (addition, subtraction, multiplication, and division) and simple functions (e.g., sine, cosine, exponential, logarithms). The idea is to compute projections into $\mathcal{L}_{M,N}$ vis-à-vis Eq. 52.7 for each intermediate variable used in the evaluation of f or $\partial f / \partial x$ using simple rules for each of these elementary operations and simple functions.

Let a and b be two intermediate variables in a given calculation and assume, by way of induction, their polynomial chaos projections

$$a(\xi) \approx \hat{a}(\xi) \equiv \sum_{i=0}^P a^i \Psi^i(\xi), \quad b(\xi) \approx \hat{b}(\xi) \equiv \sum_{i=0}^P b^i \Psi^i(\xi)$$

have already been computed. Let $c = \varphi(a, b)$ where φ is some elementary operation/simple function and the polynomial chaos projection of c must be computed. For the elementary arithmetic operations, simple formulas for the coefficients $\{c^i\}$ can be readily obtained as shown in Table 52.1. Note the rule for division requires solving a linear system for the coefficients $\{c^i\}$. The tensor $C_{ijk} \equiv \langle \Psi^i \Psi^j \Psi^k \rangle / \langle (\Psi^i)^2 \rangle$ is precomputed and stored in a sparse format. Rules for transcendental operations and non-smooth functions (e.g., min/max, abs) are more challenging, but a number of approaches have been investigated [7, 21]. The approach recommended in Stokhos is the use of numerical integration, e.g.,

$$\begin{aligned} c^i &= \frac{1}{\langle (\Psi^i)^2 \rangle} \int_{\Gamma} \varphi(\hat{a}(y), \hat{b}(y)) \Psi^i(y) \rho(y) dy \\ &\approx \frac{1}{\langle (\Psi^i)^2 \rangle} \sum_{k=0}^Q w_k \varphi(\hat{a}(y_k), \hat{b}(y_k)) \Psi^i(y_k) \end{aligned} \quad (52.13)$$

Table 52.1 Projection rules for elementary operations

Operation	Rule
$c = a \pm b$	$c^i = a^i \pm b^i$
$c = ab$	$c^i = \sum_{j,k=0}^P a^j b^k \langle \Psi^i \Psi^j \Psi^k \rangle / \langle (\Psi^i)^2 \rangle$
$c = a/b$	$\sum_{j,k=0}^P b^j c^k \langle \Psi^i \Psi^j \Psi^k \rangle / \langle (\Psi^i)^2 \rangle = a^i$

where $\{(w_k, y_k) : k = 0, \dots, Q\}$ is a quadrature rule determined by the measure ρ . Stokhos provides a number of sparse-grid quadrature rules [3, 22, 36], allowing (52.13) to be implemented for many standard simple math functions (Note the use of sparse-grid quadrature in Eq. 52.13 can result in additional numerical error if care is not taken to preserve orthogonality of the polynomial chaos basis functions $\{\Psi^i\}$ using the discrete inner product defined by the quadrature rule. This can be remedied by replacing Eq. 52.13 by a more general rule based on the Smolyak formula [5, 6]).

Stokhos provides a C++ data type designed to store the polynomial chaos coefficients for each variable and overloads of all of the elementary/simple functions to compute projections in the manner described above, referred to as the *polynomial chaos scalar type*. The code to evaluate $\{f^i\}$ and $\{A^i\}$ is then obtained by replacing the fundamental floating-point scalar type in the code to evaluate f and $\partial f / \partial x$ with this new data type, leveraging the standard operator overloading resolution rules for the C++ language. While not required, it is recommended to facilitate this transformation by instead turning the code into general template code, where the scalar type becomes a template parameter. Then the original code can be obtained by instantiating the template code on the original floating-point type and the transformed code by instantiating it on the polynomial chaos scalar type.

With an ability to evaluate the stochastic Galerkin residual F and Jacobian $\partial f / \partial X$ available, the next challenge is solving the resulting linear systems appearing in Eq. 52.10. Due to the very large size of these systems, Stokhos provides interfaces and data structures for solving these systems using iterative solver methods such as CG and GMRES implemented by other packages in the Trilinos framework. In this context, the Jacobian matrix $\partial f / \partial X$ does not need to be formed directly; rather matrix-vector products may be computed efficiently using the Kronecker product structure of the Jacobian:

$$\frac{\partial F}{\partial X} \approx A \equiv \sum_{k=0}^P G^k \otimes A^k \quad (52.14)$$

where each matrix $G^k \in \mathbb{R}^{(P+1) \times (P+1)}$ satisfies $G_{ij}^k = C_{ijk} = \langle \Psi^i \Psi^j \Psi^k \rangle / \langle (\Psi^i)^2 \rangle$, $i, j, k = 0, \dots, P$. An algorithm to efficiently evaluate matrix-vector products using this representation is described in detail here [30].

Critical to the efficiency of these solvers are effective preconditioning strategies, and Stokhos provides implementations of several preconditioners that have been studied in the literature, including mean-based [32], relaxation [33], Kronecker product [38], and Schur complement [37] that couple to a variety of algebraic preconditioners implemented in Trilinos designed for the original system $f(x) = 0$ (such as incomplete factorizations and multi-grid). Finally Stokhos provides implementations of several interfaces in Trilinos allowing nonlinear, transient, and optimization solvers to be applied to the stochastic Galerkin system. Examples of applying these capabilities to several simple problems will be described later in this chapter.

4 Uncertainty Quantification on Emerging Computer Architectures

Over the coming decade, it is expected that computer architectures will evolve considerably in order to achieve increasing levels of computing throughput with only modest increases in overall power consumption. Harnessing this increased computational power is likely to place tremendous demands on the efficiency and scalability of scientific and engineering simulation codes by requiring:

- Regular memory access patterns to contiguous regions of memory in order to avoid long access latencies.
- Arithmetic that maps well to arithmetic on wide vectors (vectorization).
- Good spatial and temporal data locality in order to effectively utilize deep memory hierarchies that can be shared by multiple independent execution contexts.

Unfortunately many simulation codes struggle to meet these demands, in particular those involving complex physics and sparse linear algebra on unstructured meshes. Sparse linear algebra inherently introduces indirect memory addressing which introduces latency effects into the overall calculation and generally results in poor cache utilization making effective use of hardware threads impossible. Also complicated loop structures in complex simulation codes often make translating those loops to arithmetic on wide vectors challenging. Thus it is entirely possible that many simulation codes may achieve lower performance on these next-generation architectures than they do today. Considering that the aggregate performance of sampling-based uncertainty quantification is limited by the performance of the underlying simulation, this reduction in performance will directly translate into increased cost for uncertainty quantification calculations built on top of these simulations.

However embedded uncertainty quantification methods such as the stochastic Galerkin methods described above provide an opportunity to improve performance on these architectures. The operator overloading-based, scalar-level uncertainty propagation method discussed above for evaluating Galerkin residual and Jacobian values naturally replaces scalar floating-point operations with operations on arrays of polynomial chaos coefficients. This will generate more regular memory access patterns if these coefficients are stored in continuous memory locations. It also exposes new dimensions of fine-grained parallelism by parallelizing the operations in Table 52.1 through fine-grained threading and vectorization. Finally, it improves temporal data locality and cache-reuse as only one uncertainty propagation sweep through the simulation code is required instead of numerous sweeps at each sample.

To take advantage of these features for the solution of the stochastic Galerkin linear systems however, some modifications of the approach discussed above are required. The Kronecker structure of the Galerkin matrix (52.14) gives rise to a block system with a two-level sparsity structure: an outer structure as determined

by the sparse C_{ijk} tensor and an inner structure determined by the deterministic Jacobian operator as demonstrated in Fig. 52.1a. In many cases, this structure is not ideal for emerging architectures when the sparsity pattern of the deterministic Jacobian operator is unstructured. However by commuting the terms of the Kronecker product,

$$\tilde{A} = \sum_{k=0}^P A^k \otimes G^k, \quad (52.15)$$

the sparsity structure is inverted as shown in Fig. 52.1b. This amounts to merely a reordering of the stochastic and deterministic degrees-of-freedom, ordering all of the stochastic degrees-of-freedom corresponding to a given deterministic degree-of-freedom consecutively.

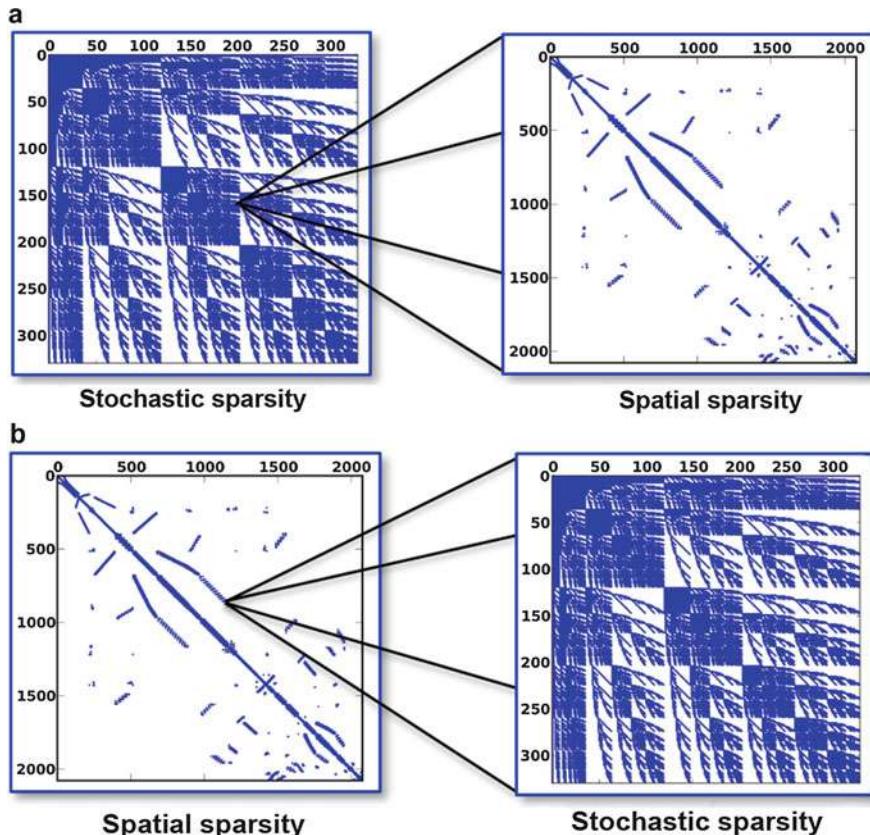

Fig. 52.1 Two-level sparsity structure of stochastic Galerkin operator using traditional layout (a) corresponding to Eq. 52.14 and commuted layout (b) corresponding to Eq. 52.15. For each figure, every nonzero in the *left*, outer sparsity structure is a block of size and sparsity indicated by the *right*, inner sparsity structure. This can result in a denser outer structure with sparse inner structure for the traditional layout (a) and a sparse outer structure with denser inner structure for the commuted layout (b)

This ordering allows all of the properties described above with regard to evaluation of the stochastic Galerkin residual and Jacobian entries to also be applied to sparse linear algebra with the Galerkin matrix. In Stokhos, solution of stochastic Galerkin linear systems in this layout is implemented by instantiating next-generation templated solver and preconditioner libraries in Trilinos such as Tpetra [2, 19], Belos [4], Ifpack2 [18], and MueLu [10, 20] on the polynomial chaos scalar type discussed above. Furthermore, Stokhos provides specializations of the Kokkos many-core parallelism portability library [8, 9] to map fine-grained parallelism across the uncertainty dimension for use in the solver libraries mentioned previously as well as simulation codes that use Kokkos directly in their residual/Jacobian evaluations. For a more thorough description of how Stokhos interacts with these libraries, discussion of custom linear algebra kernels exploiting the commuted Kronecker-product structure (52.15), and performance comparisons of solving representative PDEs with uncertain input data on a variety of emerging multi-core and many-core architectures, see [30, 31].

5 Sample Propagation Methods with Stokhos

In addition to providing tools for implementing embedded stochastic Galerkin methods, Stokhos also provides similar tools for embedded sampling methods. The idea behind this approach is to enable some of the same computer architecture benefits the Galerkin approach provides, such as improved memory access patterns and exposing new dimensions of structured fine-grained parallelism, without the additional solver challenges that arise from the Galerkin approach. In particular, collections of samples called ensembles are propagated together at the scalar level of the simulation code as in the Galerkin approach described above. Stokhos provides an *ensemble scalar type* containing an array (whose length is fixed at compile time) to store the ensemble values for each intermediate variable, and corresponding overloaded operators are provided for all elementary/simple functions that trivially map those operations across the ensemble array. By choosing the length of the ensemble array to be a multiple of the natural vector width of the architecture, it becomes simple for vectorization and fine-grained threading to implement the operations on this ensemble array in parallel. Furthermore, scalar loads and stores become loads/stores of entire ensemble arrays resulting in improved memory access patterns. By implementing the method through the template-based generic programming approach, applying the method to a code already templated on the scalar amounts to just another template instantiation for that code. Just as in the Galerkin case, Stokhos provides the necessary specializations for incorporating the approach into the Kokkos many-core programming library and the template solver libraries in Trilinos.

This approach is amenable to any sampling-based method such as stochastic collocation, nonintrusive polynomial chaos, and Monte Carlo. Samples generated from the method are grouped into ensembles of the chosen size and then propagated together. This provides the best-of-both-worlds hybrid between purely intrusive and nonintrusive methods by propagating some UQ information together at the

scalar level of the code in order to exploit fine-grained parallelism but still allows traditional coarse-grained parallelism between ensembles. The primary challenge of this approach is determining how to group samples to get the most benefit out of the ensemble propagation. Current research is underway to address that question, particularly in the context of adaptive sampling methods applied to systems with non-smooth responses.

6 Examples

In this section, several examples demonstrating the use of Stokhos for simple uncertainty propagation problems are described. First, the steps necessary for obtaining, configuring, and compiling stokhos are described. Then three examples of using Stokhos are covered: computing a polynomial chaos approximation for a simple function using the polynomial chaos scalar type and its overloaded operators, the same example instead using the embedded ensemble propagation approach within the context of nonintrusive spectral projection, and demonstration of the nonlinear solver interface in Stokhos for formulating and solving nonlinear, steady-state stochastic Galerkin problems. These techniques form the building blocks of applying the methods to large-scale systems such as discretized partial differential equations. The section then concludes with a demonstration of these capabilities for solving a fluid flow problem with uncertain input data as computed by the Albany simulation code [26, 35]. Applying Stokhos in multi-core/many-core programming environments is beyond the scope of this chapter. Trilinos provides a complete PDE example called FENL capable of running on modern multi-core and many-core architectures in the TrilinosCouplings package including uncertainty quantification capabilities provided by Stokhos. For performance results in that context, please see here [31].

6.1 Obtaining, Configuring, and Compiling the Stokhos Package

Stokhos is a package within Trilinos and therefore is obtained by downloading Trilinos. Trilinos is currently available for download from <https://trilinos.org/download>, including both periodic source code releases as well as the most recent development sources through the `publicTrilinos` Git repository (`git clone https://software.sandia.gov/trilinos/repositories/publicTrilinos`). In the future Trilinos will be available from GitHub (<https://github.com>). Trilinos is released as open-source software; however the licensing requirements of packages within Trilinos vary. Stokhos is released under the BSD license. Currently only Trilinos sources are provided for download, requiring the user to configure and build Trilinos based on their intended use. Due to the large number of packages within Trilinos and myriad of ways Trilinos can be configured, it is not feasible to provide precompiled binary versions.

Once the Trilinos sources have been obtained, it must be configured before compiling. Trilinos uses CMake (<https://cmake.org>) to manage the configuration

and build process, and documentation is provided by CMake on its use for a variety of computer architectures. For Unix-like environments, this is most often accomplished through a configuration script such as the one shown below.

```
rm -f CMakeCache.txt;
rm -rf CMakeFiles

cmake \
-D CMAKE_INSTALL_PREFIX=$PWD/../install_uq_handbook \
-D CMAKE_BUILD_TYPE=RELEASE \
-D Trilinos_ENABLE_EXPLICIT_INSTANTIATION=ON \
-D Trilinos_ENABLE_ALL_OPTIONAL_PACKAGES=ON \
-D BUILD_SHARED_LIBS=ON \
-D CMAKE_CXX_COMPILER=g++ \
-D CMAKE_C_COMPILER=gcc \
-D CMAKE_Fortran_COMPILER=gfortran \
-D Trilinos_ENABLE_Stokhos=ON \
-D Stokhos_ENABLE_TESTS=ON \
-D Stokhos_ENABLE_EXAMPLES=ON \
-D Trilinos_ENABLE_Trikota=OFF \
../Trilinos
```

This configure script enables Stokhos, its tests and examples, and all of the other packages that it may optionally use (except for TriKota, which is explicitly disabled, since it additionally requires the Dakota library [1]). It configures Trilinos for a serial build (no MPI or shared memory parallelism), using the GNU C (gcc), C++ (g++), and Fortran (gfortran) compilers (Note that the compilers used must support the C++11 standard. In the case of GNU compilers, this is version 4.7 or later). It is likely the user will need/want to customize this configure script based on their computer environment, desired set of Trilinos packages, and third-party libraries. Describing the full set of configuration options for Trilinos/Stokhos is well beyond the scope of this chapter. More information for controlling which packages are enabled, enabling parallelism, and enabling various third-party libraries is described at <https://trilinos.org/docs/files/TrilinosBuildReference.html>. The last line of the configure script is the path to the Trilinos sources, which in this case assumes a separate build directory next to the Trilinos source directory (it is not recommended to compile Trilinos within the source directory).

Trilinos is configured by running the configuration script such as the one described above. In a Unix environment, CMake defaults to generating GNU Makefiles to compile, test, and install Trilinos (Other generation options are available for integrating with common IDEs such as Xcode, Eclipse, and VisualStudio). For the default Makefile generation, Trilinos is then compiled by executing

```
make -j
```

The tests for all enabled packages can then be run (to ensure Trilinos configured and compiled correctly) by executing

```
make test
```

Optionally, the headers and libraries can be installed to the location specified by `CMAKE_INSTALL_PREFIX` via

```
make -j install
```

This will also install various CMake configuration files and GNU Makefiles allowing Trilinos to be easily compiled in to external applications. However this will not install any of the examples or tests. Those must be run from within the build directory for each package.

The above steps will build all of the examples described below within `path_to_build_directory/packages/stokhos/examples`. The executable for each example begins with the prefix `Stokhos_uq_handbook`.

6.2 Simple Polynomial Chaos Example

A brief example of applying Stokhos to compute a polynomial chaos approximation of a simple function using the template-based generic programming features of Stokhos is now described. This example is contained within the Stokhos code distribution as `Trilinos/packages/stokhos/example/uq_handbook/pce_example.cpp`.

This example computes a polynomial chaos approximation of the simple function

$$v(\xi) = \frac{1}{\log^2(u(\xi)) + 1} \quad (52.16)$$

where

$$u(\xi) = 1.0 + 0.1\xi_1 + 0.05\xi_2 + 0.01\xi_3 \quad (52.17)$$

and ξ_1, ξ_2, ξ_3 are Gaussian random variables with zero mean and unit variance. Thus $v(\xi)$ is approximated using Hermite polynomials. First the function is defined (written as a C++ template function), to which the polynomial chaos discretization will be applied.

```
#include "Stokhos_Sacado.hpp"

// The function to compute the polynomial chaos expansion of,
// written as a template function
template <class ScalarType>
ScalarType simple_function(const ScalarType& u) {
    ScalarType z = std::log(u);
    return 1.0/(z*z + 1.0);
}
```

Next comes the boilerplate code for the example, enabling short-hand for several classes used by the example.

```

int main(int argc, char **argv)
{
    // Typename of Polynomial Chaos scalar type
    typedef Stokhos::StandardStorage<int,double> storage_type;
    typedef Sacado::PCE::OrthogPoly<double, storage_type> pce_type;

    // Short-hand for several classes used below
    using Teuchos::Array;
    using Teuchos::RCP;
    using Teuchos::rcp;
    using Stokhos::OneDOrthogPolyBasis;
    using Stokhos::HermiteBasis;
    using Stokhos::CompletePolynomialBasis;
    using Stokhos::Quadrature;
    using Stokhos::TensorProductQuadrature;
    using Stokhos::Sparse3Tensor;
    using Stokhos::QuadOrthogPolyExpansion;

    try {

```

This includes a type alias for the polynomial chaosscalar type `pce_type` used for construction of a polynomial chaos approximation of the function contained within `simple_function`. Next a complete polynomial basis of total order 4 in 3 random variables using Hermite orthogonal polynomials is constructed.

```

// Basis of dimension 3, order 4
const int d = 3;
const int p = 4;
Array< RCP<const OneDOrthogPolyBasis<int,double> > > bases(d);
for (int i=0; i<d; i++) {
    bases[i] = rcp(new HermiteBasis<int,double>(p));
}
RCP<const CompletePolynomialBasis<int,double> > basis =
    rcp(new CompletePolynomialBasis<int,double>(bases));

```

Stokhos uses the reference-counted smart pointer class `RCP` extensively to enable correct memory management (The `RCP` class is similar to the smart pointer class `std::shared_ptr` now provided by the C++11 standard). Next a set of quadrature points commensurate with this polynomial basis are built, in this case a tensor product of one-dimensional Gauss-Hermite abscissas (Similarly, sparse-grid rules may be constructed. Stokhos provides an interface to the Dakota library [1] to construct these sparse grids as well as a smaller internal implementation for a more limited set of sparse-grid rules.) The sparse C_{ijk} tensor for this basis and an object implementing the overloaded math operators are also constructed. The quadrature data will be used for the transcendental operations and the sparse tensor for multiplications.

```

// Triple product tensor
RCP<Sparse3Tensor<int,double> > Cijk =
    basis->computeTripleProductTensor();

// Expansion method
RCP<QuadOrthogPolyExpansion<int,double> > expn =
    rcp(new QuadOrthogPolyExpansion<int,double>(basis, Cijk, quad));

```

The polynomial chaos expansion of u is then initialized (By default, each one-dimensional basis in Stokhos is constructed using the standard normalization of that basis. This ensures $\psi_i^1(\xi_i) = \xi_i$. By adding `true` to the second argument of the basis constructor, e.g., `HermiteBasis<int, double>(p, true)`, the basis is normalized to unit norm. However in this case $\psi_i^1(\xi_i) \neq \xi_i$ in general.), followed by the approximation of v using the overloaded operators:

```
// Polynomial expansion of u
pce_type u(expn);
u.term(0,0) = 1.0;           // zeroth order term
u.term(0,1) = 0.1;           // first order term for dimension 0
u.term(1,1) = 0.05;          // first order term for dimension 1
u.term(2,1) = 0.01;          // first order term for dimension 2

// Compute PCE expansion of function
pce_type v = simple_function(u);
```

Finally, the polynomial chaos coefficients, the mean and variance of v , and the value of the polynomial chaos approximation at a point are printed.

```
// Print u and v
std::cout << "\tu_=";
u.print(std::cout);
std::cout << "\tv_=";
v.print(std::cout);

// Compute moments
double mean = v.mean();
double std_dev = v.standard_deviation();

// Evaluate PCE and function at a point = 0.25 in each dimension
Teuchos::Array<double> pt(d);
for (int i=0; i<d; i++)
    pt[i] = 0.25;
double up = u.evaluate(pt);
double vp = simple_function(up);
double vp2 = v.evaluate(pt);

// Print results
std::cout << "\tv_mean_=" << mean << std::endl;
std::cout << "\tv_std_dev_=" << std_dev << std::endl;
std::cout << "\tv(0.25)_("true)_=" << vp << std::endl;
std::cout << "\tv(0.25)_("pce)_=" << vp2 << std::endl;
}

catch (std::exception& e) {
    std::cout << e.what() << std::endl;
}
```

This results in the following terminal output:

```
u = Stokhos::OrthogPolyApprox of size 35 in basis
Complete polynomial basis (Hermite, Hermite, Hermite):
(0, 0, 0) = 1
(1, 0, 0) = 0.1

(0, 4, 0) = 1.57928e-06
(0, 3, 1) = 1.32759e-06
(0, 2, 2) = 3.97685e-07
(0, 1, 3) = 5.30256e-08
(0, 0, 4) = 2.64633e-09
```

```

v mean          = 0.987468
v std. dev.    = 0.0182702
v(0.25) (true) = 0.998464
v(0.25) (pce)  = 0.998569

```

In printing the polynomial chaos expansions of u and v , the tuple before each term indicates the polynomial orders for each random variable corresponding to that term, e.g., $(0, 1, 3)$ represents the zeroth-, first-, and third-order Hermite polynomial terms for ξ_1 , ξ_2 , and ξ_3 respectively.

6.3 Simple Ensemble Propagation Example

Next, a variation on the previous example that employs the embedded ensemble propagation capabilities is described. The source code for this example is contained within `Trilinos/packages/stokhos/example/uq_handbook/ensemble_example.cpp`. As seen below, much of the boilerplate setup is similar to the polynomial chaos example above.

```

#include "Stokhos_Sacado.hpp"
#include "Stokhos_Sacado_Kokkos.hpp"

// The function to compute the polynomial chaos expansion of,
// written as a template function
template <class ScalarType>
ScalarType simple_function(const ScalarType& u) {
    ScalarType z = std::log(u);
    return 1.0/(z*z + 1.0);
}

int main(int argc, char **argv)
{
    // Typename of Polynomial Chaos scalar type
    typedef Stokhos::StandardStorage<int,double> pce_storage_type;
    typedef Sacado::PCE::OrthogPoly<double, pce_storage_type> pce_type;

    // Typename of ensemble scalar type
    const int EnsembleSize = 8;
    typedef Kokkos::DefaultExecutionSpace ExecSpace;
    typedef Stokhos::StaticFixedStorage<int,double,EnsembleSize,ExecSpace>
        ensemble_storage_type;
    typedef Sacado::MP::Vector<ensemble_storage_type> ensemble_type;

    // Short-hand for several classes used below
    using Teuchos::Array;
    using Teuchos::RCP;
    using Teuchos::rcp;
    using Stokhos::OneDOrthogPolyBasis;
    using Stokhos::HermiteBasis;
    using Stokhos::CompletePolynomialBasis;
    using Stokhos::Quadrature;
    using Stokhos::TensorProductQuadrature;
    using Stokhos::Sparse3Tensor;
    using Stokhos::QuadOrthogPolyExpansion;

    try {

        // Basis of dimension 3, order 4
        const int d = 3;
        const int p = 4;

```

```

Array< RCP<const OneDOrthogPolyBasis<int,double> > > bases(d);
for (int i=0; i<d; i++) {
    bases[i] = rcp(new HermiteBasis<int,double>(p));
}
RCP<const CompletePolynomialBasis<int,double> > basis =
    rcp(new CompletePolynomialBasis<int,double>(bases));

// Quadrature method
RCP<const Quadrature<int,double> > quad =
    rcp(new TensorProductQuadrature<int,double>(basis));

// Triple product tensor
RCP<Sparse3Tensor<int,double> > Cijk =
    basis->computeTripleProductTensor();

// Expansion method
RCP<QuadOrthogPolyExpansion<int,double> > expn =
    rcp(new QuadOrthogPolyExpansion<int,double>(basis, Cijk, quad));

// Polynomial expansion of u
pce_type u(expn);
u.term(0,0) = 1.0;           // zeroth order term
u.term(0,1) = 0.1;           // first order term for dimension 0
u.term(1,1) = 0.05;          // first order term for dimension 1
u.term(2,1) = 0.01;          // first order term for dimension 2

```

The only differences are an additional include for the ensemble scalar type and a set of type aliases for defining the ensemble scalar type `ensemble_type` (The execution space template parameter, which determines where and how Kokkos employs shared memory parallelism, is necessary for controlling where the ensemble array data is allocated when a dynamically sized storage scheme is chosen. In this case the array size is fixed at compile time (implying no dynamic memory allocation) and therefore the execution space parameter is not strictly necessary, but is kept for compatibility purposes). The length of the ensemble array is determined by the `EnsembleSize` template parameter, which is chose to be 8 in this case.

Next, instead of computing the polynomial chaos approximation of $v(u)$ directly using the Stokhos overloaded operators for the polynomial chaos scalar type, these coefficients will be computed through numerical integration

$$\begin{aligned}
v(u(\xi)) &\approx \sum_{i=0}^P v^i \Psi^i(\xi), \\
v^i &= \frac{1}{\langle (\Psi^i)^2 \rangle} \int_{\Gamma} v(u(x)) \Psi^i(y) \rho(y) dy \\
&\approx \frac{1}{\langle (\Psi^i)^2 \rangle} \sum_{k=0}^Q w_k v(u(y_k)) \Psi^i(y_k), \quad i = 0, \dots, P,
\end{aligned} \tag{52.18}$$

using ensemble propagation to evaluate v at multiple points simultaneously. To implement this calculation, first the quadrature weights $\{w_k\}$, quadrature points $\{y_k\}$, and values of basis functions at the quadrature points $\{\Psi^i(y_k)\}$ are extracted.

```

// Compute PCE expansion with ensemble propagation
//

// Extract quadrature data
const int pce_size = basis->size();
const int num_quad_points = quad->size();
const Array<double>& quad_weights = quad->getQuadWeights();
const Array< Array<double> >& quad_points= quad->getQuadPoints();
const Array< Array<double> >& quad_values= quad->getBasisAtQuadPoints();

```

Then a loop occurs over the quadrature points in blocks of size EnsembleSize where u is evaluated at each quadrature point within the ensemble.

```

// Loop over quadrature points in blocks of size EnsembleSize
pce_type v(expn);
ensemble_type u_ensemble;
for (int qp_block=0; qp_block<num_quad_points; qp_block+=EnsembleSize) {
    const int qp_sz = qp_block+EnsembleSize <= num_quad_points ?
        EnsembleSize : num_quad_points-qp_block;

    // Evaluate u at each quadrature point
    for (int qp=0; qp<qp_sz; ++qp)
        u_ensemble.fastAccessCoeff(qp) =
            u.evaluate(quad_points[qp_block+qp], quad_values[qp_block+qp]);
    for (int qp=qp_sz; qp<EnsembleSize; ++qp)
        u_ensemble.fastAccessCoeff(qp) =
            u_ensemble.fastAccessCoeff(qp_sz-1);
}

```

If the number of quadrature points is not evenly divisible by EnsembleSize, the remaining values in the last ensemble are duplicated from the last quadrature point. Then v is evaluated for each value of u within its ensemble, using the Stokhos ensemble overloaded operators:

```

// Evaluate function at each quadrature point
ensemble_type v_ensemble = simple_function(u_ensemble);

```

Next the polynomial chaos coefficients of v are computed using Eq. 52.18.

```

// Sum results into PCE integral
for (int pc=0; pc<pce_size; ++pc) {
    const double inv_nrm_sq = 1.0 / basis->norm_squared(pc);
    for (int qp=0; qp<qp_sz; ++qp) {
        const double w = quad_weights[qp_block+qp];
        const double psi = quad_values[qp_block+qp][pc];
        v.fastAccessCoeff(pc) +=
            inv_nrm_sq * w * v_ensemble.fastAccessCoeff(qp) * psi;
    }
}

```

Finally the chaos coefficients are printed out as before, along with statistics on v and the true and polynomial chaos approximations of v at a given point.

```

// Print u and v
std::cout << "\tu=";
u.print(std::cout);
std::cout << "\tv=";
v.print(std::cout);

// Compute moments
double mean = v.mean();
double std_dev = v.standard_deviation();

// Evaluate PCE and function at a point = 0.25 in each dimension
Teuchos::Array<double> pt(d);
for (int i=0; i<d; i++)
    pt[i] = 0.25;
double up = u.evaluate(pt);
double vp = simple_function(up);
double vp2 = v.evaluate(pt);

// Print results
std::cout << "\tv_mean=" << mean << std::endl;
std::cout << "\tv_std.dev=" << std_dev << std::endl;
std::cout << "\tv(0.25)_(true)=" << vp << std::endl;
std::cout << "\tv(0.25)_(pce)=" << vp2 << std::endl;
}
catch (std::exception& e) {
    std::cout << e.what() << std::endl;
}
}

```

This results in screen output similar to the previous example, with slightly different values due to the different method in computing the polynomial chaos coefficients.

```

u = Stokhos::OrthogPolyApprox of size 35 in basis

6.4 Nonlinear Stochastic Galerkin Example

The last example demonstrates the use of Stokhos for solving a nonlinear stochastic Galerkin problem. It computes the solution to the following simple nonlinear system of equations:

$$\begin{aligned} a^2 - x_0 &= 0 \\ x_1^2 - x_0 &= 0 \end{aligned} \tag{52.19}$$

where a is a model parameter. It is easy to see that the solution is $x_0 = a^2$, $x_1 = a$. The problem will be made stochastic by letting a become a random variable:

$$a(\xi) = 2 + \xi \tag{52.20}$$

where ξ is uniform random variable over $(-1, 1)$. Thus x_0 and x_1 will be approximated in terms of Legendre polynomials $\{\Psi^i(\xi)\}$ up to a given order N :

$$\begin{aligned} x_0(\xi) &\approx \hat{x}_0(\xi) \equiv \sum_{i=0}^N x_0^i \Psi^i(\xi) \\ x_1(\xi) &\approx \hat{x}_1(\xi) \equiv \sum_{i=0}^N x_1^i \Psi^i(\xi). \end{aligned} \quad (52.21)$$

Equations for the unknown coefficients $\{x_j^i\}$ are formulated according to the stochastic Galerkin method described above:

$$\left. \begin{aligned} \langle (a^2 - \hat{x}_0) \Psi^i \rangle &= 0 \\ \langle (\hat{x}_1^2 - \hat{x}_0) \Psi^i \rangle &= 0 \end{aligned} \right\}, \quad i = 0, \dots, N. \quad (52.22)$$

It is easy to see the exact solution is

$$\begin{aligned} x_0(\xi) &= a(\xi)^2 = 4 + 4\xi + \xi^2 = 4 \frac{1}{3} \Psi^0(\xi) + 4 \Psi^1(\xi) + \frac{2}{3} \Psi^2(\xi), \\ x_1(\xi) &= a(\xi) = 2 + \xi = 2\Psi^0(\xi) + \Psi^1(\xi). \end{aligned} \quad (52.23)$$

since $\Psi^0(\xi) = 1$, $\Psi^1(\xi) = \xi$, and $\Psi^2(\xi) = \frac{3}{2}\xi^2 - \frac{1}{2}$.

The steps necessary for formulating and solving this problem using Stokhos are described below. As with the two previous examples, the source code for this example may be found within the Stokhos distribution in the directory `Trilinos/packages/stokhos/examples/uq_handbook`. Unlike the previous two examples however, it is split into multiple source files. This example demonstrates:

- Encapsulating a nonlinear, stochastic problem into the EpetraExt ModelEvaluator [15] nonlinear interface.
- Using the Stokhos overloaded operators for computing the stochastic Galerkin residual and Jacobian coefficients in the implementation of this interface.
- The Stokhos interface for formulating the nonlinear stochastic Galerkin problem.
- Solving this nonlinear problem using the NOX [24] nonlinear solver package in Trilinos.
- Directing the NOX nonlinear solver to use various stochastic Galerkin preconditioners provided by Stokhos.

First, a class called `SimpleME` declared below contains an implementation of the nonlinear system (52.19). This class implements the `EpetraExt::ModelEvaluator` interface, which is an interface designed to provide functionality for a variety of different nonlinear solution and analysis methods: explicit and implicit time integration, direct-to-steady-state nonlinear solvers, optimization, stability

analysis, and uncertainty quantification. It leverages the Epetra package [14] in Trilinos for distributed memory (i.e., MPI) parallelism. Fully describing the Epetra object model and use of Epetra classes is beyond the scope of this chapter; however the basic Epetra classes used within this example are:

- **Epetra_Comm**: An abstract object representing a distributed memory communicator. The most common examples are **Epetra_SerialComm** when there is no parallelism and **Epetra_MPIComm** for an MPI-based communicator. It provides methods for determining the size and layout of a parallel machine, as well as basic methods for communicating data between processes.
- **Epetra_Map**: A concrete class representing the distribution of an Epetra object across a parallel machine. Each entry in the object (such as a vector entry or row of a matrix) is given a unique identifier across the parallel distribution (called a GID). **Epetra_Map** then encapsulates which GIDs are located on each processor. While GIDs must be unique, the entry corresponding to a given GID may be located on multiple processors, often called at overlapped map.
- **Epetra_Vector**: A concrete class representing double-precision vector distributed across a parallel machine. It contains an **Epetra_Map** which describes how the vector entries are distributed. The class provides various routines for accessing vector entries and performing vector arithmetic.
- **Epetra_CrsGraph**: A concrete class which represents the sparsity pattern of a general, unstructured sparse matrix, stored in the compressed row storage format. The rows of the graph are distributed in parallel through the specification of the graph's row map.
- **Epetra_CrsMatrix**: A concrete class representing a double-precision sparse matrix, which uses **Epetra_CrsGraph** to store the matrix sparsity pattern. It provides methods for accessing matrix entries as well as common linear algebra operations such as matrix-vector products and sparse triangular solves.

The **EpetraExt::ModelEvaluator** is designed to provide an interface for general (differential) algebraic systems of the form

$$\begin{aligned} 0 &= f(\dot{x}, x, p_1, \dots, p_{N_p}, t), \\ h_j &= g_j(\dot{x}, x, p_1, \dots, p_{N_p}, t), \quad k = 1, \dots, N_g. \end{aligned} \tag{52.24}$$

Here f is the set of residual equations defining the nonlinear system, g_j , $j = 1, \dots, N_g$ is a set of response functions, x is the solution vector, \dot{x} is its time derivative, p_i , $i = 1, \dots, N_p$ are model parameter vectors, and t is time. Each quantity except t above is represented by an **Epetra_Vector** with an arbitrary **Epetra_Map**. The input quantities x , \dot{x} , p_i , and t are called in-args, whereas the output quantities f , g_j , and various derivatives of these quantities such as

$$W = \alpha \frac{\partial f}{\partial \dot{x}} + \beta \frac{\partial f}{\partial x} \tag{52.25}$$

are called out-args. The `EpetraExt::ModelEvaluator` then provides an interface for specifying what in- and out-args are supported by the model, their parallel maps, the initial values of the in-args, and a function to compute the supported out-args from given values of the in-args.

For stochastic Galerkin methods, each in- and out-arg has a corresponding version that represents the polynomial chaos expansion of that quantity (with the name of that in- or out-arg appended with `_sg`). For example, the x in-arg (called `IN_ARG_x`) has a corresponding in-arg (called `IN_ARG_x_sg`) that represents

$$\hat{x}(\xi) = \sum_{i=0}^P x^i \Psi^i(\xi). \quad (52.26)$$

These in- and out-args are encapsulated within the `EpetraVectorOrthogPoly` and `EpetraOperatorOrthogPoly` classes provided by Stokhos. These classes are similar to the polynomial chaos scalar type in Stokhos; however their coefficients are Epetra vectors or matrices instead of scalars.

The declaration of the model evaluator representing (52.19) is shown below and is contained within the file `SimpleME.hpp`. In most cases the function names should be self-explanatory. For this problem there are no response functions ($N_g = 0$) and so functions dealing with response functions resort to their default (empty) implementation. Furthermore, there is only a single parameter vector to store a . The class stores maps for constructing the solution vector x where each vector entry is stored on a unique processor (`x_map`) and where all processors have every entry of x (`x_overlapped_map`), an object for importing entries between these two maps (`importer`), the initial guess for x (`x_init`), a vector to store x in the overlapped distribution (`x_overlapped`), a map to generate the parameter vector p (`p_map`), the initial value of p (`p_init`), the string name of the parameter (`p_names`), and the sparse matrix graph for the matrix $\partial f / \partial x$ (`graph`).

```
#include "Teuchos_RCP.hpp"

};
```

Next the implementation of the member functions of `SimpleME` is shown below, which is contained within the file `SimpleME.cpp`. The C++ function defining f is encapsulated in the nonmember function `func` that is templated on the scalar type. This allows a single implementation compute the residual vector f , its derivative $\partial f / \partial x$ using Sacado [28, 29] automatic differentiation [13], and the polynomial chaos approximations of these functions using the Stokhos polynomial chaos scalar type and overloaded operators.

```
#include "SimpleME.hpp"
#include "Teuchos_Assert.hpp"
#include "Stokhos_Epetra.hpp"
#include "Stokhos_Sacado.hpp"
#include "Sacado.hpp"

namespace {

template <typename ScalarA, typename ScalarX>
void func(const ScalarA& a, const ScalarX x[2], ScalarX y[2]) {
    y[0] = a*a - x[0];
    y[1] = x[1]*x[1] - x[0];
}

}
```

The constructor initializes all of the class data members described above. Since the solution vector x only has two entries, `x_map` stores two GIDs, starting with 0. The overlapped version of the map is constructed using `Epetra_LocalMap` which creates a map with all entries replicated on each processor. The initial guess for x is initialized to 1.5. The parameter map only has one entry, and the corresponding vector is initialized to 2.0. Finally the sparse matrix graph is constructed as a dense 2×2 matrix, with either of the two rows placed on a processor only if the GID for that row is contained within the map on that processor.

```
SimpleME::SimpleME(const Teuchos::RCP<const Epetra_Comm>& comm)
{
    // Solution vector map
    x_map = Teuchos::rcp(new Epetra_Map(2, 0, *comm));

    // Overlapped solution vector map
    x_overlapped_map = Teuchos::rcp(new Epetra_LocalMap(2, 0, *comm));

    // Importer
    importer = Teuchos::rcp(new Epetra_Import(*x_overlapped_map, *x_map));

    // Initial guess, initialized to 1.5
    x_init = Teuchos::rcp(new Epetra_Vector(*x_map));
    x_init->PutScalar(1.5);

    // Overlapped solution vector
    x_overlapped = Teuchos::rcp(new Epetra_Vector(*x_overlapped_map));
```

```

// Parameter vector map
p_map = Teuchos::rcp(new Epetra_LocalMap(1, 0, *comm));

// Initial parameters
p_init = Teuchos::rcp(new Epetra_Vector(*p_map));
(*p_init)[0] = 2.0;

// Parameter names
p_names = Teuchos::rcp(new Teuchos::Array<std::string>(1));
(*p_names)[0] = "alpha";

// Jacobian graph (dense 2x2 matrix)
graph = Teuchos::rcp(new Epetra_CrsGraph(Copy, *x_map, 2));
int indices[2];
indices[0] = 0; indices[1] = 1;
if (x_map->MyGID(0))
    graph->InsertGlobalIndices(0, 2, indices);
if (x_map->MyGID(1))
    graph->InsertGlobalIndices(1, 2, indices);
graph->FillComplete();
graph->OptimizeStorage();
}
}

```

Next comes the implementation of several boilerplate functions whose implementation is self-explanatory.

```

Teuchos::RCP<const Epetra_Map>
SimpleME::get_x_map() const
{
    return x_map;
}

Teuchos::RCP<const Epetra_Map>
SimpleME::get_f_map() const
{
    return x_map;
}

Teuchos::RCP<const Epetra_Map>
SimpleME::get_p_map(int l) const
{
    TEUCHOS_TEST_FOR_EXCEPTION(l != 0,
        std::logic_error,
        std::endl <<
        "Error! SimpleME::get_p_map(): " <<
        "Invalid parameter index_l=" << l << std::endl);

    return p_map;
}

Teuchos::RCP<const Teuchos::Array<std::string> >
SimpleME::get_p_names(int l) const
{
    TEUCHOS_TEST_FOR_EXCEPTION(l != 0,
        std::logic_error,
        std::endl <<
        "Error! SimpleME::get_p_names(): " <<
        "Invalid parameter index_l=" << l << std::endl);

    return p_names;
}

Teuchos::RCP<const Epetra_Vector>
SimpleME::get_x_init() const
{
}

```

```

    return x_init;
}

Teuchos::RCP<const Epetra_Vector>
SimpleME::get_p_init(int l) const
{
    TEUCHOS_TEST_FOR_EXCEPTION(l != 0,
                               std::logic_error,
                               std::endl <<
                               "Error! SimpleME::get_p_init(): "
                               "Invalid parameter index l = " << l << std::endl);

    return p_init;
}

Teuchos::RCP<Epetra_Operator>
SimpleME::create_W() const
{
    Teuchos::RCP<Epetra_CrsMatrix> A =
        Teuchos::rcp(new Epetra_CrsMatrix(Copy, *graph));
    A->FillComplete();
    A->OptimizeStorage();
    return A;
}

```

Next are the functions that determine what in- and out-args are supported by this model. In this case the model supports x and a single parameter vector as in-args, as well as the polynomial chaos expansions of these quantities. It also supports the Stokhos basis, quadrature, and expansion objects which are used to compute the stochastic Galerkin residual and Jacobian. As out-args it supports f , $W = \partial f / \partial x$, and their polynomial chaos expansions.

```

EpPetraExt::ModelEvaluator::InArgs
SimpleME::createInArgs() const
{
    InArgsSetup inArgs;
    inArgs.setModelEvalDescription("Simple_Model_Evaluator");

    // Deterministic InArgs
    inArgs.setSupports(IN_ARG_x,true);
    inArgs.set_Np(1); // 1 parameter vector

    // Stochastic InArgs
    inArgs.setSupports(IN_ARG_x_sg,true);
    inArgs.setSupports(IN_ARG_p_sg, 0, true); // 1 SG parameter vector
    inArgs.setSupports(IN_ARG_sg_basis,true);
    inArgs.setSupports(IN_ARG_sg_quadrature,true);
    inArgs.setSupports(IN_ARG_sg_expansion,true);

    return inArgs;
}

EpPetraExt::ModelEvaluator::OutArgs
SimpleME::createOutArgs() const
{
    OutArgsSetup outArgs;
    outArgs.setModelEvalDescription("Simple_Model_Evaluator");

    // Deterministic OutArgs
    outArgs.set_Np_Ng(1, 0);
    outArgs.setSupports(OUT_ARG_f,true);
    outArgs.setSupports(OUT_ARG_W,true);

    // Stochastic OutArgs

```

```

    outArgs.setSupports(OUT_ARG_f_sg, true);
    outArgs.setSupports(OUT_ARG_W_sg, true);

    return outArgs;
}

```

Next the evalModel function is shown below that computes the requested out-args from the given set of in-args. There are essentially two large blocks of code within its implementation. The first implements a deterministic calculation where x and p are supplied as in-args and f and/or W are requested as out-args. This is signaled by `inArgs.get_x()` returning a non-null RCP. In this case, the vector is copied to the overlapped distribution so that all entries are on all processors, x_0 and x_1 are extracted, the parameter value a is extracted, and the residual f or Jacobian W are computed based on which out-args are non-null. These quantities are obtained by evaluating `func` with x_0 and x_1 or AD objects representing x_0 and x_1 to compute the necessary partial derivatives.

```

void
SimpleME::evalModel(const InArgs& inArgs, const OutArgs& outArgs) const
{
    //
    // Deterministic calculation
    //

    // Solution vector
    Teuchos::RCP<const Epetra_Vector> x = inArgs.get_x();
    if (x != Teuchos::null) {
        x_overlapped->Import(*x, *importer, Insert);
        double x0 = (*x_overlapped)[0];
        double x1 = (*x_overlapped)[1];

        // Parameters
        Teuchos::RCP<const Epetra_Vector> p = inArgs.get_p(0);
        if (p == Teuchos::null)
            p = p_init;
        double a = (*p)[0];

        // Residual
        // f = | a*a - x0 |
        //     | x1*x1 - x0 |
        // where a = p[0].
        Teuchos::RCP<Epetra_Vector> f = outArgs.get_f();
        if (f != Teuchos::null) {
            double x[2] = { x0, x1 };
            double y[2];
            func(a, x, y);

            if (x_map->MyGID(0)) {
                int row = 0;
                f->ReplaceGlobalValues(1, &y[0], &row);
            }
            if (x_map->MyGID(1)) {
                int row = 1;
                f->ReplaceGlobalValues(1, &y[1], &row);
            }
        }

        // Jacobian
        // J = | -1   0   |
        //      | -1  2*x1 |
        Teuchos::RCP<Epetra_Operator> W = outArgs.get_W();
    }
}

```

```

if (W != Teuchos::null) {
    typedef Sacado::Fad<double,2> fad_type;
    fad_type x[2], y[2];
    x[0] = fad_type(2, 0, x0);
    x[1] = fad_type(2, 1, x1);
    func(a, x, y);
}

Teuchos::RCP<Epetra_CrsMatrix> jac =
    Teuchos::rcp_dynamic_cast<Epetra_CrsMatrix>(W, true);
int indices[2] = { 0, 1 };
if (x_map->MyGID(0)) {
    int row = 0;
    jac->ReplaceGlobalValues(row, 2, y[0].dx(), indices);
}
if (x_map->MyGID(1)) {
    int row = 1;
    jac->ReplaceGlobalValues(row, 2, y[1].dx(), indices);
}
}

```

The second block, shown below, implements the stochastic Galerkin calculation and is evaluated if the `x_sg` in-arg is not null. In this case, the orthogonal polynomial basis and expansion object are also extracted, which are used in the polynomial chaos evaluation of f and W (this code uses type aliases such as `InArgs::sg_const_vector_t` for `EpetraVectorOrthogPoly` for simplicity). The workflow is similar to the deterministic calculation above; however values for x_0 and x_1 are created using the polynomial chaos scalar type instead of double-precision numbers. This requires looping over each vector entry of `x_sg`, importing the entries of that vector, extracting each coefficient, and setting the corresponding polynomial chaos coefficient in `x0` and `x1`. In a similar manner the polynomial chaos expansion of a is extracted from the `p_sg` in-arg. Finally the polynomial chaos expansions of f and W are computed using the Stokhos overloaded operators described above by calling the same template function `func`. For the Jacobian matrix W , this uses the polynomial chaos scalar type nested within the Sacado automatic differentiation scalar type.

```

// Stochastic Galerkin calculation
//
// Stochastic solution vector
InArgs::sg_const_vector_t x_sg = inArgs.get_x_sg();
if (x_sg != Teuchos::null) {
    // Get stochastic expansion data
    Teuchos::RCP<const Stokhos::OrthogPolyBasis<int,double> > basis =
        inArgs.get_sg_basis();
    Teuchos::RCP<Stokhos::OrthogPolyExpansion<int,double> > expn =
        inArgs.get_sg_expansion();
    typedef Stokhos::StandardStorage<int,double> storage_type;
    typedef Sacado::PCE::OrthogPoly<double, storage_type> pce_type;

    pce_type x0(expn), x1(expn);
    for (int i=0; i<basis->size(); i++) {
        x_overlapped->Import((*x_sg)[i], *importer, Insert);
        x0.fastAccessCoeff(i) = (*x_overlapped)[0];
        x1.fastAccessCoeff(i) = (*x_overlapped)[1];
    }
}

```

```

// Stochastic parameters
InArgs::sg_const_vector_t p_sg = inArgs.get_p_sg(0);
pce_type a(expn);
if (p_sg != Teuchos::null) {
    for (int i=0; i<basis->size(); i++) {
        a.fastAccessCoeff(i) = (*p_sg)[i][0];
    }
}

// Stochastic residual
// f[i] = |<a*x - x0, psi_i>/<psi_i^2>| +
//         |<x1*x1 - x0, psi_i>/<psi_i^2>|
OutArgs::sg_vector_t f_sg = outArgs.get_f_sg();
if (f_sg != Teuchos::null) {
    pce_type x[2] = { x0, x1 };
    pce_type y[2];
    func(a, x, y);

    if (x_map->MyGID(0)) {
        int row = 0;
        for (int i=0; i<basis->size(); i++) {
            double c = y[0].coeff(i);
            (*f_sg)[i].ReplaceGlobalValues(1, &c, &row);
        }
    }
    if (x_map->MyGID(1)) {
        int row = 1;
        for (int i=0; i<basis->size(); i++) {
            double c = y[1].coeff(i);
            (*f_sg)[i].ReplaceGlobalValues(1, &c, &row);
        }
    }
}

// Stochastic Jacobian
// J[0] = | -1      0      |,   J[i] = |  0      0      |,   i > 0
//          | -1  2*x0[0] |
OutArgs::sg_operator_t W_sg = outArgs.get_W_sg();
if (W_sg != Teuchos::null) {
    typedef Sacado::Fad::SFad<pce_type,2> fad_type;
    fad_type x[2], y[2];
    x[0] = fad_type(2, 0, x0);
    x[1] = fad_type(2, 1, x1);
    func(a, x, y);

    for (int i=0; i<basis->size(); i++) {
        Teuchos::RCP<Epetra_CrsMatrix> jac =
            Teuchos::rcp_dynamic_cast<Epetra_CrsMatrix>(W_sg->getCoeffPtr(i),
                                                          true);
        int indices[2] = { 0, 1 };
        if (x_map->MyGID(0)) {
            int row = 0;
            double values[2] = { y[0].dx(0).coeff(i), y[0].dx(1).coeff(i) };
            jac->ReplaceGlobalValues(row, 2, values, indices);
        }
        if (x_map->MyGID(1)) {
            int row = 1;
            double values[2] = { y[1].dx(0).coeff(i), y[1].dx(1).coeff(i) };
            jac->ReplaceGlobalValues(row, 2, values, indices);
        }
    }
}
}

```

One can see that the use of the Stokhos polynomial chaos scalar type in conjunction with C++ templates for implementing the equations defining the nonlinear model makes evaluation of a stochastic Galerkin residual and Jacobian nearly as simple as evaluating deterministic residuals and Jacobians. Furthermore, most of the code shown above is independent of the actual problem being solved and only depends on the number of degrees-of-freedom, the parallel layout, and the sparsity pattern of the matrix. Thus in a large simulation code, this code can often be written once and then applied to a wide range of different physical problems with different implementations of the templated, physics-specific code (which are in turn independent of Stokhos).

Finally the driver code that uses the `SimpleME` model evaluator above to actually solve the stochastic Galerkin system is shown below and is contained within the file `nonlinear_sg_example.cpp`. It includes a function to create and initialize the NOX nonlinear solver (`create_nox_solver()`) whose implementation is suppressed for brevity.

```
#include <iostream>

// NOX
#include "NOX.H"
#include "NOX_Epetra.H"

// Epetra communicator
#ifndef HAVE_MPI
#include "Epetra_MpiComm.h"
#else
#include "Epetra_SerialComm.h"
#endif

// Stokhos Stochastic Galerkin
#include "Stokhos_Epetra.hpp"

// Utilities
#include "Teuchos_GlobalMPISession.hpp"
#include "Teuchos_StandardCatchMacros.hpp"

// Our model
#include "SimpleME.hpp"

// Function to setup the NOX nonlinear solver from a given model evaluator
Teuchos::RCP<NOX::Solver::Generic>
create_nox_solver(int MyPID,
                  const Teuchos::RCP<EpetraExt::ModelEvaluator>& model);
```

First the Epetra communicator is initialized, depending on whether MPI was enabled (note that the configure script above does not enable MPI).

```
int main(int argc, char *argv[]) {
    using Teuchos::rcp;
    using Teuchos::RCP;
    using Teuchos::Array;
    using Teuchos::ParameterList;
    using Stokhos::OneDOrthogPolyBasis;
    using Stokhos::LegendreBasis;
    using Stokhos::CompletePolynomialBasis;
```

```

using Stokhos::OrthogPolyExpansion;
using Stokhos::AlgebraicOrthogPolyExpansion;
using Stokhos::ParallelData;
using Stokhos::SGModelEvaluator;
using Stokhos::EpetraVectorOrthogPoly;

// Initialize MPI
Teuchos::GlobalMPISession mpiSession(&argc, &argv);

int MyPID;
bool success = true;
try {

    // Create a communicator for Epetra objects
    RCP<const Epetra_Comm> globalComm;
#ifndef HAVE_MPI
    globalComm = rcp(new Epetra_MpiComm(MPI_COMM_WORLD));
#else
    globalComm = rcp(new Epetra_SerialComm);
#endif
    MyPID = globalComm->MyPID();
}

```

Then the Stokhos objects describing the polynomial chaos discretization are generated, as described before. This code creates a basis for a single uniform random variable using Legendre polynomials up to order $N = 5$. Included here as well is code to enable Stokhos to distribute polynomial chaos coefficients across the parallel machine. By changing `num_spatial_procs` to 1, the polynomial chaos coefficients for x would be distributed in parallel (the default -1 used here means to use all processors for distributing the entries of x in parallel).

```

// Create Stochastic Galerkin basis and expansion
const int p = 5;
Array< RCP<const OneDOrthogPolyBasis<int,double> > > bases(1);
bases[0] = rcp(new LegendreBasis<int,double>(p));
RCP<const CompletePolynomialBasis<int,double>> basis =
    rcp(new CompletePolynomialBasis<int,double>(bases));
RCP<Stokhos::Sparse3Tensor<int,double>> Cijk =
    basis->computeTripleProductTensor();
RCP<OrthogPolyExpansion<int,double>> expansion =
    rcp(new AlgebraicOrthogPolyExpansion<int,double>(basis, Cijk));

// Create stochastic parallel distribution
int num_spatial_procs = -1;
ParameterList parallelParams;
parallelParams.set("Number_of_Spatial_Processors", num_spatial_procs);
RCP<ParallelData> sg_parallel_data =
    rcp(new ParallelData(basis, Cijk, globalComm, parallelParams));
RCP<const Epetra_Comm> app_comm = sg_parallel_data->getSpatialComm();

```

Next, the model evaluator encapsulating the model is created. Parameters for describing how the stochastic Galerkin matrix should be preconditioned are also specified. In this case a mean-based preconditioner using an incomplete LU factorization of the mean is chosen. Other options for both the stochastic and mean preconditioners are available (most stochastic preconditioners require specifying the mean preconditioner to control how the inverse of the mean blocks is approximated). For example, by replacing “mean-based” with “approximate Gauss-Seidel” allows a Gauss-Seidel method applied to the stochastic blocks to be chosen.

```
// Create application model evaluator
RCP<EpetraExt::ModelEvaluator> model = rcp(new SimpleME(app_comm));

// Setup stochastic Galerkin algorithmic parameters
RCP<ParameterList> sgParams = rcp(new ParameterList);
ParameterList& sgPrecParams = sgParams->sublist("SG_Preconditioner");
sgPrecParams.set("Preconditioner_Method", "Mean-based");
//sgPrecParams.set("Preconditioner Method", "Approximate Gauss-Seidel");
sgPrecParams.set("Mean_Preconditioner_Type", "Ifpack");
```

Next an adapter called `SGModelEvaluator` is created that wraps the `SimpleME` model evaluator and translates the stochastic Galerkin system to a deterministic system suitable for traditional nonlinear solution and analysis algorithms. For example, it translates a polynomial chaos representation of x to and from a block-vector representation:

$$\hat{x} \equiv \sum_{i=0}^P x^i \Psi^i(\xi) \leftrightarrow X \equiv \begin{bmatrix} x^0 \\ \vdots \\ x^P \end{bmatrix} \quad (52.27)$$

Similarly, given the polynomial chaos approximation $\partial f / \partial x \approx \sum_{i=0}^P A^i \Psi^i(\xi)$, this adapter creates an operator for $\partial F / \partial X$ using Eq. 52.14. This allows stochastic models implementing the polynomial chaos in- and out-args to be applied to standard time integrators, nonlinear solvers, and optimizers. In this case, this model evaluator will be given to the NOX nonlinear solver to solve for the unknown polynomial chaos coefficients of x .

```
// Create stochastic Galerkin model evaluator
RCP<SGModelEvaluator> sg_model =
    rcp(new SGModelEvaluator(model, basis, Teuchos::null, expansion,
                           sg_parallel_data, sgParams));
```

Next the initial guess for `x_sg` is constructed by taking the initial guess from `SimpleME` and setting the mean term with the higher-order coefficients set to zero. Similarly the polynomial chaos expansion of the parameter is set to the mean term provided by `SimpleME`, the first-order term set to 1, and all higher-order terms set to 0.

```
// Stochastic Galerkin initial guess
// Set the mean to the deterministic initial guess, higher-order terms
// to zero
RCP<EpetraVectorOrthogPoly> x_init_sg = sg_model->create_x_sg();
x_init_sg->init(0.0);
(*x_init_sg)[0] = *(model->get_x_init());
sg_model->set_x_sg_init(*x_init_sg);

// Stochastic Galerkin parameters
// Linear expansion with the mean given by the deterministic initial
// parameter values, linear terms equal to 1, and higher order terms
// equal to zero.
RCP<EpetraVectorOrthogPoly> p_init_sg = sg_model->create_p_sg(0);
p_init_sg->init(0.0);
(*p_init_sg)[0] = *(model->get_p_init());
```

```

for (int i=0; i<model->get_p_map(0)->NumMyElements(); i++)
    (*p_init_sg)[i+1][i] = 1.0;
sg_model->set_p_sg_init(0, *p_init_sg);
std::cout << "Stochastic_Galerkin_parameter_expansion_=" << std::endl
    << *p_init_sg << std::endl;

```

Finally, the NOX nonlinear solver is created and solved. The details of creating this solver are not shown here. Once the nonlinear solver terminates, the final solution is extracted, converted to a polynomial chaos expansion, and then printed to the screen.

```

// Build nonlinear solver (implemented above)
RCP<NOX::Solver<Generic> solver = create_nox_solver(MyPID, sg_model);

// Solve the system
NOX::StatusTest::StatusType status = solver->solve();

// Get final solution
const Epetra_Vector& finalSolution = get_final_solution(*solver);

// Convert block Epetra_Vector to orthogonal polynomials
RCP<Stokhos::EpetraVectorOrthogPoly> x_sg =
    sg_model->create_x_sg(View, &finalSolution);

if (MyPID == 0)
    std::cout << "Final_Solution_=" << std::endl;
    std::cout << *x_sg << std::endl;

if (status != NOX::StatusTest::Converged)
    success = false;
}
TEUCHOS_STANDARD_CATCH_STATEMENTS(true, std::cerr, success);

if (success && MyPID == 0)
    std::cout << "Example_Passed!" << std::endl;

if (!success)
    return 1;
return 0;
}

```

The screen output of the nonlinear solution process is shown below, along with the computed final solution.

```

Destroying preconditioner
Example Passed!

In this case, five Newton iterations are required to drive the nonlinear residual norm of the stochastic Galerkin system down below a tolerance of 10^{-10} . The linear system for each Newton iteration is solved by GMRES using the mean-based preconditioner provided by Stokhos, where the inverse of the mean is approximated by an incomplete LU factorization. The linear solver tolerance was set to 10^{-6} . By examining the computed solution, one can see the correct solution is obtained as derived above (up to the nonlinear solver tolerance).

6.5 Nonlinear Fluid Flow Problem with Albany

The previous examples demonstrate the utility of the template-based generic programming approach provided by Stokhos in making complicated, intrusive uncertainty propagation methods simpler to implement in simulation codes. The application must incorporate a small amount of code to set up the various Stokhos objects, provide Stokhos-specific code to evaluate stochastic Galerkin linear algebra objects such as residual vectors and Jacobian matrices, and then “merely” template the rest of the simulation code on the scalar type. While templating the code on the scalar type can involve substantial effort, this only needs to occur once. It has been observed that once the code has been templated, maintaining and extending the code (e.g., adding new physics or features) become simple for code developers that aren’t experts in uncertainty quantification methods. This approach has been used quite effectively in the Albany simulation code [26, 35], which implements PDE simulations of many types of complex physics. Furthermore, the code necessary to setup Stokhos is largely independent of the details of the simulation code and therefore can often be written once for a large class of simulation codes. This setup code has been incorporated into the Trilinos package Piro [34] making it possible to add Stokhos capabilities with only a few additional lines of code.

As a demonstration of applying these techniques in more realistic scientific computing scenarios, results from applying Stokhos to compute the solution to a fluid flow problem with uncertain input data are provided. A two-dimensional domain $D = [-5, 25] \times [-4, 4]$ is considered where fluid flows in from the left side

of the domain with a prescribed velocity and flows around a small cylinder within the domain and out the right side. No-slip boundary conditions are applied at the top and bottom walls of the domain as well as the cylinder. In the interior of the domain, the fluid is modeled by the incompressible Navier-Stokes equations:

$$\begin{aligned} -\nu \Delta u + u \cdot \nabla u + \nabla p &= 0, \\ \nabla \cdot \rho u &= 0, \end{aligned} \quad (52.28)$$

where u is the two-dimensional fluid velocity, p is pressure, ν is the kinematic viscosity, and ρ is the fluid density. In this case ν is considered uncertain and modeled by a truncated Karhunen-Loëve expansion

$$\nu(x, \xi) = \nu_0 + \sigma \sum_{i=0}^M \nu_i(x) \xi_i, \quad (52.29)$$

where each ξ_i is a uniform random variable over $[-1, 1]$, ν_0 is the mean field, σ is its standard deviation, the ν_i are eigenfunctions of the exponential covariance function

$$C(x, x') = \sigma^2 e^{-\frac{\|x-x'\|_1}{L}}, \quad x, x' \in D \quad (52.30)$$

and L is the correlation length. For this problem, $\rho = 1$, $\nu_0 = 1$, $\sigma = 0.1$, $L = 1$, $M = 2$, and the inlet velocity is fixed at 40.

The spatial domain D is discretized into roughly 13,300 quadrilateral cells and discretized via linear finite elements with Albany. Albany incorporates all of the embedded uncertainty quantification tools described above. It implements the `EpetraExt::ModelEvaluator` described above to formulate the nonlinear stochastic Galerkin problem and can use the Stokhos polynomial chaos scalar type for evaluating the finite element residual and Jacobian entries for each mesh cell. These coefficients are then assembled into Epetra residual and Jacobian objects in a manner similar to the one shown above. The Piro package handles the initialization of the relevant Stokhos objects from an input XML file as well as the NOX nonlinear solver. In this case, a total polynomial order of $N = 3$ was chosen for building the polynomial chaos approximation of u and p . The resulting nonlinear equations were solved by NOX using Newton's method, where the solution to each linear system was computed by GMRES. The Stokhos approximate Gauss-Seidel stochastic preconditioner was used to precondition each linear system using an incomplete LU factorization of the mean blocks. The linear solver tolerance was set to 10^{-3} and six Newton iterations were required to achieve relative solution updates smaller than 10^{-6} . The nonlinear stochastic Galerkin system was then solved in parallel using MPI on 32 processors. Once the stochastic Galerkin solution was computed, the mean and standard deviation of the fluid velocity were computed directly from its polynomial chaos expansion and are shown in Fig. 52.2.

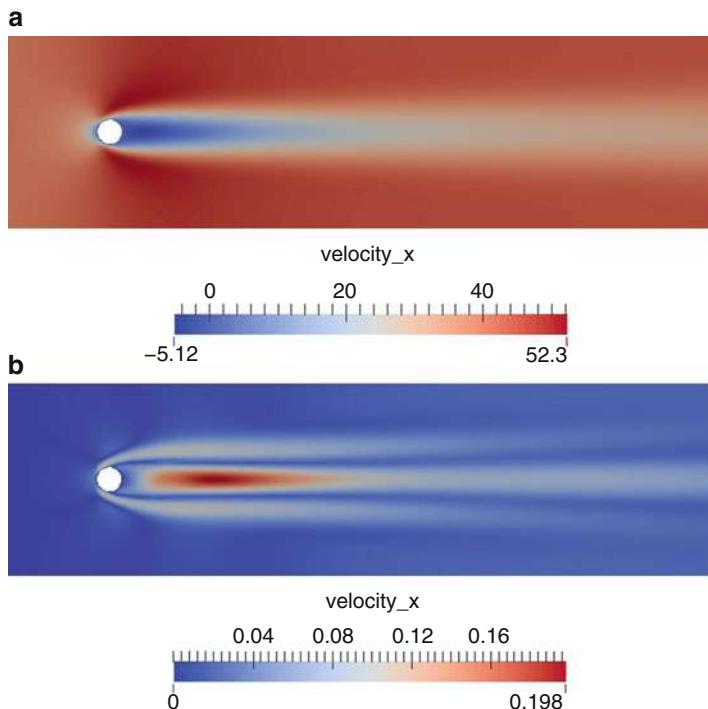

Fig. 52.2 Mean (a) and standard deviation (b) of the horizontal component of the fluid velocity for fluid flow around a cylinder with uncertain viscosity field

7 Conclusions

As described above, Stokhos provides a complete set of software tools for implementing embedded uncertainty quantification methods such as stochastic Galerkin and embedded sampling methods in general C++ simulation codes. It provides polynomial chaos and ensemble scalar types that allow uncertainty information to be propagated at the lowest levels of the simulation code using the operator overloading capabilities of the C++ language. These scalar types, in conjunction with judicious use of C++ templates, allow simulation codes to be easily modified to incorporate these embedded uncertainty propagation capabilities. Furthermore, these scalar types have been integrated with the Kokkos and Tpetra packages enabling their use in both shared and distributed memory parallel environments and enable application of fine-grained hardware parallelism across uncertainty dimensions. Finally, Stokhos provides capabilities for formulating the large-scale linear and nonlinear systems these embedded uncertainty quantification methods generate through a general nonlinear system interface that has been integrated with numerous nonlinear simulation and analysis packages within Trilinos. These packages, in conjunction with custom linear solver and preconditioning algorithms provided by Stokhos, allow large-scale embedded uncertainty quantification systems to be solved

in a scalable and efficient manner. All of these techniques have been incorporated into the Albany simulation code, enabling embedded uncertainty quantification of a diverse set of physical simulations.

Abstract

The UQ Toolkit (UQTk) is a collection of tools for uncertainty quantification, ranging from intrusive and nonintrusive forward propagation of uncertainty to inverse problems and sensitivity analysis. This chapter first outlines the UQTk design philosophy, followed by an overview of the available methods and the way they are implemented in UQTk. The second part of this chapter is a detailed example that illustrates a UQ workflow from surrogate construction, and calibration, to forward propagation and attribution.

Keywords

UQTk • UQ toolkit • Polynomial chaos • Quadrature • Bayesian inference • Markov chain Monte Carlo • Global sensitivity analysis • Surrogate modeling • Uncertainty propagation

1 Introduction

As the name implies, the UQ Toolkit (UQTk) is a collection of tools for uncertainty quantification (UQ) in computational models. Both the terms *tools* and *UQ* are to be interpreted quite broadly here. The term *tools* refers to C++ classes and libraries, stand-alone applications, or *apps*, as well as Python scripts. UQ refers to all operations involved in assessing and improving the confidence in a numerical model prediction such as parameter inference, sensitivity analysis, surrogate construction, or forward propagation of uncertainty.

In terms of design philosophy, UQTk is meant to be a set of UQ tools that is straightforward to download, install, and use. The target users are people who are learning about UQ methods, or who are developing new UQ algorithms, or who have a need for UQ tools that are tailored to their applications. Rather than implementing a comprehensive set of functionalities in one single software library, UQTk offers a set of tools, each implementing specific operations that can be strung together to build a complete UQ workflow. The current UQTk version is 3.0, which is available on the web at <http://www.sandia.gov/UQToolkit> [7] under the Lesser General Public License (LGPL).

The next section gives an overview of the various UQ algorithms and methods that are implemented in UQTk, followed by a section that covers some of the implementation and installation details. An example of comprehensive UQ workflow with UQTk is detailed at the end.

2 Methods

The UQTk library implements several methodologies using a modular approach facilitated by the C++ programming language. The current software release, UQTk v3.0, provides capabilities for numerical quadrature, polynomial chaos representations, Markov chain Monte Carlo, Bayesian compressive sensing, and random field representations via Karhunen-Loeve expansions. These capabilities are implemented via C++ classes or functions and are briefly described below.

The numerical quadrature C++ class, *Quad*, constructs multidimensional full tensor and sparse quadrature rules based on several 1D quadrature rules. The weights for 1D Newton-Cotes (NC) rules [13] are computed via the solution of Vandermonde systems, while the weights and grid points for Clenshaw-Curtis (CC) [4] rules are computed analytically. Both closed and open NC and CC rules are provided by the library. In addition to NC and CC rules, 1D quadrature rules are also

Table 53.1 Polynomial bases implemented in UQTk and the corresponding random variables

Polynomial basis	Random variable
Legendre	Uniform
Hermite	Gaussian
Jacobi	Beta
Laguerre	Gamma

computed based on a series of orthogonal polynomials in the Askey scheme [1, 25]: e.g., Legendre, Hermite, Jacobi, and Laguerre. The quadrature points and weights for this set of rules are computed based on the Golub-Welsch algorithm [11]. The Quad class can also create custom quadrature rules for orthogonal polynomials given via two-term recurrence coefficients provided by the user. Multidimensional rules are created using either full tensor products, generally feasible for low dimensionality. Smolyak constructions [9, 23] are employed for sparse quadrature rules.

Methods pertaining to polynomial chaos constructions [10] are implemented via two C++ classes, *PCSet* and *PCBasis*. The latter provides implementations for polynomial bases orthogonal with respect to various continuous random variables. These are shown in Table 53.1.

This class is connected with the *Quad* class for the purpose of retrieving quadrature points and weights corresponding to a specific polynomial basis. The *PCBasis* class provides these functionalities to the *PCSet* class which implements operations for both intrusive (ISP) and nonintrusive (NISP) spectral projection [6]. Briefly, the latter class provides several methods for unitary operations, such as logarithm, and binary operations, e.g., addition or division, with PC expansions (PCE). Arithmetic operations involving a larger number of PCEs can be cast in a sequence of unitary and binary operations. In order to reduce the aliasing errors, *PCSet* also provides a method for products of three PCEs. Methods for Galerkin projection include both quadrature and Monte Carlo integration approaches. The *PCSet* class provides several other functionalities like computing main and joint effect sensitivity indices or evaluating PCEs at custom germ values.

For inverse problems, Bayesian inference methods are provided in the *MCMC* class. Several Markov chain Monte Carlo (MCMC) algorithms are implemented in this class, such as Gibbs sampling [8], the adaptive MCMC methodology [12], and the Metropolis-adjusted Langevin algorithm (MALA) [15] to sample probability densities that are otherwise difficult to estimate analytically. The *MCMC* class provides several methods to set algorithm parameters, including parameter bounds and initial proposal densities. Similarly, several methods are implemented for the retrieval of information from the sample chain. If necessary, this class connects to an optimization library to compute and start the chain samples at the maximum a posteriori estimate.

The Bayesian compressive sensing (BCS) approach of Babacan [2] is implemented via a C++ function named *bcs*. This function uses Laplace priors and a greedy algorithm to detect sparsity in high-dimensional settings. Python scripts, available via PyUQTk, wrap around this function to provide an iterative BCS formulation [19].

The *kle* class implements functionalities for representing random fields via Karhunen-Loëve (KL) expansions [10]. This class constructs orthogonal basis functions via the solution of an eigensystem constructed from the random field covariance matrix provided by the user. Further, the *kle* class allows the user to specify custom grid weights, thus enabling KL expansions for random fields of arbitrary meshes and dimensionality. Currently, this class uses the LAPACK library to compute eigenvalues/eigenvectors for the KL expansion. The class also provides methods for projecting the random field samples on the eigenmodes and retrieving samples of random variables corresponding to each mode.

3 Implementation and Installation

UQTk is primarily a collection of C++ classes and functions for quadrature, polynomial approximation, Markov chain Monte Carlo sampling, Bayesian compressive sensing, and Karhunen-Loeve construction. UQTk relies on a few additional FORTRAN and C libraries for linear algebra (LAPACK and BLAS), quadrature, optimization (LBFGS), ordinary different equation solvers (cvode), and other general purpose mathematical and statistics routines (SLATEC). These third-party libraries are packaged as part of UQTk and do not need to be downloaded separately. UQTk v3.0 also comes with the option of installing a Python interface to the C++ classes and functions using SWIG (Simplified Wrapper Interface Generator).

The software can be downloaded from <http://www.sandia.gov/UQToolkit> [7] as a tar file. UQTk uses CMake for cross-platform building and installation. In order to compile the default C++ libraries, the user will need C, C++, and FORTRAN compilers. To install the Python interface to UQTk, PyUQTk, the user will also need Python and SWIG. For more details about compiler versions and architectures, e.g., Mac OSX and Linux compatibility, etc., the reader is referred to the INSTALL file located in the UQTk source code directory or to the UQTk manual, which is available online at <http://www.sandia.gov/UQToolkit>.

After UQTk is built and installed, the user can run a series of tests using the CTest command to make sure the libraries were successfully compiled. Assuming the installation was successful, the installation directory should contain *include* and *lib* directories, which contain all the C++ header files and libraries, respectively. The user can use these header files and libraries to integrate UQTk into their existing C++ codes by linking their existing C++ code to these libraries. UQTk is designed to be modular in that the user has the option of linking to a desired subset of the libraries. For example, if the user wants to utilize the quadrature library, then he or she only needs the *libuqtarray.a* and *libuqtquad.a* libraries along with their respective header files. For simplicity, the *libuqt.a* library contains all UQTk classes and routines and *libuqtdep.a* contains all dependent libraries, e.g., LAPACK, BLAS, SLATEC, etc., except for cvode, which is included in the libraries *libdep_cvode.a* and *libdep_nvvec.a*. Examples of how to integrate UQTk into existing C++ code can be found under the *cpp/tests* directory. It is important to note that most of these libraries rely on a UQTk-specific array class defined in the *ArrayID.h* and

Array2D.h header files. These array classes are simply a wrapper for the standard C++ vector class.

So far, this text covered the integration of UQTk with existing C++ code. However, UQTk also provides a collection of separate executables or applications to be used outside the scope of the user code. These executables can be found in the *bin* folder in the installation directory. For example, the executable *model_inf* can be used to infer model parameters from user-provided data. More examples of how to use these applications can be found in the *examples* directory or in the *Workflows* section of this chapter.

The most recent addition to UQTk is PyUQTk, which is a collection of pure Python and SWIG interface files to the UQTk C++ classes routines. The pure Python routines mostly consist of functions for plotting and post-processing of data. In order to also compile and create the SWIG interface, the user needs to set the *PyUQTk* flag to ON in the CMake setup stage. After successful compilation, this will generate Python libraries that wrap UQTK's C++ classes and methods and allow easy translation from Numpy style arrays to the arrays used in UQTk. To see examples of how to use the SWIG interface, see the test directory under the *PyUQTk* folder.

4 Example Workflow

In this section, an example workflow is performed demonstrating many of the forward and inverse UQ capabilities of UQTk. Consider a model $g(\lambda)$ that is used to compute some quantity of interest. In this model, λ is a set of parameters that have some uncertainty associated with them. *For example*, $g(\lambda)$ may be a model to compute the heat losses of a house, while λ is the set of conductive and convective heat transfer coefficients that are needed to compute the heat fluxes through the walls and windows of the house. The main goal of the UQ workflow described here is to determine the uncertainty in the predictions made with $g(\lambda)$ due to the uncertainty in the model inputs λ . In essence, this is a typical forward UQ problem. However, the uncertainty in λ first needs to be characterized before it can be propagated through $g(\lambda)$. This is done through calibration, i.e., an inverse problem. Often, the calibration relies on a different model $f(\lambda)$ instead of $g(\lambda)$. In the example of the computation of the heat losses of a house, $f(\lambda)$ may represent an experiment for the measurement of heat transfer coefficients by applying known heat fluxes to well-controlled samples of the materials that make up the walls and windows of the house.

A schematic of the resulting overall workflow is depicted in more detail in Fig. 53.1. In the calibration step, the parameters λ are determined given data $\mathcal{D} = \{y_i\}$ and the model $f(\lambda)$ associated with the data. Such parameter estimation requires *training* evaluations of the model $f(\lambda)$ at selected values of λ . This is typically computationally intensive when $d \gg 1$, i.e., the input parameter vector λ is high dimensional, as well as when $f(\cdot)$ itself is a complex model that takes significant computational resources to run for a fixed set of parameters λ . In such

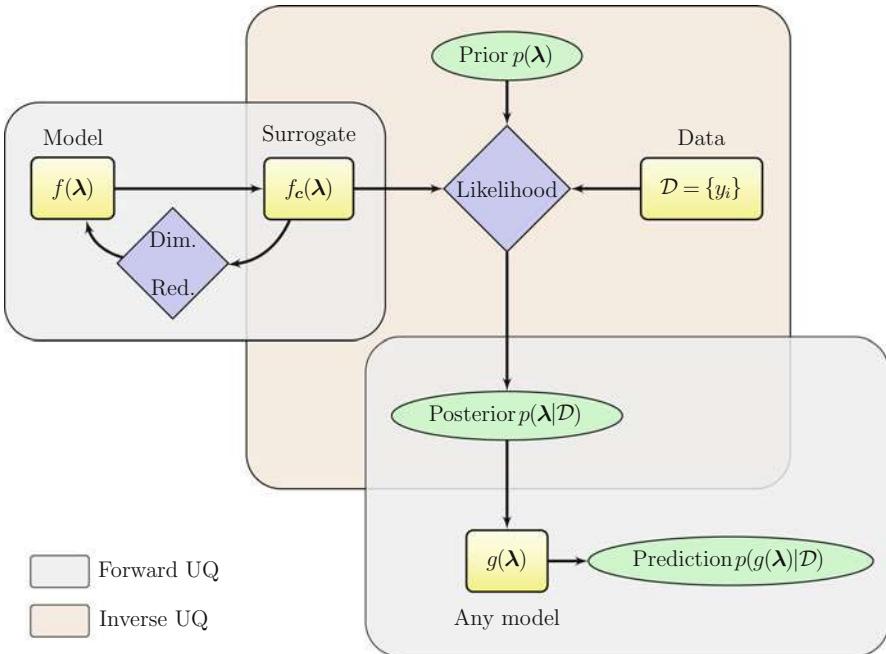

Fig. 53.1 Forward and inverse UQ schematic. Inverse UQ corresponds to parameter estimation, also called calibration. The first forward UQ task consists of sensitivity analysis, dimensionality reduction, and surrogate construction, while the second forward UQ task is for forward prediction with already calibrated parameters

situations, it is common to precompute a computationally cheap surrogate for the model $f(\lambda)$ to replace it in computationally intensive studies. While UQTk offers a few different types of surrogates (e.g., radial basis function expansions or Gaussian process regression), here the use of polynomial chaos (PC) surrogates is highlighted. Besides being cheap to evaluate, a PC surrogate offers readily available sensitivity indices that can help identify the parameters that actually impact the model output, which can in turn be used to derive a reduced-dimensionality surrogate. Such surrogate construction and subsequent sensitivity analysis can be viewed as a *forward UQ* task since it is equivalent to propagating uniformly distributed, *i.i.d* input parameters λ through the model $f(\lambda)$. If there is a clear indication that the problem dimensionality can be reduced, one should repeat this forward UQ step to construct a lower-dimensional surrogate that approximates the model over the range of variability of the most important parameters only, while keeping the non-important ones at their nominal values. Such a lower-dimensional surrogate will in principle be more accurate as more training points per dimension can be afforded in the low-dimensional space, and it will render the subsequent calibration to be much more well-conditioned.

The outcome of the calibration or *inverse UQ* step is the characterization of the uncertainties in the relevant parameters λ in the form of the posterior distribution for these parameters. This posterior distribution can then in turn be pushed through any predictive model of interest $g(\lambda)$. As mentioned before, this is also a forward UQ step, but with a much more informed input parameter distribution for λ compared to the uniform *i.i.d.* one that was used for the surrogate construction. Note that one could also push the parameter posterior through the calibrated model $f(\lambda)$ itself in order to validate or check the quality of calibration. However, in general, any model of interest can be employed for forward UQ even if there is no observed data associated with it.

In the sections below, the implementation with UQTK for the elements in the workflow of Fig. 53.1 is illustrated for arbitrarily chosen functions $f(\lambda)$ and $g(\lambda)$.

4.1 Polynomial Chaos Surrogate Construction

Consider a function $f(\lambda)$, where $\lambda = (\lambda_1, \dots, \lambda_d)$ is a d -dimensional input parameter vector defined on a hypercube $\Omega = \prod_{i=1}^d [a_i, b_i]$. Computationally intensive studies that require many model evaluations often necessitate the usage of *surrogates*, i.e., fast-to-evaluate approximations $f_c(\lambda) \approx f(\lambda)$ over the domain of interest Ω , parameterized by a vector c . This workflow will demonstrate surrogates based on polynomial chaos machinery. To this end, it is worth observing that surrogate construction is a special case of PC-based forward propagation of uncertainty. One first casts the input vector λ as uniformly distributed, *i.i.d.* random variables or a linear PC expansion with respect to standard uniform, *i.i.d.* random vector ξ with component-wise linear scaling:

$$\lambda_i = \frac{a_i + b_i}{2} + \frac{b_i - a_i}{2} \xi_i, \quad \text{for } i = 1, \dots, d. \quad (53.1)$$

The forward uncertainty propagation task then becomes constructing a PC for the output:

$$f(\lambda(\xi)) \approx \sum_{\alpha \in \mathcal{S}} c_\alpha \Psi_\alpha(\xi), \quad (53.2)$$

where $\lambda(\xi)$ is the relationship encoded in the linear PC (53.1). From the surrogate construction viewpoint, one seeks an approximation $f(\lambda) \approx f_c(\lambda) = \sum_{\alpha \in \mathcal{S}} c_\alpha \Psi_\alpha(\xi(\lambda))$ over the range of the inputs λ . The basis $\Psi_\alpha(\xi) = \psi_{\alpha_1}(\xi_1) \cdots \psi_{\alpha_d}(\xi_d)$ is a multivariate Legendre polynomial, corresponding to a *multiindex* $\alpha = (\alpha_1, \dots, \alpha_d)$, and each individual α_i denotes the order of the univariate Legendre polynomial $\psi_{\alpha_i}(\xi_i)$. The basis/multiindex set \mathcal{S} can be truncated according to predefined rules. Here the most commonly used total-order truncation is employed, i.e., $\mathcal{S} = \left\{ \alpha : \sum_{i=1}^d \alpha_i \leq p \right\}$ for some *order* p . With such truncation, the cardinality of the basis is $|\mathcal{S}| = K = (p+d)!/(p!d!)$.

The forward UQ task or, in this case, surrogate construction now boils down to computing the PC coefficient vector $\mathbf{c} = c_\alpha$ given a set of *training* simulations of the model at parameter settings $\boldsymbol{\lambda}^{(i)} = \boldsymbol{\lambda}(\boldsymbol{\xi}^{(i)})$ corresponding to values $(\boldsymbol{\xi}^{(1)}, \dots, \boldsymbol{\xi}^{(N)})$ of the underlying standard random variable $\boldsymbol{\xi}$, i.e., a set of input-output pairs $\left\{(\boldsymbol{\lambda}^{(i)}, f^{(i)})\right\}_{i=1}^N$, where $f^{(i)} = f(\boldsymbol{\lambda}^{(i)})$.

Typically, the number of PC coefficients is smaller than the number of data points, i.e., $K < N$, and therefore it is generally impossible to exactly interpolate $f_c(\boldsymbol{\lambda}^{(i)}) = f^{(i)}$. Regression-based approaches search for a minimum of some distance measure between the vectors of model simulation $\mathbf{f} = (f^{(1)}, \dots, f^{(N)})$ and surrogate evaluation at the training points $\mathbf{f}_c = (f_c(\boldsymbol{\lambda}^{(1)}), \dots, f_c(\boldsymbol{\lambda}^{(N)}))$, i.e., $\mathbf{c} = \arg \min \rho(\mathbf{f}, \mathbf{f}_c)$. For example, the most commonly used least-squares approach corresponds to $\rho(\mathbf{f}, \mathbf{f}_c) = \|\mathbf{f} - \mathbf{f}_c\|_2$.

For the purposes of this workflow, another approach, *orthogonal projection*, is employed, which makes use of the orthogonality of the basis polynomials $\Psi_\alpha(\boldsymbol{\xi})$, and minimizes the function-norm $R(f, f_c) = \int_{\Omega} [f(\boldsymbol{\lambda}) - f_c(\boldsymbol{\lambda})]^2 \pi_\lambda(\boldsymbol{\lambda}) d\boldsymbol{\lambda}$ with respect to the probability density function (PDF) of $\boldsymbol{\lambda}$, denoted by $\pi_\lambda(\boldsymbol{\lambda})$. Namely, the coefficient c_α is found by:

$$c_\alpha = \frac{1}{\|\Psi_\alpha(\boldsymbol{\xi})\|^2} \langle f(\boldsymbol{\lambda}(\boldsymbol{\xi})) \Psi_\alpha(\boldsymbol{\xi}) \rangle, \quad (53.3)$$

where $\|\Psi_\alpha(\boldsymbol{\xi})\| = \sqrt{\langle \Psi_\alpha(\boldsymbol{\xi})^2 \rangle}$ are precomputed norms, and the expectation is defined as $\langle f(\boldsymbol{\lambda}(\boldsymbol{\xi})) \Psi_\alpha(\boldsymbol{\xi}) \rangle = \frac{1}{2^d} \int_{[-1,1]^d} f(\boldsymbol{\lambda}(\boldsymbol{\xi})) \Psi_\alpha(\boldsymbol{\xi}) d\boldsymbol{\xi}$. For smooth functions $f(\boldsymbol{\lambda})$ that are amenable to reasonably accurate polynomial representation (53.2), Gaussian quadrature integration is the most appropriate approach. Namely:

$$\frac{1}{2^d} \int_{[-1,1]^d} f(\boldsymbol{\lambda}(\boldsymbol{\xi})) \Psi_\alpha(\boldsymbol{\xi}) d\boldsymbol{\xi} \approx \sum_{i=1}^N f\left(\boldsymbol{\lambda}\left(\boldsymbol{\xi}^{(i)}\right)\right) \Psi_\alpha\left(\boldsymbol{\xi}^{(i)}\right) w_i, \quad (53.4)$$

requiring the training points $\boldsymbol{\lambda}^{(i)} = \boldsymbol{\lambda}(\boldsymbol{\xi}^{(i)})$ to correspond to Gaussian quadrature points with associated weights w_i that integrate polynomials up to a certain order exactly. This is one drawback of the projection approach compared to regression techniques – the training set is predefined at Gaussian quadrature locations.

UQTk primarily focuses on Galerkin projection approaches for forward UQ, with most of the methods offered involving nonintrusive quadrature-based approaches using either full or sparse tensor products. However, for cases where the samples are very sparse in a high-dimensional space, UQTk also offers a Bayesian compressed sensing method.

In this specific workflow, a Gauss quadrature approach is used. The UQTk app `generate_quad` generates quadrature points $\boldsymbol{\xi}^{(i)}$, while another app, called `pce_eval`, will map the points to the “physical” model inputs $\boldsymbol{\lambda}$ according to the

input PC coefficients defined in a given file. Note that for surrogate construction, the input PC expansion (53.1) is linear, and, writing the input PC in the full form:

$$\lambda_i = l_{0i} + \sum_{k=1}^d l_{ki} \xi_i, \quad (53.5)$$

the input PC matrix $L_{(d+1) \times d}$ to be given to the app `pce_eval` is “nearly” diagonal. That is, the first row of L is defined as $l_{0i} = \frac{a_i+b_i}{2}$, while the rest of the matrix is diagonal, $l_{ki} = \delta_{ki} \frac{b_i-a_i}{2}$ using the Kronecker- δ . The matrix L in a text format should be stored in a file that is given as a command-line argument to `pce_eval` (Note that the linear map (53.1) can be easily accomplished by other means; here `pce_eval` is selected simply to illustrate general PC evaluation capabilities.).

The accuracy of the surrogate is estimated by comparing the model and PC surrogate outcomes at a set of M randomly chosen input samples, called *validation* samples. This can be accomplished prior to projection, by random sampling of the input PC *germ* ξ using the UQTk application `pce_rv`, followed by input PC evaluation using another app, called `pce_eval`. This concludes steps F1-F4 listed in Table 53.2 at the end of this section. With both training and validation samples in place, one can proceed to model evaluation (step F5) and to the projection itself (step F6), which is implemented via the UQTk app `pce_resp`, essentially carrying out the integration according to (53.4). Note that the model should be evaluated *offline* – the fully nonintrusive approach is taken – as a black-box, generally, independent of UQTk.

Figure 53.2 demonstrates the surrogate construction results for two test functions:

$$\begin{aligned} \text{Gaussian: } f^G(\boldsymbol{\lambda}) &= \exp\left(-\sum_{i=1}^d a_i^2 \lambda_i^2\right) \\ \text{Exponential: } f^E(\boldsymbol{\lambda}) &= \exp\left(\sum_{i=1}^d a_i \lambda_i\right). \end{aligned} \quad (53.6)$$

The dimensionality is set to $d = 5$, and the dimensional coefficients are set to $\boldsymbol{a} = (0.4, 0.3, 0.2, 0.1, 0.05)$. The surrogate order was set to $p = 3$, while the quadrature rule was chosen to be a product grid with 4 points per dimension, i.e., a total of $N = 4^5 = 1024$ training points. Finally, $M = 111$ random validation samples are selected in order to assess the accuracy of the surrogates. In these tests, the relative error was below 0.1%, suggesting the surrogates are very accurate for the current purposes. Creating good-quality high-dimensional surrogates is generally challenging, however. One reason is the high number of samples needed to inform the surrogate construction. Also, it is not uncommon that some of the input parameters do not significantly impact the outputs of interest, which makes the subsequent parameter estimation or inverse UQ studies challenging. Therefore, surrogates should generally be investigated for potential dimensionality reduction. To illustrate this process, a global sensitivity analysis is applied to the surrogate derived here.

Table 53.2 Forward UQ steps, Forward (DIM, PCTYPE, INPC). Note that the arguments DIM, PCTYPE, INPC are kept general to capture various forward UQ tasks, such as high- and low-dimensional surrogate construction, as well as uncertainty propagation given a general input PC expansion. Besides the command-line inputs, the relevant “hardwired” input/output file names are highlighted, with the necessary file saving/copying commands to help navigate between the command-line apps

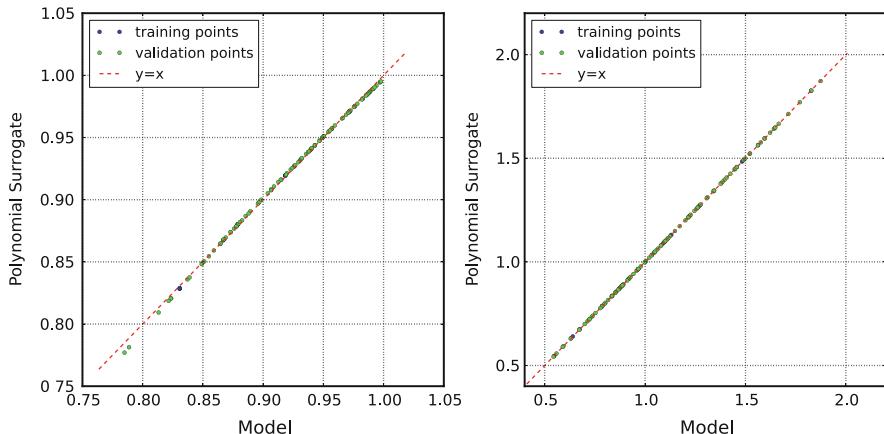

Fig. 53.2 Comparison between the model and its surrogate for two test functions, (left) Gaussian and (right) exponential

4.2 Global Sensitivity Analysis

Global sensitivity analysis (GSA) relies on variance-based decomposition and computes Sobol sensitivity indices [3, 5, 24]. For generic functions, one can employ a sampling-based approach [14, 17]. However, accurate estimation of these indices often requires prohibitively many model evaluations; hence, surrogate construction can provide a computationally feasible route. Here the PC surrogate approach renders itself particularly useful as one can compute sensitivity indices *exactly* from the polynomial form (53.2) without having to sample the surrogate model itself. To this end, the UQTK app `pce_sens` is employed to demonstrate the main sensitivity index computation for the test models outlined in the previous subsection (see step F7 in Table 53.2). The formula for the main sensitivity index for the i -th dimension reads:

$$S_i = \frac{\sum_{\alpha \in S_i} \|\Psi_\alpha(\xi)\|^2}{\sum_{\alpha \in S} \|\Psi_\alpha(\xi)\|^2}, \quad (53.7)$$

where $S_i = \left\{ \left(0, 0, \dots, \underbrace{0}_{i-1}, \underbrace{k}_{i}, \underbrace{0}_{i+1}, \dots, 0, 0 \right) \right\}_{k=1}^p$ is the set of multi-indices that contain only dimension i , while the denominator is nothing more than the variance of the surrogate model assuming uniform inputs. The formula (53.7) corresponds to the fraction of the total variance that can be attributed to the i -th parameter only.

Figure 53.3 demonstrates the main sensitivity indices for the two models considered in this workflow. Clearly, as the dimensional importance coefficients

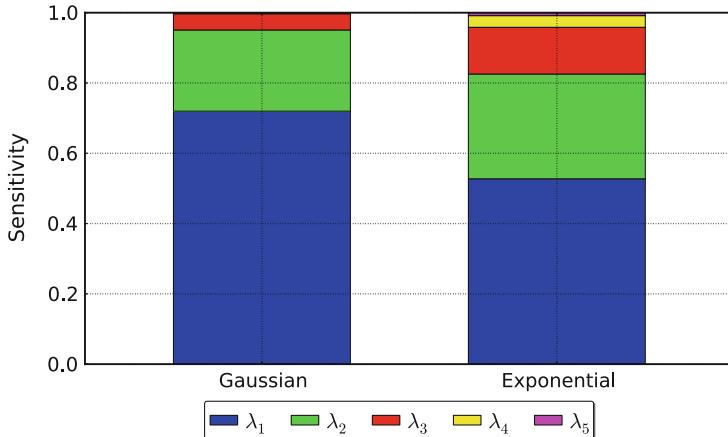

Fig. 53.3 Main sensitivity indices, i.e., variance fractions, for two test functions

of the test functions (53.6) are selected as $\boldsymbol{a} = (0.4, 0.3, 0.2, 0.1, 0.05)$, most of the variance can be attributed to the leading dimensions. This type of analysis allows for dimensionality reduction. For example, more than 80% of the variance can be attributed to the first two dimensions; therefore, one may want to focus on these two dimensions for more accurate surrogate construction as well as for the subsequent parameter inference to be well defined. This will be demonstrated within the workflow as follows.

As the initial, higher-dimensional study suggests, one can reduce the dimensionality of the problem from $d = 5$ to $d = 2$ without considerable accuracy reduction. Therefore, the rest of the inputs will be fixed at their nominal values $\lambda_3 = \lambda_4 = \lambda_5 = 0$, and the models are reformulated as *two*-dimensional, i.e., $d = 2$ and $\boldsymbol{a} = (0.4, 0.3)$. The surrogate construction should ideally be repeated for $d = 2$ or, in the absence of extra computational resources for running the model, one can analytically reduce the already constructed *five*-dimensional surrogate and cast it as a function of 2 parameters only. Now, assuming the *two*-dimensional surrogate is in place, the workflow proceeds to the inverse UQ task, i.e., parameter estimation given observational data.

4.3 Model Parameter Inference

Consider observational data that corresponds to the output of the test models Gaussian $f^G(\boldsymbol{\lambda})$ and Exponential $f^E(\boldsymbol{\lambda})$. Namely, let us assume y_j^G and y_j^E , for $j = 1, \dots, R$ are R experimental observations of the “physical” quantities that are outputs of the models $f^G(\boldsymbol{\lambda})$ and $f^E(\boldsymbol{\lambda})$, correspondingly. Assuming there is Gaussian noise in the data, one can write a *data noise model*:

$$y_j^{G(E)} = f^{G(E)}(\boldsymbol{\lambda}) + \sigma \underbrace{\epsilon_j^{G(E)}}_{N(0,1)}, \quad (53.8)$$

Table 53.3 Inverse UQ steps, `Inverse()`

--	-------------------

Similar to model evaluation, this synthetic data generation is in principle carried out independently from UQTk (Step I1 in Table 53.3). Given observational data, one then employs Bayesian techniques [22] to infer the posterior distribution for λ , given synthetically generated data $\mathbf{y} = (\mathbf{y}^G, \mathbf{y}^E)$, denoted by \mathcal{D} . For this, one relies on the UQTk application `model_inf` (step I2) that applies MCMC sampling to generate samples from the posterior distribution of λ defined via Bayes formula

$$\overbrace{p(\lambda|\mathcal{D})}^{\text{Posterior}} \propto \overbrace{p(\mathcal{D}|\lambda)}^{\text{Likelihood}} \overbrace{p(\lambda)}^{\text{Prior}}. \quad (53.9)$$

For the sake of illustration, normal, independent identically distributed priors with vanishing mean, and standard deviation $s = 0.3$ for the components of λ will be employed $p(\lambda) \propto \exp\left(-\frac{\lambda_1^2 + \lambda_2^2}{2s^2}\right)$, while the likelihood is dictated directly from the assumed noise model (53.8):

$$\mathcal{L}_{\mathcal{D}}(\lambda) = p(\mathcal{D}|\lambda) \propto \prod_{j=1}^R \exp\left(-\frac{(y_j^G - f^G(\lambda))^2}{2\sigma^2}\right) \exp\left(-\frac{(y_j^E - f^E(\lambda))^2}{2\sigma^2}\right). \quad (53.10)$$

Note that the choice of Gaussian likelihood is implemented in the app `model_inf` (for the full set of options implemented in the app, the reader is referred to the UQTk manual), but in general one should view the app as a use case illustration of the *MCMC* library. For non-Gaussian likelihoods, a custom posterior function evaluation can be written in C++ and linked to the MCMC library, similar to the `model_inf` app. Samples of the posterior obtained via MCMC are shown in Fig. 53.4. The data is generated as $y^G \sim N(1.0, 0.05)$ and $y^E \sim N(0.7, 0.05)$, using $R = 13$ replicas. This step is typically assumed to be performed by the user, outside UQTk. After the posterior samples are obtained, one can analyze them

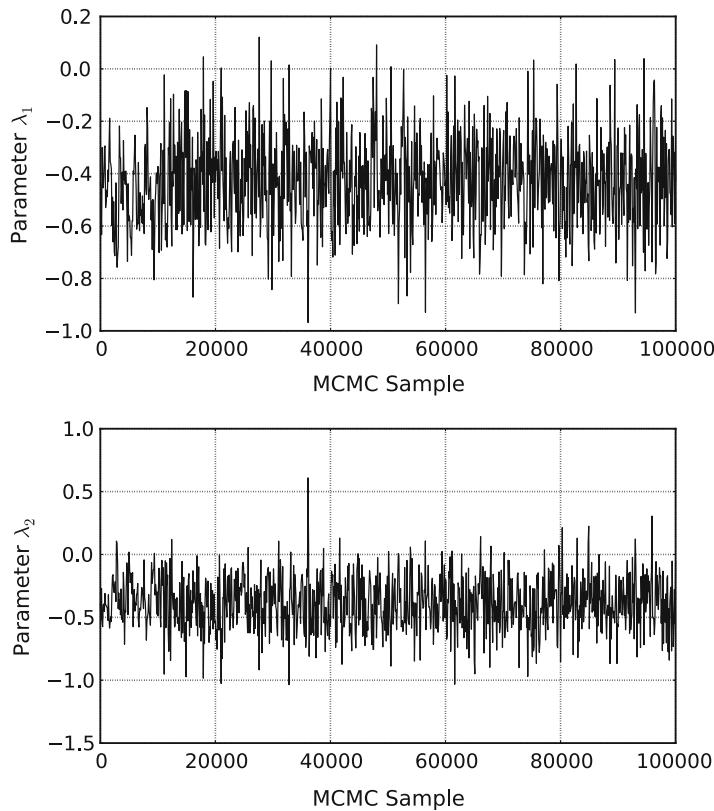

Fig. 53.4 MCMC posterior samples of inferred parameters λ_1 and λ_2

further. For example, Fig. 53.5 illustrates marginal and joint posterior distributions computed via kernel density estimation (UQTk app `pdf_c1` can be employed for this) using the MCMC posterior samples.

Having used the data to calibrate the model parameters, the next task is, armed with the posterior samples of (λ_1, λ_2) , to propagate the uncertainty associated with these parameters through an arbitrary model $g(\lambda)$ to obtain predictions of $g(\lambda)$ with quantified uncertainty. However, since at this point this parametric uncertainty is captured by a set of samples from the posterior distribution, it first needs to be represented in a format that is more suitable to the tools used here for forward propagation.

4.4 Polynomial Chaos Construction via Rosenblatt Transformation

In this example, the nonintrusive spectral projection (NISP) with polynomial chaos is employed in order to propagate posterior uncertainties of the model parameters

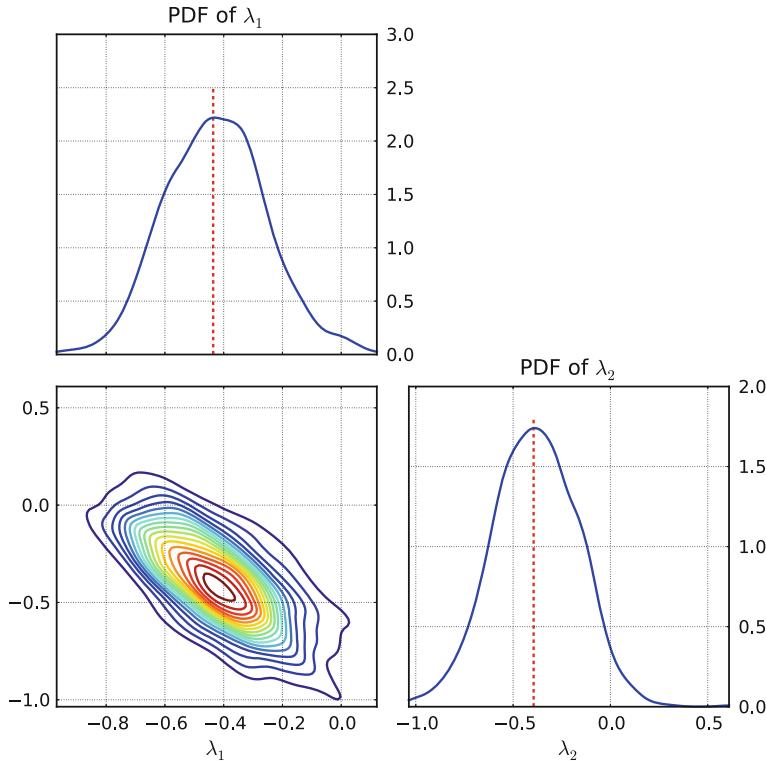

Fig. 53.5 Illustration of the marginal posterior distributions $p(\lambda_1|\mathcal{D})$ and $p(\lambda_2|\mathcal{D})$, as well as the full posterior $p(\lambda_1, \lambda_2|\mathcal{D})$ computed via kernel density estimation of the MCMC posterior samples. The dashed red line indicates maximum a posteriori (MAP) value

through models of interest. This requires a construction of polynomial chaos expansions for the input parameters given the samples obtained by MCMC in the previous stage. The application `pce_quad` performs exactly this task (step I3 in Table 53.3), i.e., given samples $\boldsymbol{\lambda}^{(j)}$ for $j = 1, \dots, M$ of a random vector $\boldsymbol{\lambda}$, build a set of joint PC expansions:

$$\lambda_i \approx \sum_{\alpha \in \mathcal{S}} l_{i\alpha} \Psi_\alpha(\xi), \text{ for } i = 1, \dots, d, \quad (53.11)$$

for a chosen truncation $\mathcal{S} = \{\alpha : \sum_{i=1}^d \alpha_i \leq s\}$ of a total order s . For this task, Gauss-Hermite PC is employed; therefore, $\Psi_\alpha(\cdot)$ are Hermite polynomials and ξ are i.i.d. standard normal random variables. The PC coefficients $l_{i\alpha}$ are determined via orthogonal projection

$$l_{i\alpha} = \frac{1}{||\Psi_\alpha(\xi)||^2} \langle \lambda_i \Psi_\alpha(\xi) \rangle, \quad (53.12)$$

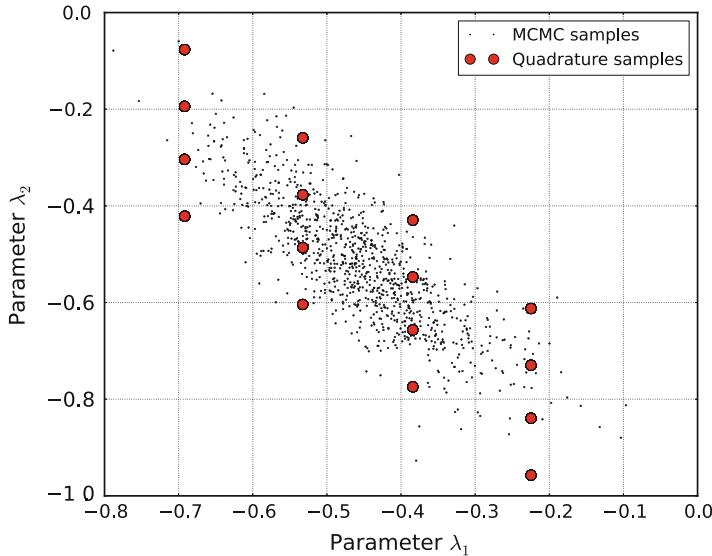

Fig. 53.6 Posterior samples of parameters λ_1, λ_2 , as well as the Gauss quadrature points mapped from (ξ_1, ξ_2) to (λ_1, λ_2)

where the integrals $\langle \lambda_i \Psi_\alpha(\xi) \rangle = \int_{\xi} \lambda_i(\xi) \Psi_\alpha(\xi) \pi_\xi(\xi) d\xi \approx \sum_{q=1}^Q \lambda_i(\xi_q) \Psi_\alpha(\xi_q) w_q$ require the mapping $\xi \rightarrow \lambda$ accomplished by the inverse Rosenblatt transformation [16] of the Gauss quadrature points ξ . For details of the Rosenblatt transformation and the overall procedure, see [18] or the UQTk manual [7]. Figure 53.6 illustrates MCMC samples of the two parameters (λ_1, λ_2) together with the 4×4 quadrature point set $\lambda_{1,2}(\xi_q)$ for $q = 1, \dots, 16$.

4.5 Uncertainty Propagation and Attribution

Having built a PC expansion for the inputs λ , one can proceed to construct the output PC expansion for any model $g(\lambda)$, including the ones used in the calibration. This is once again the same forward UQ propagation task used in surrogate construction, albeit with potentially higher order Gauss-Hermite input PC expansions (53.11) instead of the linear Legendre-Uniform PC (53.1) that was used in the surrogate construction. Both training (quadrature) and validation samples should be obtained via a combination of the UQTk apps `generate_quad`, `pce_rv` and `pce_eval` (Steps F1-F4 in Table 53.2), this time with a more involved input PC coefficient matrix that incorporates the values $l_{i\alpha}$. The PC expansion for the model $g(\lambda)$ can be written as:

$$g(\lambda) \approx \sum_{\alpha \in \mathcal{S}} g_\alpha \Psi_\alpha(\xi(\lambda)), \quad (53.13)$$

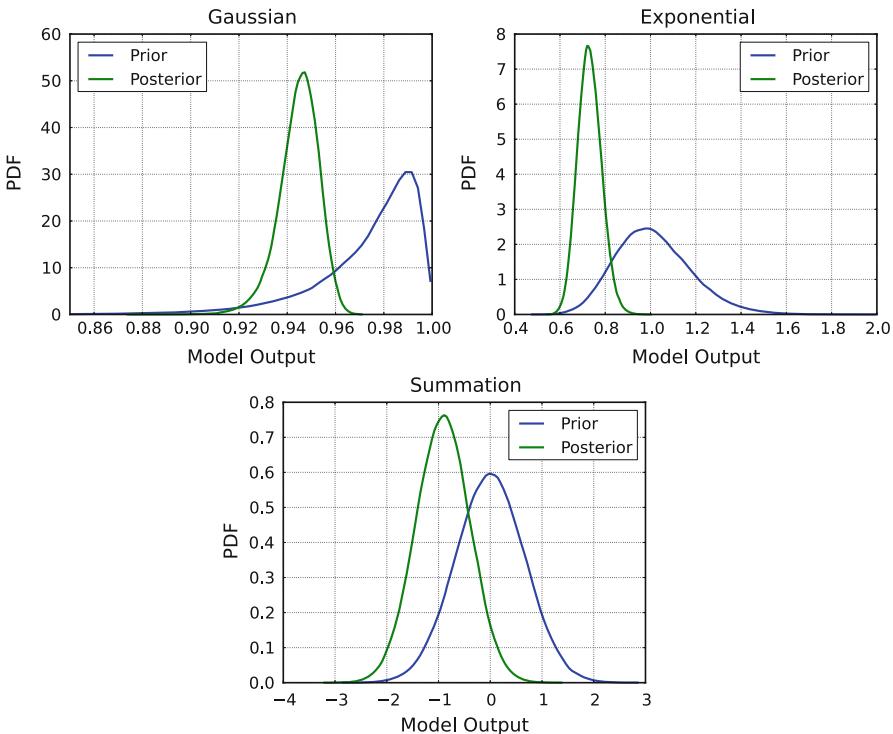

Fig. 53.7 Model output PDFs constructed by sampling the resulting PC expansions

with the orthogonal projection formula (similar to the surrogate construction, this can be accomplished using the application `pce_resp`):

$$g_\alpha = \frac{1}{||\Psi_\alpha(\xi)||^2} \langle g(\lambda(\xi)) \Psi_\alpha(\xi) \rangle, \quad (53.14)$$

and the implied relationship $\xi \leftrightarrow \lambda$ encoded in input PC (53.11). As forward propagation examples, consider a simple summation model $f^S(\lambda) = \sum_{i=1}^d \lambda_i$, as well as the two test models (53.6) used for calibration, $f^G(\lambda)$ and $f^E(\lambda)$. For the sake of the full workflow illustration, these models are considered as functions of the full set of $d = 5$ inputs. While the first two calibrated parameters, λ_1 and λ_2 , are described by their joint posterior distribution, the last three less important parameters will still obey their prior distributions, i.e., independent, $N(0, 0.3)$ normal random variables. Figure 53.7 illustrates the estimated PDFs using 100,000 samples (obtained via `pce_rv`, or step F8) of the 3-rd order output PC expansions for all three models, before and after the calibration, i.e., employing the full 5-dimensional normal i.i.d. prior or the posterior that has a joint structure in the first two parameters.

In all three cases, the effect of calibration is the narrowing of the output distribution, which reflects the fact that the information obtained from the data reduces the output uncertainty. The PDF computation is performed using UQTk app `pdf_c1` (step F9) which implements kernel density estimation (KDE) [20,21] with improved fast Gauss transform [26] for computational efficiency gains – the latter is at least an order of magnitude faster than Python’s native KDE estimators for high-dimensional data sets. Note that steps F8 and F9 of forward propagation, i.e., PDF estimation, are not necessary steps during surrogate construction as the latter is developed in order to replace the model and assess parameter sensitivities rather than for output PDF estimation.

Having computed the output PC expansion (53.13), one can evaluate the sensitivities of the model outputs with respect to components of ξ , as before, using the UQTk apps `gen_mi` and `pce_sens`. However, while ξ_3, ξ_4, ξ_5 can be fully attributed to the inputs $\lambda_3, \lambda_4, \lambda_5$, respectively, the first two inputs are now correlated. While the sampling methods would in principle help estimate the sensitivities with respect to λ_1 and λ_2 , here, they are considered together. As such, the total variance contribution from the pair (ξ_1, ξ_2) is identified with that of the pair (λ_1, λ_2) . Figure 53.8 demonstrates the main sensitivities before and after the calibration. For example, for the summation model, before the calibration, all five inputs have equal contribution to the total variance, while, after the calibration of the first two parameters, their respective contribution has reduced considerably, while the three other input parameters remain equal contributors. For the Gaussian and exponential models also, the contribution of the pair (λ_1, λ_2) , after calibration, is smaller than the sum of their contributions before calibration, due to their reduced variance.

4.6 Command-Line Reproduction

To reproduce the exact command-line executions for the example workflow described here, all of the steps are summarized in Tables 53.2 and 53.3 in terms of Forward and Inverse UQ tasks, respectively. The steps in these tables have been referred to in the previous subsections. The exact order of the workflow execution is presented below, where `Forward(DIM, PCTYPE, INPC)` and `Inverse()` are *not* specific UQTk functions – they denote groups of command-line UQTk applications including appropriate file management, model evaluation, and data generation.

- `Forward(DIM=5, PCTYPE='LU', INPC='pcf_diag.dat')`
[High-d Surrogate]
 - Generate input parameter values (Steps F1-F4)
 - For each model, evaluate it (Step F5), project to obtain PC coefficients (Step F6), and postprocess (Steps F7-F9)

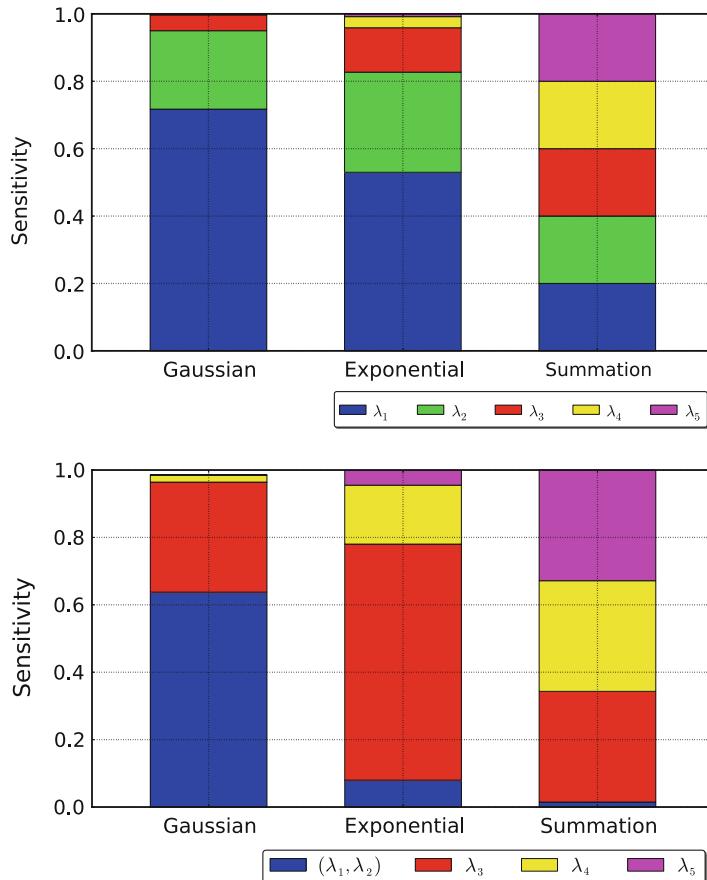

Fig. 53.8 Illustration of the variance decomposition for three models before and after the calibration of the first two inputs

- `Forward(DIM=2, PCTYPE='LU', INPC='pcf_diag.dat')` [Low-d Surrogate]
- `Inverse()` [Model calibration]
 - Obtain/generate data (Step I1)
 - Perform Bayesian inference via MCMC (Step I2)
 - Construct PC for the MCMC samples (Step I3)
- `Forward(DIM=2, PCTYPE='HG', INPC='pcf_calib.dat')` [Prediction]

The two PC input files correspond to the near-diagonal coefficients in Eq. (53.5) with $d = 5$ or $d = 2$ (`pce_diag.dat`) and to the calibrated PC expansion in Eq. (53.11) that is the output of the step I3 (`pce_calib.dat`).

As an illustration of the forward workflow, together with some of the plotting routines that have been used to produce figures in this chapter, UQTk contains a set of python scripts in *examples/uqpc* that essentially carry out the steps contained in `Forward(...)`.

5 Conclusion

The UQ Toolkit offers a collection of tools for a wide range of UQ operations, ranging from forward UQ to surrogate construction, sensitivity analysis, and inverse problems. UQTk is geared toward tutorials, UQ algorithm development, and custom UQ workflow design. The key methods are implemented as C++ libraries but are also accessible through stand-alone apps or through a Python interface. As illustrated in this chapter, the tools can be easily combined to form UQ workflows of arbitrary complexity.

The Parallel C++ Statistical Library for Bayesian Inference: QUESO

54

Damon McDougall, Nicholas Malaya, and Robert D. Moser

Abstract

The Parallel C++ Statistical Library for the Quantification of Uncertainty for Estimation, Simulation, and Optimization (QUESO) is a collection of statistical algorithms and programming constructs supporting research into the quantification of uncertainty of models and their predictions. QUESO is primarily focused on solving statistical inverse problems using Bayes' theorem, which expresses a distribution of possible values for a set of uncertain parameters (the posterior distribution) in terms of the existing knowledge of the system (the prior) and noisy observations of a physical process, represented by a likelihood distribution. The posterior distribution is not often known analytically and so requires computational methods. It is typical to compute probabilities and moments from the posterior distribution, but this is often a high-dimensional object, and standard Riemann-type methods for quadrature become prohibitively expensive. The approach QUESO takes in this regard is to rely on Markov chain Monte Carlo (MCMC) methods which are well suited to evaluating quantities such as probabilities and moments of high-dimensional probability distributions. QUESO's

intended use is as tool to assist and facilitate coupling uncertainty quantification to a specific application called a *forward problem*. While many libraries presently exist that solve Bayesian inference problems, QUESO is a specialized piece of software primarily designed to solve such problems by utilizing parallel environments demanded by large-scale forward problems. QUESO is written in C++, uses MPI, and utilizes libraries already available to the scientific community. Thus, the target audience of this library are researchers who have solid background in Bayesian methods, are comfortable with UNIX concepts and the command line, and have knowledge of a programming language, preferably C/C++.

1 Introduction

The Parallel C++ Statistical Library for the Quantification of Uncertainty for Estimation, Simulation, and Optimization (QUESO), is a collection of statistical algorithms and programming constructs supporting research into the uncertainty quantification (UQ) of models and their predictions. It has been designed with three objectives: (a) to be sufficiently abstract in order to handle a large spectrum of large-scale computationally intensive models; (b) to be extensible, allowing easy creation of custom-defined objects; and (c) leverage parallel computing through use of high-performance vector and matrix libraries. Such objectives demand a combination of an object-oriented design with robust software engineering practices. QUESO is written in C++, uses MPI, and utilizes libraries already available to the scientific community.

The purpose of this book chapter is not to teach uncertainty quantification methods, but rather to introduce the QUESO library so it can be used as a tool to assist and facilitate coupling UQ to a specific application (forward problem). Thus, the target audience of this chapter is researchers who have solid background in Bayesian methods, are comfortable with UNIX concepts and the command line, and have knowledge of a programming language, preferably C/C++.

The rest of the document is organized as follows. Section 2 has a brief discussion of statistical inverse problems, and in doing so, provides the impetus behind the QUESO library. Section 4 then discusses the types of problems the library is designed to solve, as well as introducing the notation used for the rest of this document. Several illustrative examples, including the new infinite-dimensional capability, are provided in Sect. 5 along with code snippets demonstrating typical software call-patterns. Section 6 discusses how the library design can easily be extended for bespoke user-defined random variables, probability distribution functions, and realizers. Section 7 discusses the design and internals of the library, as well as providing a software snapshot of the current library status. Finally, we conclude by discussing several areas in which to focus future QUESO development efforts.

All of the examples in this document are present in the QUESO source tree of the latest release, 0.53.0. Users should consult the website, libqueso.com, for the latest news and source code.

This chapter builds on the 2012 paper that introduced the QUESO library [1] and the current QUESO user's manual [2] by including a myriad of changes that have since been incorporated into the library.

2 Motivation

Statistical inverse problems using a Bayesian formulation model all quantities as random variables, where probability distributions of the quantities capture the uncertainty in their values. The solution to the inverse problem is then the probability distribution of the quantity of interest when all information available has

been incorporated in the model. This (posterior) distribution describes the degree of confidence about the quantity after the measurement has been performed [3].

Thus, the solution to the statistical inverse problem is given by Bayes' formula, which expresses the posterior distribution in terms of the prior distribution and the data represented through the likelihood function.

For all but toy problems, the likelihood function has an open form and its evaluation is highly computationally intensive. Worse, simulation-based posterior inference often requires a large number of these evaluations of the forward model. Therefore, fast and efficient sampling techniques are desirable for posterior inference.

It is often not straightforward to obtain explicit posterior point estimates of the solution, since it usually involves the evaluation of a high-dimensional integral with respect to a possibly non-smooth posterior distribution. In such cases, an alternative integration technique is the Markov chain Monte Carlo method where posterior moments may be estimated using the samples from a series of (correlated) random draws from the posterior distribution.

QUESO is designed in an abstract way so that it can be used by any computational model, as long as a likelihood function (in the case of statistical inverse problems) and a quantity of interest (QoI) function (in the case of statistical forward problems) are provided by the user application.

With this framework in mind, QUESO provides tools for both sampling algorithms for statistical inverse problems, following Bayes' formula, and statistical forward problems. It provides Markov chain Monte Carlo algorithms using the Metropolis-Hastings acceptance ratio [4, 5]: these are the multilevel Monte Carlo [6] method and DRAM [7]. QUESO is also capable of handling several chains in parallel computational environments.

3 Alternatives to QUESO

QUESO is certainly not the only quality statistical software library. There are many different libraries that can be used to solve Bayesian inference problems. QUESO is a specialized piece of software, primarily designed to solve such problems utilizing the, often required, parallel environment demanded by large-scale forward problems. This focus is simultaneously the QUESO's greatest strength and weakness, depending on user's target problem. For instance, QUESO would be less effective to use for serial problems than several alternative libraries, as there is significant turnaround time from learning how to build QUESO and link a custom forward code to it. In instances where parallelization is not necessary and the forward problem is relatively cheap to execute, there are good alternatives to QUESO. We now provide a simple survey of several other major libraries that we consider useful for problems of Bayesian inference, along with a brief discussion some unique strengths and weaknesses.

As discussed above, for inference problems that do not require parallelization, serial libraries can be leveraged with less development. An excellent example of this is PyMC [8]. A modern software package, PyMC is a python-based software library for Bayesian estimation and MCMC. Its strengths lie in its flexibility and excellent post-processing, especially when coupled with matplotlib [9]. emcee [10] is another python-based package, with a particular emphasis on Bayesian parameter estimation. Both of these libraries are useful for rapid software prototyping using serial inference problems.

On the other end of the spectrum, there are complete statistical software languages. These are often more mature software projects which are capable of much more general statistical computations than QUESO. However, these languages are often weaker for specialized problems, because they are not as well optimized for solving Bayesian inference problems, particularly at scale. The ultimate example of this is R [11]. R is a free software programming language and software environment for statistical computing and graphics. R is arguably the most general and complete source of open-source statistical packages in the world. It is not limited to Bayesian techniques and has packages across a wide range of topics in statistics. However, it is not easy to couple R with other codebases (for the forward problem, for instance). Furthermore, while some packages supporting parallelism are now being developed, the language is still primarily focused on serial computations. Another alternative is Stan [12]. Stan is a probabilistic programming language written in C++ implementing full Bayesian statistical inference.

Another major library is WinBUGS [13]. WinBUGS is statistical software for Bayesian analysis using MCMC methods. WinBUGS is of particular historical importance, as it was one of the earliest openly available MCMC libraries, with development starting the late 1980s. It is also unique in that it is developed for the Windows platform, instead of Linux. It is also primarily based on the Gibbs sampler algorithm.

Finally, the DAKOTA [14] toolkit is a very general library developed at Sandia National Laboratories, containing a vast array of algorithms with applications to uncertainty quantification, optimization, emulation, experimental design, prediction, and sensitivity analysis. DAKOTA is written in C++ and supported on Linux, OS X, and Windows and represents 20 years of advanced algorithms research. Furthermore, given DAKOTA's advanced certainty propagation algorithms, the QUESO and DAKOTA development teams are working together to establish a seamless integration of QUESO's algorithms into DAKOTA to give users a matured and coupled forward and inverse UQ software solution.

4 Formulation

Here we give a rigorous description of the types of problems that QUESO solves. This will crystallize both the terminology and notation in an attempt to make everything in this chapter self-contained.

4.1 The Forward Problem

Here we set out the auspices under which we will operate. We make two high-level assumptions: (1) we have access to a set of observations of some physical phenomenon; and (2) we have a mathematical model that attempts to model the observed physical phenomenon. Ensuring that the mathematical model is *valid* is an exercise left to the reader. We will denote the observed data by y and the mathematical model by \mathcal{G} . The model will certainly depend on various parameters, and we call the process of mapping these parameters to model output the *forward problem*. In many physical engineering applications, the forward problem is expensive and may involve the solution of a set of partial differential equations.

4.2 The Inverse Problem

In the subsection above, we described the forward problem. It may be the case that the mathematical model in the forward problem may depend on some parameters that are unknown and that we wish to estimate. We will refer to these unknown parameters as θ . The process of estimating θ given observations goes by many names, but is generally referred to as the *inverse problem*. There are several frameworks for solving inverse problems. We will focus only on the *Bayesian framework*, which we rigorously describe now.

As noted above, we are given a set of observations y . This dataset is corrupted by errors made during the experiment. These errors could be human errors, equipment errors, or errors in the setup of the experimental scenario. In complete generality, it is difficult to say with certainty what statistical distribution these errors follow. In a lot of experimental cases, however, a Gaussian distribution with some, perhaps unknown, variance is quite a reasonable characterization.

The unknown parameters themselves might have some inherent constraining property. For example, if the unknown parameter were a concentration of a contaminant underground then it is not possible for this unknown parameter to be negative. The constraint varies depending on the physical domain, but it is rarely the case one knows *nothing* about the unknown parameters. This information can be translated to constraints on a prior distribution.

To regroup, we have a statistical distribution governing the behavior of the experimental errors given the unknown parameters, $\mathbb{P}(y|\theta)$. We also have some prior distribution on the unknown parameters $\mathbb{P}(\theta)$. The Bayesian solution to the inverse problem of finding θ is the distribution of θ given y , $\mathbb{P}(\theta|y)$. By Bayes' rule, this can be written as follows:

$$\mathbb{P}(\theta|y) \propto \mathbb{P}(y|\theta)\mathbb{P}(\theta).$$

The left-hand side is referred to as the posterior distribution. The right-hand side is the product of the likelihood distribution and the prior distribution. QUESO solves

the Bayesian inverse problem by providing samples that are distributed according to the posterior distribution using Markov chain Monte Carlo. This chapter does not provide the details of how MCMC works. The authors refer the reader to the expansive body of available literature on the topic cited throughout this work.

4.3 Prediction

The prediction step in the Bayesian framework is that of estimating some quantity $\mathcal{Q}(\theta)$ dependent on the unknown parameters. This is usually referred to as a *statistical forward problem*. QUESO is equipped to solve statistical forward problems, but throughout this chapter we will focus mainly on the statistical inverse problem.

5 Examples

5.1 A Template Example

Here we walk through a template example. This template should be general enough to serve as a good starting point for most Bayesian inverse problems. Before we step through the example, here it is in its entirety:

```
#include <queso/GslVector.h>
#include <queso/GslMatrix.h>
#include <queso/UniformVectorRV.h>
#include <queso/StatisticalInverseProblem.h>
#include <queso/ScalarFunction.h>
#include <queso/VectorSet.h>

template<class V = QUESO::GslVector, class M = QUESO::GslMatrix>
class Likelihood : public QUESO::BaseScalarFunction<V, M>
{
public:

    Likelihood(const char * prefix, const QUESO::VectorSet<V, M> & domain)
        : QUESO::BaseScalarFunction<V, M>(prefix, domain)
    {
        // Setup here
    }

    virtual ~Likelihood()
    {
        // Deconstruct here
    }

    virtual double lnValue(const V & domainVector, const V * domainDirection,
                          V * gradVector, M * hessianMatrix, V * hessianEffect) const
    {
        // 1) Run the forward code at the point domainVector
        //     domainVector[0] is the first element of the parameter vector
        //     domainVector[1] is the second element of the parameter vector
        //     and so on
    }
}
```

```
//  
// 2) Compare to data, y  
//     Usually we compute something like  
//     || MyModel(domainVector) - y ||^2 / (sigma * sigma)  
//  
// 3) Return below  
  
double misfit = 0.0;  
  
return -0.5 * misfit;  
}  
  
virtual double actualValue(const V & domainVector, const V * domainDirection,  
    V * gradVector, M * hessianMatrix, V * hessianEffect) const  
{  
    return std::exp(this->lnValue(domainVector, domainDirection, gradVector,  
        hessianMatrix, hessianEffect));  
}  
  
private:  
    // Maybe store the observed data, y, here.  
};  
  
int main(int argc, char ** argv) {  
    MPI_Init(&argc, &argv);  
  
    // Step 0 of 5: Set up environment  
    QUESO::FullEnvironment env(MPI_COMM_WORLD, argv[1], "", NULL);  
  
    // Step 1 of 5: Instantiate the parameter space  
    QUESO::VectorSpace<> paramSpace(env,  
        "param_", 1, NULL);  
  
    double min_val = 0.0;  
    double max_val = 1.0;  
  
    // Step 2 of 5: Set up the prior  
    QUESO::GslVector paramMins(paramSpace.zeroVector());  
    paramMins.cwSet(min_val);  
    QUESO::GslVector paramMaxs(paramSpace.zeroVector());  
    paramMaxs.cwSet(max_val);  
  
    QUESO::BoxSubset<> paramDomain("param_", paramSpace, paramMins, paramMaxs);  
  
    // Uniform prior here. Could be a different prior.  
    QUESO::UniformVectorRV<> priorRv("prior_", paramDomain);  
  
    // Step 3 of 5: Set up the likelihood using the class above  
    Likelihood<> lhood("llhd_", paramDomain);  
  
    // Step 4 of 5: Instantiate the inverse problem  
    QUESO::GenericVectorRV<> postRv("post_", paramSpace);  
  
    QUESO::StatisticalInverseProblem<> ip("", NULL, priorRv, lhood, postRv);  
  
    // Step 5 of 5: Solve the inverse problem  
    QUESO::GslVector paramInitials(paramSpace.zeroVector());  
  
    // Initial condition of the chain  
    paramInitials[0] = 0.0;
```

```

paramInitials[1] = 0.0;

QUESO::GslMatrix proposalCovMatrix(paramSpace.zeroVector());

for (unsigned int i = 0; i < 2; i++) {
    // Might need to tweak this
    proposalCovMatrix(i, i) = 0.1;
}

ip.solveWithBayesMetropolisHastings(NULL, paramInitials, &proposalCovMatrix);

MPI_Finalize();

return 0;
}

```

Notice that this template example is fairly short, weighing in at roughly 100 lines of boilerplate C++ code. Incorporating a specific physical model into the likelihood will certainly increase the size of the statistical application. In the meantime, we will walk through the boilerplate setup that will be common to many use cases.

We will start with the main function. This is where most of the setup takes place. Firstly, since QUESO uses MPI, we must call the MPI_Init function before using any of the classes in QUESO. The next line,

```
QUESO::FullEnvironment env(MPI_COMM_WORLD, argv[1], "", NULL);
```

sets up the QUESO environment. The constructor parameters are, in order, an MPI communicator and could be a custom sub-communicator; the filename of a QUESO input file; a prefix, if a different from the default is desired, for input file options specific to the QUESO environment; and an optional EnvOptionsValues object so that the user can set environment options programmatically. The next thing we do is define the dimension of the state space by created a object representing a vector space:

```
QUESO::VectorSpace<> paramSpace(env, "param_", 1, NULL);
```

In this particular example, the dimension of the state space is 1. The constructor parameters here are the QUESO environment; a prefix, if a different from the default is desired, for input file options specific to this parameter space object; and a vector of strings to name components of the vectors belonging to this vector space. Now we are in a position to set up the domain of the statistical inverse problem. QUESO only supports box domains, but the bounds for the box may be arbitrary. We store the bounds for the domain in GslVector objects like so:

```
QUESO::GslVector paramMins(paramSpace.zeroVector());
paramMins.cwSet(min_val);
QUESO::GslVector paramMaxs(paramSpace.zeroVector());
paramMaxs.cwSet(max_val);
```

Here min_val and max_val will be specific to the user's problem. The box domain uses these bounds and is constructed as follows:

```
QUESO::BoxSubset<> paramDomain("param_",
    paramMins,
    paramMaxs);
```

We have finished setting up the domain of the statistical inverse problem. Recall the ingredients we need for a well-posed statistical inverse problem; a prior distribution and a likelihood distribution. QUESO supports many statistical distributions that can all be used as a prior, and the user may choose to implement their own prior distribution if (see Sect. 6) such customization is needed. The following line creates an object representing a uniform random variable:

```
QUESO::UniformVectorRV<> priorRv("prior_",
    paramDomain);
```

This object contains all the necessary information to fully define a uniformly distributed random variable, namely, its probability density function and mechanisms by which one can make draws with this density. The second ingredient needed for a statistical inverse problem is the definition of a likelihood distribution, and this is done now:

```
Likelihood<> lhood("lhood_", paramDomain);
```

This line may look different to the one for your specific application, as it is intended to interact with a specific physical model. The `Likelihood` class is a custom-defined class. We will come back to the full `Likelihood` class in Sects. 5.3 and 5.2 explain how it is implemented. For now, we will continue with the setup of the inverse problem and all the necessary code needed to initialize the sampling. We construct a placeholder object that represents a posterior random variable:

```
QUESO::GenericVectorRV<> postRv("post_", paramSpace);
```

QUESO will operate on this object during the sampling. After QUESO has finished its sampling, this object is then available to you for post-processing. Next, we pass the prior, likelihood, and posterior over to the `StatisticalInverseProblem` class like so:

```
QUESO::StatisticalInverseProblem<> ip("", NULL,
    priorRv, lhood, postRv);
```

We are now ready to finalize the setup of the inverse problem. We do this by giving QUESO an initial condition for the sampler:

```
QUESO::GslVector paramInitials(
    paramSpace.zeroVector());
paramInitials[0] = 0.0;
paramInitials[1] = 0.0;
```

We also give QUESO an initial covariance matrix:

```
QUESO::GslMatrix proposalCovMatrix(
    paramSpace.zeroVector());
```

```
for (unsigned int i = 0; i < 1; i++) {
    proposalCovMatrix(i, i) = 0.1;
}
```

The closer this matrix is to the covariance between parameters under the posterior measure, the better the Markov chain will perform. Providing a bad initial covariance does not change the posterior distribution in the limit of infinite samples. Finally, we begin sampling with the following call:

```
ip.solveWithBayesMetropolisHastings(NULL,
    paramInitials, &proposalCovMatrix);
```

5.2 Defining the Likelihood Distribution

As can be observed in the example illustrated above, the user must pass a likelihood to QUESO. QUESO expects, as a likelihood, anything that subclasses the `BaseScalarFunction` abstract base class. This base class has two pure virtual functions that must be implemented in any subclass. These functions are `lnValue()` and `actualValue()`. The function `lnValue` takes a number of parameters, the most important of which is `const V & domainVector`. When the user implements this function, it should return the natural logarithm of the likelihood distribution evaluated at the point `domainVector`. A concrete example of this can be seen in the next subsection. The function `actualValue` should return exactly the likelihood distribution evaluated at the point `domainVector`. For most practical applications, this function will usually just return `std::exp` of `lnValue`, but the user has the freedom to implement a more optimized computation if one is needed.

A typical Gaussian likelihood distribution will look something like this:

```
template<class V, class M>
double
Likelihood<V = QUESO::GslVector,
            M = QUESO::GslMatrix>::lnValue(
    const V & domainVector,
    const V * domainDirection, V * gradVector,
    M * hessianMatrix, V * hessianEffect) const
{
    double misfit = 0.0;
    unsigned int vec_len = domainVector.sizeLocal()

    for (unsigned int i = 0; i < vec_len; i++) {
        misfit += domainVector[i] - observation[i];
    }

    return -0.5 * misfit;
}
```

To avoid numerical problems computing the acceptance probability in an MCMC algorithm, QUESO will call `lnValue` instead of `actualValue` to do the accept-reject step in log space.

5.3 Ball Drop Example

This section presents an example of how to use QUESO as an application that solves a statistical inverse problem (SIP) and a statistical forward problem (SFP), where the solution of the former serves as input to the later. This example will use the canonical “ball drop” problem, a standard problem in uncertainty quantification. The objective of the SIP is to infer the acceleration due to gravity on an object in free fall near the surface of the Earth. During the SFP, the distance traveled by a projectile launched at a given angle and altitude is calculated using the calibrated magnitude of the acceleration of gravity gathered during the SIP. As expressed in Sect. 4, both the inference and forward problem will be performed using a Bayesian methodology, and so, the resulting quantities of interest (QoIs) will be expressed as probability distributions.

5.4 Statistical Inverse Problem

A deterministic mathematical model for the vertical motion of an object in free fall near the surface of the Earth is given by

$$h(t) = -\frac{1}{2}gt^2 + v_0t + h_0. \quad (54.1)$$

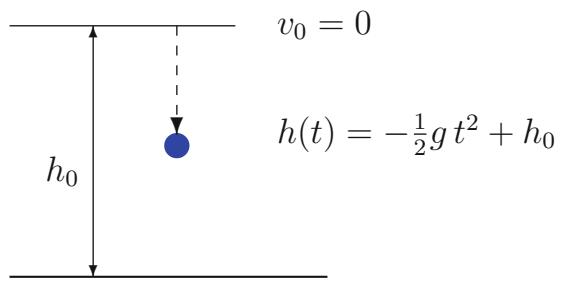

where, v_0 [m/s] is the initial velocity, h_0 [m] is the initial altitude, $h(t)$ [m] is the altitude with respect to time, t [s] is the elapsed time, and g [m/s^2] is the magnitude of the acceleration due to gravity (the parameter which cannot be directly measured and will be statistically inferred).

This model is an expression of a high-fidelity model, Newton’s second law of motion. However, the model is imperfect, as it does not account resistive force of air resistance, for example.

5.4.1 Experimental Data

The experimental data will be generated from an identical object falling from several different heights, each with zero initial velocity (see Fig. 54.1). We collect data, y , of the time taken for the ball to impact the ground starting from various different initial heights. Each experimental observation error is treated as Gaussian with some known mean and variance standard deviation, σ . The error is a result of measurement uncertainties, such as estimates of the actual height the object was dropped from, the human error introduced by operating a stopwatch for time measurement, and any other possible sources of error. The actual observation values can be found in the accompanying source code that will follow shortly.

Fig. 54.1 An object falls from altitude h_0 with zero initial velocity ($v_0 = 0$)

5.4.2 The Prior, Likelihood, and Posterior

In Bayesian inference, the prior probability signifies the modeler's expectation of the result of an experiment before any data is provided. In this problem, a prior must be provided for the parameter g . Near the surface of the Earth, an object in free fall in a vacuum will accelerate at approximately 9.8 m/s^2 , independent of its mass. For this gravitational inference problem, we will place a uniform prior on our unknown variable θ , over the interval [8,11]:

$$\mathbb{P}(\theta) = \mathcal{U}(8, 11). \quad (54.2)$$

We select a Gaussian likelihood function that assigns greater probabilities to parameter values that result in model predictions close to the data:

$$\mathbb{P}(\mathbf{y}|\theta) \propto \exp\left(-\frac{1}{2} (\mathcal{G}(\theta) - \mathbf{y})^T \mathbf{C}^{-1} (\mathcal{G}(\theta) - \mathbf{y})\right), \quad (54.3)$$

where \mathbf{C} is a given covariance matrix, \mathbf{y} is the experimental data, and $\mathcal{G}(\theta)$ is the model output.

Using the deterministic model for the acceleration of gravity (Eq. 54.1) with no initial velocity, the observations \mathbf{y} , and equation (54.3), we have

$$\theta \stackrel{\text{def.}}{=} g, \quad \mathcal{G}(\theta) = \begin{bmatrix} \sqrt{\frac{2h_1}{g}} \\ \sqrt{\frac{2h_2}{g}} \\ \vdots \\ \sqrt{\frac{2h_{n_d}}{g}} \end{bmatrix}, \quad \mathbf{y} = \begin{bmatrix} t_1 \\ t_2 \\ \vdots \\ t_{n_d} \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} \sigma_1^2 & 0 & \cdots & 0 \\ 0 & \sigma_2^2 & \cdots & 0 \\ \vdots & \vdots & \ddots & 0 \\ 0 & 0 & \cdots & \sigma_{n_d}^2 \end{bmatrix}, \quad (54.4)$$

where $n_d = 14$ is the number of observations. We now invoke Bayes' formula in order to obtain the posterior PDF $\mathbb{P}(\theta|\mathbf{y})$:

$$\mathbb{P}(\theta|\mathbf{y}) \propto \mathbb{P}(\mathbf{y}|\theta)\mathbb{P}(\theta). \quad (54.5)$$

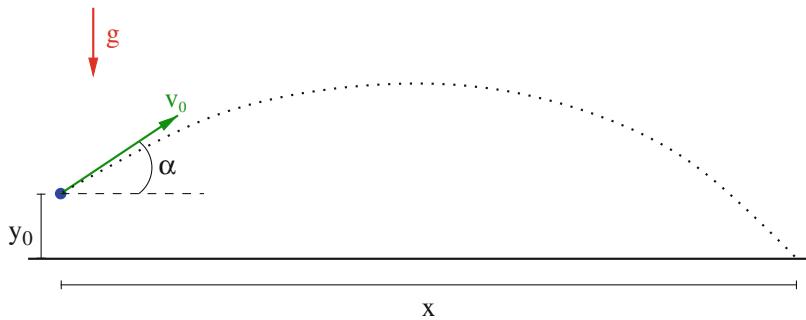

Fig. 54.2 Object traveling with projectile motion

5.5 Statistical Forward Problem

Projectile motion refers to the motion of an object projected into the air at an angle, e.g., a soccer ball being kicked, a baseball being thrown, or an athlete long jumping. In the absence of a propulsion system and neglecting air resistance, the only force acting on the object is proportional to a constant gravitational acceleration g . A deterministic two-dimensional mathematical model for the vertical motion of an object projected from near the surface of the Earth is given by

$$v_x = v_{0x}, \quad (54.6)$$

$$v_y = v_{0y} - gt, \quad (54.7)$$

$$x = v_{0x}t, \quad (54.8)$$

$$h = h_0 + v_{0y}t - \frac{1}{2}gt^2, \quad (54.9)$$

where h_0 is the initial height, $x = x(t)$ is the distance traveled by the object, $\mathbf{v}_0 = (v_{0x}, v_{0y})$ is the initial velocity, $v_{0x} = v_0 \cos(\alpha)$, $v_{0y} = v_0 \sin(\alpha)$, and $v_0 = \|\mathbf{v}_0\|^2$. Figure 54.2 displays the projectile motion of an object in these conditions.

In this example, we assume that h_0 , α , and v_0 are all known, with $h_0 = 0$, $\alpha = \pi/4$, $v_0 = 5$, and g is the result of the SIP described in Sect. 5.4.

Since the result of the SIP is a PDF on g , the output of the mathematical model (54.6) will be a random variable, and our forward problem result will also be statistical in nature.

5.5.1 The Input Random Variable, QoI, and Output Random Variable

The input for the statistical forward problem is the random variable g , the acceleration of gravity. This is the solution (posterior PDF) of the inverse problem described in Sect. 5.4. The QoI for this example is the distance x traveled by an object in projectile motion.

Combining the expressions in Eq. (54.6) and rearranging them, the QoI function for x is

$$x = \frac{v_0 \cos \alpha}{g} \left(v_0 \sin \alpha + \sqrt{(v_0 \sin \alpha)^2 + 2g y_0} \right). \quad (54.10)$$

Here x is the distance traveled and our quantity of interest (QoI).

5.6 Example Code

The source code for the SIP and the SFP is composed of several files. Three of them are common for both problems, `gravity_main.C`, `gravity_compute.h`, and `gravity_compute.C`; they combine both problems and use the solution of the SIP (the posterior PDF for the gravity) as an input for the SFP. We present only the statistical inverse problem here. The forward problem is very similar to the inverse problem, and the user is encouraged to visit the source tree (<https://libqueso.com>) for the full treatment.

The files common to the inverse (and forward) problem are in Listings 1 and 2. Two files specifically handle the SIP: `gravity_likelihood.h` and `gravity_likelihood.C`. These are displayed in Listings 3 and 4.

Listing 1 File `gravity_main.C`.

```
#include <gravity_compute.h>

int main(int argc, char* argv[])
{
    // Initialize QUESO environment
    MPI_Init(&argc,&argv);
    QUESO::FullEnvironment* env =
        new QUESO::FullEnvironment(MPI_COMM_WORLD, argv[1], "", NULL);

    // Call application
    computeGravityAndTraveledDistance(*env);

    // Finalize QUESO environment
    delete env;
    MPI_Finalize();

    return 0;
}
```

Listing 2 File `gravity_compute.C`. The first part of the code (lines 4–44) handles the statistical forward problem, whereas the second part of the code (lines 53–76) handles the statistical forward problem.

```
1 void computeGravityAndTraveledDistance(const QUESO::FullEnvironment& env) {
2     // Statistical inverse problem (SIP): find posterior PDF for 'g'
3
4     // SIP Step 1 of 6: Instantiate the parameter space
5     QUESO::VectorSpace<QUESO::GslVector, QUESO::GslMatrix> paramSpace(env,
6         "param_", 1, NULL);
7 }
```

```

8 // SIP Step 2 of 6: Instantiate the parameter domain
9 QUESO::GslVector paramMinValues(paramSpace.zeroVector());
10 QUESO::GslVector paramMaxValues(paramSpace.zeroVector());
11 paramMinValues[0] = 8.;
12 paramMaxValues[0] = 11.;
13
14 QUESO::BoxSubset<QUESO::GslVector, QUESO::GslMatrix> paramDomain("param_",
15 paramSpace, paramMinValues, paramMaxValues);
16

5.7 Running the Gravity Example with Several Processors

QUESO requires MPI, so any compilation of the user's statistical application will look like this:

```
mpicxx -I/path/to/boost/include -I/path/to/gsl/include \
       -I/path/to/queso/include -L/path/to/queso/lib \
       YOURAPP.C -o YOURAPP -lqueso
```

This will produce a file in the current directory called YOURAPP. To run this application with QUESO in parallel, you can use the standard `mpirun` command:

```
mpirun -np N ./YOURAPP
```

Here `N` is the number of processes you would like to give to QUESO. They will be divided equally among the number of chains requested (see `env_numSubEnvironments` below). If the number of requested chains does not divide the number of processes, an error is thrown.

Even though the application described in Sect. 5.6 is a serial code, it is possible to run it using more than one processor, i.e., produce multiple chains. Supposing

the user's workstation has $N_p = 8$ processors, then, the user may choose to have $N_s = 1, \dots, 8$ subenvironments. This complies with the requirement that the total number of processors in the environment (eight) must be a multiple of the specified number of subenvironments (one). Each subenvironment has only one processor because the forward code is serial.

Thus, to build and run the application code with $N_p = 8$, and $N_s = 8$ subenvironments, the user must set the variable `env_numSubEnvironments = 8` in the input file and enter the following command lines:

```
mpirun -np 8 ./gravity_gsl gravity_inv_fwd.inp
```

The steps above will create a total number of eight raw chains, of size defined by the variable `ip_mh_rawChain_size`. QUESO internally combines these eight chains into a single chain of size $8 \times \text{ip_mh_rawChain_size}$ and saves it in a file named according to the variable `ip_mh_rawChain_dataOutputFileName`. QUESO also provides the user with the option of writing each chain—handled by its corresponding processor—in a separate file, which is accomplished by setting the variable `ip_mh_rawChain_dataOutputAllowedSet = 0 1 ... Ns-1`.

Note: Although the discussion in the previous paragraph refers to the raw chain of a SIP, the analogous is true for the filtered chains (SIP), and for the samples employed in the SFP (`ip_mh_filteredChain_size`, `fp_mc_qseq_size` and `fp_mc_qseq_size`, respectively). See the QUESO user's manual for further details.

5.8 Data Post-processing and Visualization

5.8.1 Statistical Inverse Problem

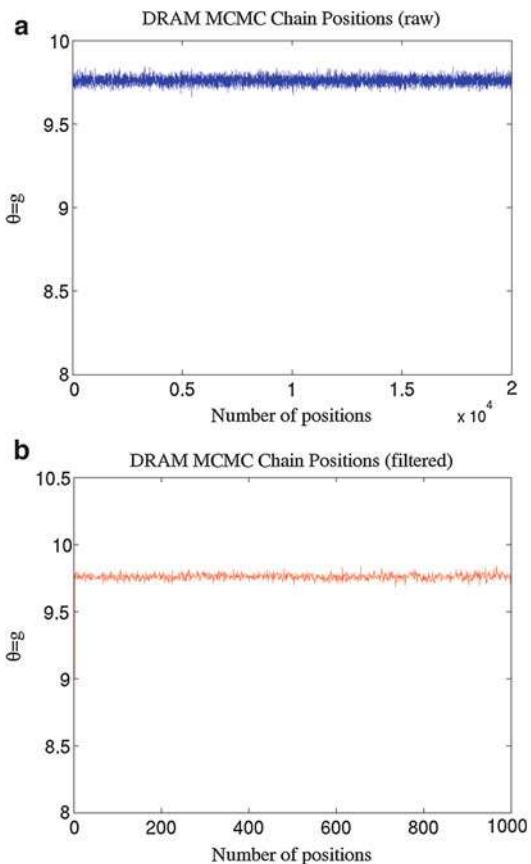

QUESO supports both python and Matlab for post-processing. This section illustrates several forms of visualizing QUESO output and discusses the results computed by QUESO with the code of Sect. 5.6. For Matlab-ready commands for post-processing the data generated by QUESO, refer to the QUESO user's manual.

It is quite simple to plot, using Matlab, the chain of positions used in the DRAM algorithm implemented within QUESO. Figure 54.3a, b show what raw and filtered chain output look like, respectively.

Predefined Matlab and numpy/matplotlib functions exist for converting the raw or filtered chains into histograms. The resulting output can be seen in Fig. 54.4a, b, respectively.

There are also standard built-in functions in Matlab and SciPy to compute kernel density estimates. Resulting output for the raw and filtered chains can be seen in Fig. 54.5a, b, respectively.

Fig. 54.3 MCMC raw chain with 20,000 positions and a filtered chain with lag of 20 positions (a) Raw chain.
(b) Filtered chain

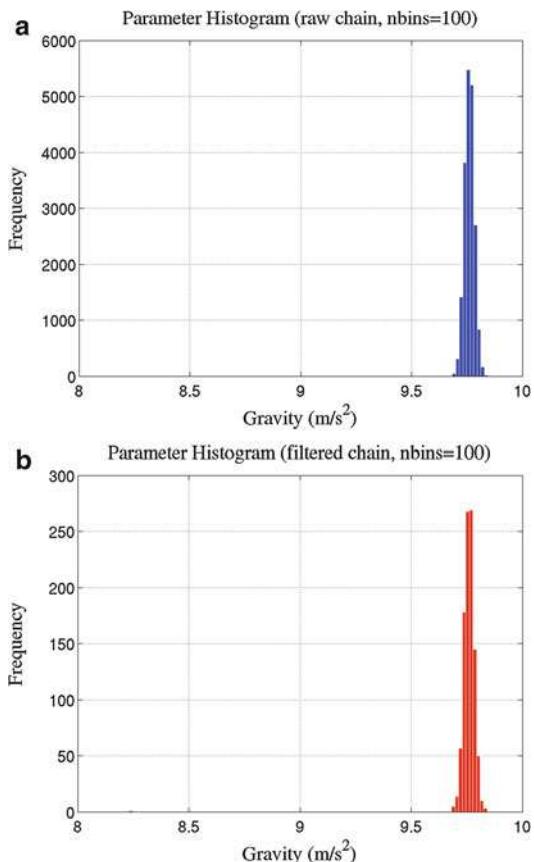

5.9 Infinite-Dimensional Inverse Problems

QUESO has functional but limited support for solving infinite-dimensional inverse problems. Infinite-dimensional inverse problems are problems for which the posterior distribution is formally defined on a function space. After implementation, this distribution will lie on a discrete space, but the MCMC algorithm used is robust to mesh refinement of the underlying function space.

There is still substantial work to be done to bring the formulation of these class of inverse problems in QUESO in line with that of the finite-dimensional counterpart described above, but what currently exists in QUESO is usable. The reason for the departure in design pattern to that of the finite-dimensional code is that for infinite-dimensional problems, QUESO must be agnostic to any underlying vector type representing the random functions that are sampled. To achieve this, a finite element back end is needed to represent functions. There are many choices of finite element libraries that are freely available to download and use, and the design of the infinite-dimensional part of QUESO is such that addition of new back ends should

Fig. 54.4 Histograms of parameter $\theta = g$. (a) Raw chain. (b) Filtered chain

be attainable without too much effort. libMesh is the default and only choice currently available in QUESO. libMesh is open source and freely available to download and use. Visit the libMesh website for further details: <http://libmesh.github.io>

We proceed with showing a concrete example of how to formulate an infinite-dimensional inverse problem in QUESO.

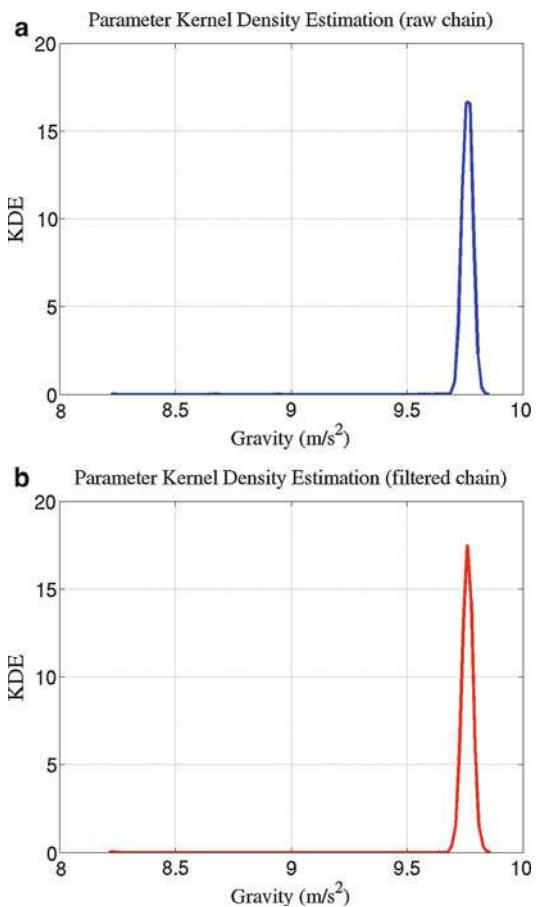

First, we assume the user has access to a `libMesh::Mesh` object on which their forward problem is defined. In what follows, we shall call this object `mesh`.

5.9.1 Defining the Prior

Currently, the only measure you can define is a Gaussian measure. This is because Gaussian measures are well-defined objects on function space and their properties are well understood.

To define a Gaussian measure on function space, one needs a mean function and a covariance operator. QUESO has a helper object to help the user build functions

Fig. 54.5 Kernel density estimation (a) Raw chain.
(b) Filtered chain

and operators called `FunctionOperatorBuilder`. This object has properties that are set by the user that define the type and order of the finite elements used by `libMesh` to represent functions:

```
// Use a helper object to define some of the properties
// of our samples
QUESO::FunctionOperatorBuilder fobuilder;
fobuilder.order = "FIRST";
fobuilder.family = "LAGRANGE";
fobuilder.num_req_eigenpairs = num_pairs;
```

This object will be passed to the constructors of functions and operators and will instruct `libMesh`, in this case, to use first-order Lagrange finite elements. The `num_req_eigenpairs` variable dictates how many eigenpairs to solve for in an eigenvalue problem needed for the construction of random functions. The more eigenpairs used in the construction of Gaussian random functions, the more high-

frequency information is present in the function. The downside to asking for a large number of eigenpairs is that the solution of the eigenvalue problem will take longer. Solving the eigenvalue problem, however, is a one-time cost. The details of the construction of Gaussian random fields can be found in [15–17]. To define a function, one can do the following:

```
QUESO::LibMeshFunction mean(fobuilder, mesh);
```

This function is initialized to be exactly zero everywhere. For more fine-grained control over point values, one can access the internal `libMesh EquationSystems` object using the `get_equation_systems()` method.

Specifying a Gaussian measure on a function space is often more convenient to do in terms of the precision operator rather than the covariance operator. Currently, the only precision operators available in QUESO are powers of the Laplacian operator. However, the design of the class hierarchy for precision operators in QUESO should be such that implementation of other operators is easily achievable. To create a Laplacian operator in QUESO one can do the following:

```
QUESO::LibMeshNegativeLaplacianOperator
    precision(fobuilder, mesh);
```

The Gaussian measure can then be defined by the mean and precision above (where the precision can be taken to a power) as such:

```
QUESO::InfiniteDimensionalGaussian
    mu(env, mean, precision, alpha, beta);
```

Here `beta` is the coefficient of the precision operator, and `alpha` is the power to raise the precision operator to.

5.9.2 Defining the Likelihood

Defining the likelihood is very similar to the ball drop example. We have to subclass `InfiniteDimensional LikelihoodBase` and implement the `evaluate(FunctionBase & flow)` method. This method should return the logarithm of the likelihood distribution evaluated at the point `flow`.

One's specific likelihood implementation will vary from problem to problem, but an example, which is actually independent of `flow`, is shown here for completeness:

```
double
Likelihood::evaluate(QUESO::FunctionBase & flow)
{
    const double obs_stddev = this->obs_stddev();
    const double obs = gsl_ran_gaussian(this->r, obs_stddev);
    return obs * obs / (2.0 * obs_stddev * obs_stddev);
}
```

The reader is reminded that a full working implementation of this example is available in the source tree. See <http://libqueso.com>.

5.9.3 Sampling the Posterior

The following code will use the prior and the likelihood defined above to set up the inverse problem and start sampling:

```
QUESO::InfiniteDimensionalMCMCSamplerOptions opts(env, "");

// Set the number of iterations to do
opts.m_num_iters = 1000;

// Set the frequency with which we save samples
opts.m_save_freq = 10;

// Set the RWMH step size
opts.m_rwmh_step = 0.1;

// Construct the sampler, and set the name of the output file (will only
// write HDF5 files)
QUESO::InfiniteDimensionalMCMCSampler s(env, mu, llhd, &opts);

for (unsigned int i = 0; i < opts.m_num_iters; i++) {
    s.step();
    if (i % 100 == 0) {
        std::cout << "sampler iteration: " << i << std::endl;
        std::cout << "avg acc prob is: " << s.avg_acc_prob() << std::endl;
        std::cout << "l2 norm is: " << s.llhd_val() << std::endl;
    }
}
```

The infinite-dimensional inverse problem work is still considered experimental but should produce meaningful results for a large class of simple problems. Work is ongoing to bring the user interface in line with that of the finite-dimensional inverse problem API.

6 Extensibility

QUESO is written in C++. The choice of the language inspired design decisions that the user can take advantage of. One such benefit of having a well-defined inverse problem setup and workflow is that the user is offered the freedom to extend many of the abstract base classes in QUESO. A good example of this we have seen already is the specification of the likelihood distribution by subclassing `BaseScalarFunction`.

In this section we will take this a step further and show how to extend some of the other classes in QUESO to define a custom prior measure. All of the classes we deal with here have their relationships with other objects discussed in Sect. 7.2.

6.1 Custom Priors

We will look at one of the existing measures in QUESO to get a feel for a how a measure QUESO is built. Take, for example, the Gamma distribution.

In QUESO, the user will interact with a Gamma measure by instantiating a `GammaVectorRV` class. This object has two main members that QUESO is

interested in, an object representing a probability distribution function and an object called a “realizer” through which random variates are drawn. These classes are called `GammaJointPdf` and `GammaVectorRealizer`, respectively.

The user does not, usually, need to interact with the probability distribution function or the realizer; these are objects that QUESO will utilize during the execution of the Markov chain Monte Carlo procedure.

6.1.1 PDF Objects

Probability distribution functions are represented by C++ objects. If the user wishes to create a custom prior measure, for example, then they will also have to implement a probability distribution class. The probability distribution class must derive from the `BaseJointPdf`. The `BaseJoinPdf` class subclasses from `BaseScalarFunction`, as we have seen before, and therefore any probability distribution class must implement the `lnValue` and `actualValue` methods. These methods have exactly the same purpose as when the user defines their likelihood. That is, `lnValue` returns the log of the probability distribution function evaluated at `domainVector`, and `actualValue` returns the actual value of the distribution evaluated at `domainVector`.

`BaseJointPdf` has an extra method called `computeLogOfNomalizationFactor` and so this must also be implemented. This method computes the logarithm of the normalizing constant of the probability distribution. If it is known analytically, the user can implement it here. For many distributions, this is not known analytically. In these circumstances one can use the `numSamples` argument to approximate this quantity using samples from the distribution instead. A basic algorithm for computing the log of the normalizing constant from samples is implemented in the `commonComputeLogOfNormalizationFactor` method of `BaseJointPdf`. Indeed the computation of the log of the normalization constant for the Gamma distribution is handed off to this method:

```
template<class V, class M>
double
GammaJointPdf<V, M>::computeLogOfNormalizationFactor(
    unsigned int numSamples,
    bool updateFactorInternally) const
{
    value =
        BaseJointPdf<V,M>::commonComputeLogOfNormalizationFactor(
            numSamples, updateFactorInternally);
    return value;
}
```

Notice that when we defined a custom likelihood object, we only subclassed `BaseScalarFunction` and not `BaseJointPdf`. This is because for most applications, the likelihood is not a probability distribution since it does not integrate to 1. Furthermore, it avoids needing to implement the `computeLogOfNormalizationFactor` method. This is because the normalizing constant is usually not known analytically, and computing it by samples is often intractable for large engineering problems. Note, however, that

the normalizing constant for the likelihood is not needed since MCMC methods do not require knowledge of any normalizing constant in order to draw random samples. This is crystallized in the following section.

6.1.2 Realizer Objects

Realizer objects are objects that QUESO interacts with to draw random samples from the appropriate distribution. A realizer object must subclass `BaseVectorRealizer` and must therefore implement the `realization(V & nextValues) const` method. This method fills the `nextValues` vector with a random draw from the associated distribution. The size of the vector `nextValues` is equal to the dimension of the state space on which the measure is defined.

In the case of the Gamma distribution, QUESO falls back to GSL to draw samples that are Gamma distributed.

A warning to the user: it is possible to define a measure on a space that is improper. In this case drawing realizations from the associated realizer object produces meaningless results.

6.1.3 Random Variable Objects

Random variable objects, named `*VectorRV` in QUESO, are encapsulating objects that hold references to the associated probability distribution function object and the associated realizer object. A random variable object must subclass `BaseVectorRV` which implements the getter methods `realizer()` and `pdf()` that return references to the realizer object and PDF object, respectively.

The user never has to deal with constructing the PDF object or the realizer object explicitly. Construction of these objects is handled by the random variable object's constructor.

7 The QUESO Design and Implementation

7.1 Software Engineering

High-quality software is essential for developing, analyzing, and scaling up new UQ algorithmic ideas involving complex simulation codes running on HPC platforms. QUESO helps researchers to bootstrap statistical inverse problems for large-scale models widely seen in the physics and engineering domains in parallel compute environments. With ongoing effort to enhance the API in terms of extensibility (see Sect. 10.3), in the future it will be possible to quickly prototype new algorithms in a sophisticated computation environment, rather than first coding and testing them with a scripting language and only then recoding in a C++/MPI environment. QUESO also allows researchers to more naturally translate the mathematical language present in algorithms to a concrete program in the library and to concentrate their efforts on algorithmic, load balancing, and parallel scalability issues.

We utilize various community tools to manage the QUESO development cycle. Source code traceability is provided via Git, and the GNU Autotools suite is used to

provide a portable, flexible build system, with the standard GNU package pattern: `configure`; `make`; `make check`; `make install` steps. We also utilize GitHub for project management, which provides a web-based mechanism to manage releases, milestone developments, issues, bugs, and source code changes. In case the build system or application development processes change, please consult the website (<http://libqueso.com>) for a detailed and up-to-date guide on how to build and install QUESO.

As of the latest QUESO release, 0.53.0, the library is comprised of approximately 73,000 source lines of code, with the vast majority of this instantiated across approximately 200 C/C++ source files and headers. At a minimum, QUESO compilation requires MPI and linkage against two external libraries: boost and GSL. QUESO also has several optional dependencies that enable additional functionality: Teuchos, GRVY, HDF5. The optional infinite-dimensional capabilities of QUESO in particular require libMesh and HDF5.

We employ an active regression testing, with approximately thirty regression tests, and can test latest GitHub builds using Travis-CI in order to have a continuous integration analysis of source code commits.

Contributing QUESO has been made easy with the recent explosion in popularity of GitHub. We employ the feature branch model by Driessen (<http://nvie.com/posts/a-successful-git-branching-model>), and further instructions for contribution to QUESO can be found by mirroring some of the other contributions we have merged (<https://github.com/libqueso/queso/issues>).

7.2 QUESO Internals

In this subsection, we show and discuss several of the inheritance diagrams behind the principle objects in the QUESO library. This is in order to:

- Document the QUESO internal structure
- Provide context for leveraging the existing QUESO objects in extending the library (as in Sect. 6).

This subsection addresses some of the C++ objects for the finite-dimensional Bayesian inverse problem. Objects associated with the infinite-dimensional problem exist and are available on the online documentation, but are not discussed here since development work to get the finite- and infinite-dimensinoal APIs consistent with each other is ongoing.

`BaseScalarFunction` is a templated base class for handling generic scalar functions. This provides a high-level interface and member functions for the QUESO generic class, `BaseJointPDF`, which is discussed below.

`BaseJointPdf` is a templated (base) class for handling joint PDFs. For example, Fig. 54.6 shows the inheritance of the Gamma joint PDF class, which is a derived class from the `BaseScalarFunction` class. QUESO presently has several provided joint PDFs for a wide variety of statistical distributions, including: `InvLogitGaussianJointPdf`, `ConcatenatedJointPdf`,

Fig. 54.6 Class Reference for the Gamma Joint PDF

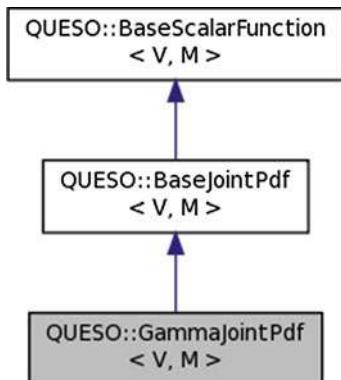

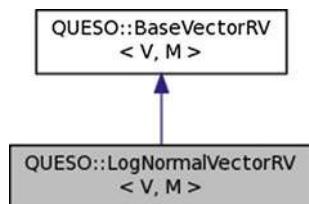

Fig. 54.7 Class reference for the LogNormalVectorRV

`GaussianJointPdf`, `BaseJointPdf`, `BayesianJointPdf`, `LogNormalJointPdf`, `PoweredJointPdf`, `BetaJointPdf`, `GammaJointPdf`, `InverseGammaJointPdf`, `WignerJointPdf`, `GenericJointPdf`, `UniformJointPdf`, `JeffreysJointPdf`, `GenericScalarFunction`, and `ConstantScalarFunction`. However, implementing a new distribution is intended to be straightforward and is detailed in Sect. 6.

Another useful internal QUESO object, `BaseVectorRV`, is a templated base class for handling vector random variables. For example, Fig. 54.7 shows the inheritance diagram of the `LogNormalVectorRV` class, which is a class that contains member functions and associated utilities to provide a random vector of draws from a `LogNormal` distribution.

Presently included in QUESO are the following: `GaussianVectorRV`, `GenericVectorRV`, `BetaVectorRV`, `GammaVectorRV`, `InverseGammaVectorRV`, `InvLogitGaussianVectorRV`, `JeffreysVectorRV`, `LogNormalVectorRV`, `UniformVectorRV`, and `WignerVectorRV`. In other words, nearly all canonical distributions from classical statistics are already available in the library. However, as stated above, QUESO is designed with extensibility in mind, and the user can implement any `*VectorRV` by deriving from the `BaseVectorRV` class. In principle, this permits a series of draws from any distribution.

Another important base class contained within QUESO is the realizer object, `BaseVectorRealizer`. A realizer is an object that, simply put, contains a `realization()` operation that returns a sample of a random variable. `BaseVectorRealizer` is therefore an abstract base class that provides the necessary interface for sampling from random variables. As before, the realizer

object contains most of the common statistical distributions. It also contains a sequence realizer class for storing samples of a MH algorithm.

8 Algorithms

8.1 DRAM

A simple Metropolis-Hastings sampling algorithm [4] can be improved by adding both “Delayed Rejection” [18–21] and “Adaptive Metropolis”. Taken together, these form the “DRAM” algorithm, which is available in QUESO. In particular, the QUESO implements the DRAM algorithm of Haario, Laine, Mira, and Saksman [7].

A “vanilla” Metropolis-Hastings sampler involves a proposal at each step, and accepts or rejects this proposal based on the ratio between proposal and prior likelihoods. Typically, the proposal is drawn from some fixed distribution, such as a Gaussian distribution, with fixed covariance and a mean centered at the value of the current state of the chain. However, this has several deficiencies. Should the proposal variance be set too high, many proposals will be rejected. This is undesirable, as it increases the auto-correlation of the chain. Furthermore, should the target distribution deviate greatly from the proposal distribution, the proposal will not match the local shape of the distribution, resulting in poor sampling.

Delayed rejection attempts to circumvents these issues. Before rejecting a sample, a series of back-up proposals each with successively smaller jumps in state space are pushed through the Metropolis-Hastings acceptance probability rejection. They are tested in order of decreasing jump size, and if one of them is accepted, the sampler continues. If they are all rejected, the sampler rejects the sample and starts again.

Conversely, when the proposal variance is too small to efficiently sample the target distribution, the sampler will randomly walk through regions of higher likelihood in the posterior distribution, without efficiently sampling the tails. This results in too high an acceptance rate.

In order to mitigate this, Adaptive Metropolis sampling continuously adapts the proposal covariance. This is accomplished by using the covariance of the history of the Markov chain as the proposal covariance matrix of the Gaussian proposal distribution instead of the arbitrary proposal covariance imposed at the start. Adapting the proposal to match the posterior covariance structure results in a better chain performance than a static proposal covariance.

8.2 Multilevel

Multilevel Monte Carlo [6] is an algorithm available in QUESO that attempts to sample probability distributions with multiple modes. Sampling multi-modal distributions is a heavily researched topic. The way multilevel Monte Carlo attempts to solve the problem of metastability in Markov chains is by “heating up” the posterior distribution to flatten out some of the modes, allowing a Markov chain to

sample the flattened distribution and then “cooling down” the posterior distribution before doing a final sampling run. The idea is identical to that of simulated tempering or simulated annealing, except that the multilevel algorithm allows for convenient and efficient computation of the posterior normalizing constant. This constant is usually intractable to compute but is essential for Bayesian model selection purposes.

8.3 Preconditioned Crank-Nicolson

The preconditioned Crank-Nicolson proposal [15] is used by QUESO for solving infinite-dimensional Bayesian inverse problems (Sect. 5.9). This particular form of proposal is typical for sampling on formally infinite-dimensional spaces since the Metropolis-Hastings acceptance probability remains unchanged when the state undergoes mesh refinement, a popular technique in large-scale engineering models involving the solution of partial differential equations by finite element methods.

9 Input File

Here we provide some of the default input file options QUESO recognizes. For detailed descriptions of the behavior of each option and how they interact with other options, consult the online QUESO documentation. For example, for the description of each DRAM option, consult the documentation for the `MhOptionsValues` object. For the description of each `FullEnvironment` option, see the documentation for the `EnvOptionsValues` object. The documentation for these is available at <http://libqueso.com> (Tables 54.1, 54.2, 54.3, 54.4, and 54.5).

10 Conclusions

We conclude this chapter with a discussion of several of the areas the QUESO development team is investing time into implementing, extending, and improving along with some of the newest features recently made available in v0.53.0. Previously, we have covered only the basics of how to interact with QUESO and to provide a resource that is accessible and can be used to bootstrap a user’s statistical inverse problem quickly and efficiently. With this in mind, there are still many areas in which QUESO can improve to become more user friendly, consistent, and extensible. In what follows, we discuss some major areas of development that would likely encourage widespread adoption of QUESO in the computational applied mathematics and engineering community.

10.1 QUESO-Provided Likelihoods

In many large-scale physics and engineering-based experimental settings, it is often the case that observations of a physical quantity are performed several times. These observations are then averaged to homogenize the effect of experimental observation error. In the case of independent experimental errors, this average will be normally distributed. Therefore, a reasonable choice for a likelihood in many applications would be a Gaussian.

At present, the user must derive from `BaseScalarFunction` and implement `lnValue` explicitly. This is a tedious task if all that is needed is the standard Gaussian error in the Euclidean 2-norm:

$$\mathbb{P}(y|\theta) = Z \exp\left(\frac{1}{2} (\mathcal{G}(\theta) - y)^\top \Sigma^{-1} (\mathcal{G}(\theta) - y)\right), \quad (54.11)$$

where Z is a normalizing constant.

A recently released and much leaner approach is to provide an abstract base class of `BaseScalarFunction` called `BaseGaussianLikelihood` with a pure virtual method called `evaluateModel` that asks for the output of the map \mathcal{G} at the point `domainVector`. Equipped with an implementation of `lnValue` that computes the log of (54.11), the user would only need to provide Σ and y , which can be passed in from the constructor. An example follows:

Here the user would pass an instance of `Likelihood` to `StatisticalInverseProblem`, as per usual.

Extensions of this idea are also available, where one wishes to treat Σ as a hyper-parameter to be sampled along with θ in so-called “hierarchical Bayesian” methods. The design described above is easily applied to this situation.

Ongoing work is being invested in developing other pre-made likelihood objects representing other likelihood forms that are commonly used.

10.2 Emulators

The two main forms of emulation used in the statistical modeling community are Gaussian processes and generalized polynomial chaos. These are both important methods in statistical inference as they can considerably reduce the computational cost of computing the posterior.

Gaussian process emulators, similar to the ready-made Gaussian likelihoods discussed in the previous section, are also a form of baked likelihood, but where the user is not required to implement a method returning the output of \mathcal{G} . For Gaussian process emulators, the user would only need to instantiate an emulator with a specific dataset and observational error covariance matrix. The rest of the statistical application the user writes is identical to any other statistical application and the output (samples) is processed as per usual.

Generalized polynomial chaos methods require different algorithms for solution, since no Markov chain Monte Carlo is done. This type of emulator is not currently on the QUESO development road map for the near future, but contributions in the area are more than welcome.

As of QUESO v0.53.0, the only supported emulator is a linear interpolation of model output values. Interested users should consult the documentation and, in particular, the example called `4d_interp.C`.

10.3 API Considerations

As mentioned in the infinite-dimensional example, the infinite-dimensional and finite-dimensional APIs are not aligned. Although the user interacts with only one of these APIs at any given time, an aligned API structure exposes the opportunity for algorithms designed on function space, which tend to be more robust algorithms, to be used in the finite-dimensional setting. Moreover, an aligned API eases the maintenance, documentation, and testing burden.

Currently, there are only two (finite-dimensional) algorithms the user can use, DRAM and multilevel. At present, there is no organized structure that Markov chains (`MetropolisHastingsSG` objects) inherit from, meaning that there is a significant hurdle involved in bootstrapping one’s own MCMC algorithm for the purposes of testing and research. Just as above, a consistent class hierarchy for MCMC algorithms would ease the burden for software maintenance.

A rather cumbersome design choice made early on in the development of QUESO was the hot-swappability of vector and matrix implementations for all of QUESO's classes. The net result of this is that any QUESO class that involves an operation with a vector or a matrix is templated around the type of that vector or matrix. This was done to ensure that optimized code could be generated that dealt with the specifics of each vector and matrix library. Assuming that, in high-performance uncertainty quantification, likelihood evaluations are the dominating cost of Markov chain Monte Carlo sampling, one need not encumber the QUESO API with such templates. Furthermore, a hierarchical class structure for vector and matrix types exists in QUESO and therefore necessitates the run-time overhead of virtual table lookups. Efforts are currently ongoing to enrich the vector and matrix class hierarchy in QUESO sufficiently such that the particulars of vector and matrix implementations still remain opaque but significantly shorten unnecessarily long class names with a negligibly small impact on run-time performance. This enrichment would also allow QUESO to pick a high-tuned vector/matrix implementation at configure time for high-performance problems in exascale compute environments. For example, QUESO's build system could default to using PETSc vectors optimized for multi-core architectures, while the user need not deal explicitly with MPI calls. All parallel logic would be handled under the hood. This offers a pleasing software experience while maintaining performance.

Python has become a very popular environment to do post-processing and visualization in multi-core HPC systems. A desirable feature to have in QUESO would be the automatic generation of python bindings. This would offer the possibility to do uncertainty quantification in statistical inverse problems as a quick-turnaround experiment for cheap forward models in an interpreted language environment. This implementation will likely leverage the Simplified Wrapper and Interface Generator (SWIG) which is not limited to Python and can provide interfaces to many modern programming languages, such as Perl, Python, Ruby, and Tcl.

10.4 Exascale

Uncertainty quantification has pushed the limits of current computational power by requiring many evaluations of large-scale engineering systems described by partial differential equations. Utilizing more information about the system can significantly increase the performance of MCMC algorithms [22–24]. In particular QUESO does not currently implement MCMC algorithms that use gradient or Hessian information to construct proposal distributions. However, the design of the API for the pure virtual methods in `BaseScalarFunction` allows this information to be passed to QUESO easily, in the form of a pointer `V * gradVector`. For more details on the parameters passed to the `lnValue` function, the reader is directed to the QUESO documentation which be found online here: <http://libqueso.com>.

Gaussian Process-Based Sensitivity Analysis and Bayesian Model Calibration with GPMSA

55

James Gattiker, Kary Myers, Brian J. Williams, Dave Higdon, Marcos Carzolio, and Andrew Hoegh

Abstract

The Gaussian Process Models for Simulation Analysis (GPMSA) package is a set of functions written in the Matlab programming language aimed at *emulating* a computer model of a system being studied, *calibrating* this computer model to observations of the system, and giving *predictions* of the expected system response. Collectively, these capabilities comprise uncertainty quantification (UQ) in model-supported inference.

This chapter will first discuss some background and motivation for the GPMSA code, then demonstrate the code's function interfaces in the context of a series of illustrative example problems.

1 Introduction

We begin with an overview of how a scientific computer model is used in inference and how UQ is performed. There is a system S whose behavior we would like to understand and predict. To study that system, observations of its state O_s are made, where these observations also have some error. To understand the system, a model for its behavior is specified that estimates the system response as a function of some conditions that influence the system model. For an example, consider studying gravity. We might notice that the position x of a dropped weight seems to be a quadratic function of time t and so postulate the system model $x = \alpha t^2$. To determine α , where α in this case corresponds to the constant of gravity, observations of the system would be taken, measuring x at time t . Observations x have Gaussian uncertainty.

Given these observations, the values of α that are consistent can be determined. Performing this evaluation in a Bayesian framework, a likelihood function defines the probability density of the observations given a value for α (appropriate for the system model). Prior probabilities express information known about the value of α before the experiment. Now, the posterior probability distribution for α can be evaluated in principle, and in simple cases, this can be performed analytically. Given the posterior for α , predictions for x at unobserved t can be made, with uncertainty. This is the operation of UQ in *calibration*, or finding posterior probability distributions of unknown settings of system model parameters.

When the system model is complicated, as with models that require computer evaluation, this procedure cannot be performed analytically. Instead, in the Bayesian setting, Monte Carlo methods are used to recover samples from the posterior distribution of α . These samples of α can be similarly used for UQ in *prediction*,

propagating them through the model to get samples of the distribution of x at specified, perhaps unobserved, values of t .

UQ becomes more complex in the case where α represents several variables instead of single scalar. When α is low dimensional, say ≤ 5 , it is possible to sample the joint posterior distribution at regular intervals, but this becomes untenable in higher dimensions. The solution in this case is to use Markov chain Monte Carlo (MCMC), a technique for generating samples of the posterior distribution. Using MCMC introduces some additional complications, which are described in a rich literature on the topic. Two typical issues are tuning the MCMC sample step size in a Metropolis-Hastings framework so that the process is efficient and in the possible need for variable transformations to avoid issues that arise with highly correlated parameters.

Scaling this up, we come to the case where the system model is a complicated computer simulation that takes hours or days to evaluate. This is not at all unusual in many areas of scientific study. Now the Monte Carlo procedures cannot be performed as needed, as hundreds or perhaps thousands of evaluations of the model (i.e., runs of the computer simulation) are required to study α . In this case, a statistical model, specifically a Gaussian process (GP) model, is used to *emulate* the system model. The strategy is to use a number of instances of the system model's input-output relationship to construct an approximation to that relationship that is fast to evaluate and accurate over the domain of interest and delivers defensible prediction uncertainty. This presumes that the system model's total behavior over the domain of interest can be well characterized by a reasonable (in evaluation time and dataset size) number of samples. Once the emulator has been constructed and its accuracy validated, it is used to provide surrogate fast system model evaluations. The main positive features of a Gaussian process model as used in GPMSA are an appropriate expressiveness of two aspects of uncertainty associated with an emulator – the uncertainty in interpolation and the uncertainty in prediction – and the ability of GP models to function in high-dimensional spaces.

It was recognized some time ago that a key feature in using complex system models in inference is an appreciation that the estimated system model is not the same as the true system model and must be expected to present a biased prediction of the system. This is often called “structural error” in the model and implies the incorporation of a *discrepancy* representing the difference in response between the system and the model. In the case of GPMSA, this discrepancy model is an additive GP. In the Bayesian framework, priors say that the discrepancy should be small if it can be, but that it can supply bias when the system model is consistently biased compared to system observations.

As a final complication (optional to GPMSA), complex system models typically have a multivariate nature, as do the system observations. In the example of studying gravity, observations may be the full curves $x(t)$. There is a mechanism to represent the multivariate system response as a linear combination of a smaller number of orthogonal basis functions, in practice typically the first few principal components constructed on examples obtained from the system model. This has several implications. A linear basis such as principal components is a consilient

dimension reduction method. It can be seen as a form of covariance definition between the raw outputs, appropriately limiting the potential expressiveness of the model output to an appropriate number of degrees of freedom and thus also limiting the complexity of the emulation problem. The dimension reduction also simplifies the computations associated with the GP model, by defining orthogonal responses that can be taken to be independent. In the discrepancy GP, it is even more appropriate to reduce the flexibility of the function with a linear basis, constraining the discrepancy response in a manner that is different from the representation of the system model response. This is typically accomplished in practice with an approximate smooth kernel basis approach.

Addressing all of these complications from the basic analytical UQ framework introduces additional parameters beyond the system model parameters that describe the GP emulator. Their value is posed in the same Bayesian framework as the system model, so their uncertainty is included in the UQ analysis and in subsequent predictions and model evaluation. GPMSA presumes that the datasets are scaled and normalized, which allowed the assignment of default priors for these additional parameters. However, it is also important to realize the function and relevance of these parameters in validating the emulator, as they are often diagnostic of emulator performance. This requires an understanding of the underlying statistical framework.

Ultimately, the joint posterior distribution of all the parameters, system model, and GP is sampled using MCMC. The core functions of GPMSA are the setting up of the emulator and model calibration as a Bayesian inference problem, the MCMC sampling of these parameters, and making predictions of system response, with uncertainty. These predictions can then be used for exploring the expected response with conditional visualizations, sensitivity analysis of system model response to parameters (a GPMSA function), and evaluation of uncertainty.

An analytical description of GPMSA is given in the next section, in notation more related to the GPMSA code compared to the detailed description in Higdon et al. [3].

GPMSA has been implemented in the Matlab environment for two main reasons. First, setting up a GPMSA analysis typically involves a significant amount of exploratory data analysis (EDA), customization according to particulars of the problem, and custom statistical and graphical analysis of the results; Matlab provides the necessary full-featured EDA environment. Second, the core GPMSA computations are based in matrix operations and linear algebra, and Matlab provides an efficient computational infrastructure supporting these types of computations.

In further discussion, *observations* will be used for observations of the system under study and *simulator* or simulation for the system model. The observations were collected in *experiments*, which included taking *measurements* of some aspects of the experimental setup. The relevant settings for the simulator are referred to as *simulator inputs* or *parameters*, and results of simulation, corresponding to system observations, are *simulator output*, or *response*.

2 Summary of the GPMSA Statistical Model

In this section, the GPMSA model, described in Higdon et al. [3], is defined using notation that more closely matches the variable names used in GPMSA code.

There are n physical (observational) experiments. From the i th physical experiment at p inputs $\mathbf{x}_i^{\text{obs}} = (x_{i1}^{\text{obs}}, \dots, x_{ip}^{\text{obs}})$, the observation $\mathbf{y}_i^{\text{obs}}(\mathbf{x}_i^{\text{obs}})$ (an $n_{y_i^{\text{obs}}} \times 1$ vector) is modeled by

$$\mathbf{y}_i^{\text{obs}}(\mathbf{x}_i^{\text{obs}}) = \eta(\mathbf{x}_i^{\text{obs}}, \boldsymbol{\theta}) + \delta(\mathbf{x}_i^{\text{obs}}) + \mathbf{e}_i^{\text{obs}}, \quad (55.1)$$

where the observation error vector $\mathbf{e}_i^{\text{obs}}$ is modeled by

$$\mathbf{e}_i^{\text{obs}} \sim MVN(\mathbf{0}_{n_{y_i^{\text{obs}}}}, \frac{1}{\lambda_{y_i^{\text{obs}}}^{\text{obs}}} \Sigma_i^{\text{obs}}). \quad (55.2)$$

$\eta(\cdot)$ is an emulator from a simulation code, $\boldsymbol{\theta}$ corresponds to inputs of the parameter, and $\delta(\cdot)$ is a discrepancy from reality.

There are m simulation experiments. From the i th simulation experiment at $p+q$ inputs $\mathbf{x}_i^{\text{sim}} = (x_{i1}^{\text{sim}}, \dots, x_{ip}^{\text{sim}})$ and $\mathbf{t}_i^{\text{sim}} = (t_{i1}^{\text{sim}}, \dots, t_{iq}^{\text{sim}})$, the observation $\mathbf{y}_i^{\text{sim}}(\mathbf{x}_i^{\text{sim}}, \mathbf{t}_i^{\text{sim}})$ (an $n_{y_i^{\text{sim}}} \times 1$ vector) is modeled by

$$\mathbf{y}_i^{\text{sim}}(\mathbf{x}_i^{\text{sim}}, \mathbf{t}_i^{\text{sim}}) = \eta(\mathbf{x}_i^{\text{sim}}, \mathbf{t}_i^{\text{sim}}) + \mathbf{e}_i^{\text{sim}}, \quad (55.3)$$

where the error vector $\mathbf{e}_i^{\text{sim}}$ is modeled by $MVN(\mathbf{0}_{n_{y_i^{\text{sim}}}}, \frac{1}{\lambda_{y_i^{\text{sim}}}^{\text{sim}}} \mathbf{I}_m)$ and \mathbf{I}_m is the $m \times m$ identity matrix.

We reexpress $\eta(\mathbf{x}_i, \mathbf{t}_i)$ and $\delta(\mathbf{x}_i)$ by linear combinations of basis functions and approximate them using a subset of the complete set of basis functions. Consequently,

$$\eta(\mathbf{x}_i^{\text{obs}}, \boldsymbol{\theta}) \approx \sum_{j=1}^{p_u} \mathbf{K}_j^{\text{obs}} u_j(\mathbf{x}_i^{\text{obs}}, \boldsymbol{\theta}) \quad (55.4)$$

for p_u basis functions $\mathbf{K}_j^{\text{obs}}$. So the matrix $\mathbf{K}^{\text{obs}} = (\mathbf{K}_1^{\text{obs}} \cdots \mathbf{K}_{p_u}^{\text{obs}})$. Similarly,

$$\delta(\mathbf{x}_i^{\text{obs}}) \approx \sum_{j=1}^{p_v} \mathbf{D}_j^{\text{obs}} v_j(\mathbf{x}_i^{\text{obs}}) \quad (55.5)$$

for p_v basis functions $\mathbf{D}_j^{\text{obs}}$. So the matrix $\mathbf{D}^{\text{obs}} = (\mathbf{D}_1^{\text{obs}} \cdots \mathbf{D}_{p_v}^{\text{obs}})$. We use the right-hand sides of (55.4) and (55.5) in (55.1) so that $\mathbf{e}_i^{\text{obs}}$ also includes their differences from reality. Also,

$$\eta(\mathbf{x}_i^{\text{sim}}, \mathbf{t}_i^{\text{sim}}) \approx \sum_{j=1}^{p_u} \mathbf{K}_j^{\text{sim}} w_j(\mathbf{x}_i^{\text{sim}}, \mathbf{t}_i^{\text{sim}}) \quad (55.6)$$

for p_u basis functions $\mathbf{K}_j^{\text{sim}}$, where $w_j(\mathbf{x}_i^{\text{sim}}, \mathbf{t}_i^{\text{sim}}) = u_j(\mathbf{x}_i^{\text{sim}}, \mathbf{t}_i^{\text{sim}}) + \epsilon_j^{\text{sim,nug}}$. Note that $\frac{1}{\lambda_{\epsilon_j^{\text{sim,nug}}}^{\text{ws}}}$ is the variance of an i.i.d. Normally distributed nugget $\epsilon_j^{\text{sim,nug}}$ with mean zero intended to account for small numerical fluctuations in the simulator. Note that only in fitting is the nugget used. In predicting, the nugget is dropped. So the matrix $\mathbf{K}^{\text{sim}} = (\mathbf{K}_1^{\text{sim}} \cdots \mathbf{K}_{p_u}^{\text{sim}})$. We use the right-hand side of (55.6) in (55.3) so that $\mathbf{e}_i^{\text{sim}}$ also includes its difference from reality.

The $u_j(\mathbf{x}, \mathbf{t})$, $j = 1, \dots, p_u$ are modeled as a GP with mean $\mathbf{0}_n$ and variance covariance matrix $\frac{1}{\lambda_{u_j}^{\text{uz}}} R_j^u$, where

$$R_j^u((\mathbf{x}_i, \mathbf{t}_i), ((\mathbf{x}_l, \mathbf{t}_l)) = \prod_{k=1}^p (\rho_{jk}^u)^{4|x_{ik} - x_{lk}|^2} \prod_{k=1}^q (\rho_{(j+p)k}^u)^{4|t_{ik} - t_{lk}|^2}, \quad (55.7)$$

whose more familiar form is

$$R_j^u((\mathbf{x}_i, \mathbf{t}_i), (\mathbf{x}_l, \mathbf{t}_l)) = \prod_{k=1}^p \exp(-\beta_{jk}^u |x_{ik} - x_{lk}|^2) \prod_{k=1}^q \exp(-\beta_{(j+p)k}^u |x_{ik} - x_{lk}|^2), \quad (55.8)$$

so that $\beta_{jk}^u = -4 \log(\rho_{jk}^u)$ or $\rho_{jk}^u = \exp(-\frac{\beta_{jk}^u}{4})$.

Similarly, the $v_j(\mathbf{x}_i^{\text{obs}})$, $j = 1, \dots, n$ are modeled as a GP with mean $\mathbf{0}_n$ and variance covariance matrix $\frac{1}{\lambda_{v_j^{\text{obs}}}^{\text{vz}}} R_j^v$, where

$$R_j^v(\mathbf{x}_i^{\text{obs}}, \mathbf{x}_l^{\text{obs}}) = \prod_{k=1}^p (\rho_{jk}^v)^{4|x_{ik} - x_{lk}|^2}, \quad (55.9)$$

whose more familiar form is

$$R_j^v(\mathbf{x}_i^{\text{obs}}, \mathbf{x}_l^{\text{obs}}) = \prod_{k=1}^q \exp(-\beta_{jk}^v |x_{ik} - x_{lk}|^2), \quad (55.10)$$

so that $\beta_{jk}^v = -4 \log(\rho_{jk}^v)$ or $\rho_{jk}^v = \exp(-\frac{\beta_{jk}^v}{4})$.

Note that the $\mathbf{x}, \mathbf{t}, \boldsymbol{\theta}$ are normalized to $[0,1]$ and the $\mathbf{y}_i^{\text{obs}}(\mathbf{x}_i^{\text{obs}})$ and $\mathbf{y}_i^{\text{sim}}(\mathbf{x}_i^{\text{sim}}, \mathbf{t}_i^{\text{sim}})$ are normalized to sample mean $\mathbf{0}$ and covariance matrices equal to identity matrices. Consequently, the Σ_i^{obs} for $\mathbf{y}_i^{\text{obs}}(\mathbf{x}_i^{\text{obs}})$ in (55.2) has to be normalized in the same way that the $\mathbf{y}_i^{\text{obs}}(\mathbf{x}_i^{\text{obs}})$ are.

A series of examples will now be presented, showing how to set up, run, and visualize the results using GPMSA. The first example will include tutorial detail; the subsequent examples illustrate alternatives and additional options in less detail. Specifically, this tutorial shows how to:

- set up a problem using GPMSA,
- calibrate model parameters using physical observations,
- make predictions for the physical system at new input settings
- assess the accuracy of the Gaussian process emulator used in the modeling.

3 Example 1: Ball Drop with Varying Radii

For the first example, the trial system will be the trajectory of balls of various radii R dropped from a tower, from heights of 5, 10, 15, and 20 m. Each dropped ball experiment produces vector output in the form of a height-time curve, i.e., a curve showing the time as function of the current height $t = t(h)$ of the ball at a set of measured heights h .

Here, these experiments will not actually be performed, but rather the system observations will be generated from

$$\frac{d^2h}{dt^2} = g - \frac{C}{R} \left(\frac{dh}{dt} \right)^2. \quad (55.11)$$

where g is the acceleration due to gravity, C is the coefficient of drag, and, as introduced above, R is the radius of the ball. For the purposes of the illustration of GPMSA, these will henceforth be referred to as system observations, although knowing their generating model will allow insight into the calibration process and results.

The system model for this example is given by

$$\frac{d^2h}{dt^2} = g - \frac{C}{R} \frac{dh}{dt} \quad (55.12)$$

that will be used as a specified radius R and a coefficient of drag C , producing a height-time curve giving the computed times t at some set of tower heights h (which are not necessarily the same heights used in the field experiments). The model is deterministic, so the same inputs (R, C) will always produce the same height-time curve.

Note that Eqs. 55.11 and 55.12 are differential equations that can be solved for height h as a function of time t and ball radius R . Observations will be the inverse of this: the data have time as the output recorded as a function of height and radius. An optimizer performs this inversion in MATLAB resulting in model output congruent with observations.

Insight into the physical process comes from Eq. 55.12 and the system observations collected at the known initial tower heights, and in analysis the true physical process, presumed unknown, described by Eq. 55.11. While Eq. 55.11 has a squared velocity term (dh/dt), Eq. 55.12 includes velocity as a linear term. Thus the system model is systematically biased from the system observations.

Acceleration due to gravity g is assumed known, but the coefficient of drag C is not and is the target of inference. That is, the goal is to find the distribution of parameters C that correspond to the simulator output being similar to the system observations. In other words, the model will be calibrated to the observations, by finding the posterior distribution on C that corresponds to the GPMSA statistical model fit to all available data.

The first step in preparing the emulator is to collect system observations and examples of the computational *simulator* that represents the system model over the feasible domain. System observations are ideally collected according to a careful design, but often they are opportunistically collected according to experimental constraints. As has been developed as a standard practice in the study of complex computer codes, a (space-filling) Latin hypercube (LH) design is used to efficiently collect these samples over the domain of the model parameters of interest, in this case (R, C) .

Here is a summary of the datasets, where n denotes the size of the experimental data set, m denotes the number of runs of the simulator, and n_η denotes the number of heights used by the simulator:

- Data are from $n = 3$ field experiments, one each for balls of radius $R \in \{0.1, 0.2, 0.4\}$ m. Each experiment produces a curve of drop times made of three or four height-time pairs. For the two smallest balls, the experimental heights are $h_e \in \{5, 10, 15, 20\}$ m. The largest has a drop time measured only from experimental heights $h_e \in \{5, 10, 15\}$ m (perhaps representing experimental or cost constraints in data collection)
- A scaled Latin hypercube design was used to select the $m = 25$ (R, C) pairs, shown in Fig. 55.1, at which to run the computer model. For each (R, C) pair in the design, the simulator produces a curve of $n_\eta = 16$ height-time pairs, where the simulation heights h_s are evenly spaced in $[1.5, 24]$ m.

3.1 How We Use the Gaussian Process Model

The Gaussian process model requires specification of inputs of two kinds:

1. $\mathbf{x} = (x_1, x_2, \dots, x_p)$ denotes inputs that are under the control of (or are observable by) the experimenter in both the field experiments and the simulator runs. In the example, there is $p = 1$ input of this type: $\mathbf{x} = x = R$, the radius of the ball being dropped.
2. $\boldsymbol{\theta} = (\theta_1, \theta_2, \dots, \theta_q)$ denotes inputs to the simulator that are needed to estimate using the experimental data. These $\boldsymbol{\theta}$ could correspond to real physical quantities or could be parameters of the simulator code. In the example, there is $q = 1$ input of this type: $\boldsymbol{\theta} = \theta = C$, the coefficient of drag.

Note that h will be used as an index of the multivariate response rather than a model parameter.

run	R	C

25	0.2676	0.0885

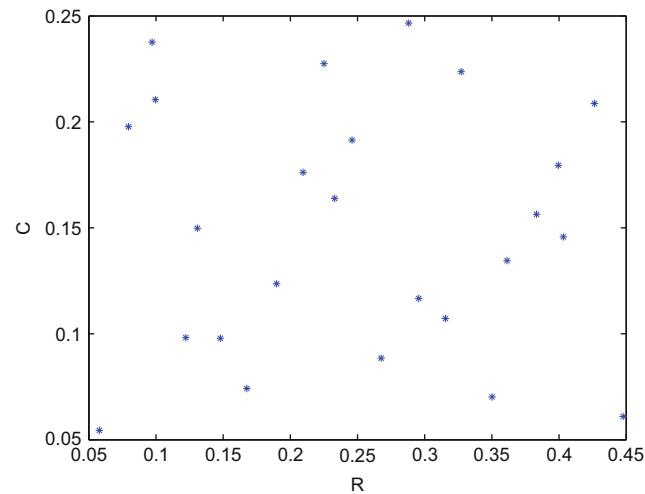

Fig. 55.1 *Left:* Scaled Latin hypercube design with $m = 25$ rows of (R, C) pairs. *Right:* A plot of the space-filling design

There are also the two types of output from system observations and the system model simulation:

1. $\mathbf{y}^{\text{obs}}(\mathbf{x})$, the system observations. For each experiment, \mathbf{y}^{obs} can be a scalar, or, as in the example, multivariate. For the tower experiments, \mathbf{y}^{obs} is a three or four element vector of times, one for each corresponding drop height.

Not all experiments produce output of the same size; in the tower experiment, there are four recorded times for the two smaller balls but only three for the largest ball.

2. $\mathbf{y}^{\text{sim}}(\mathbf{x}, \boldsymbol{\theta})$, the output of the simulation runs. \mathbf{y}^{sim} can be scalar or multivariate, corresponding to the observations. For the tower example, the simulator uses an evenly spaced grid of $n_\eta = 16$ heights and computes a time for each height on the grid, so $\mathbf{y}^{\text{sim}} = \mathbf{t}_{\text{sim}}$.

Unlike the observed data, the simulator output will always have the same size, i.e., the same number of computed times. The grid of 16 equally spaced heights between 1.5 and 24 will be the same from run to run.

3.2 Preparing the Data for Use by GPMSA

The GPMSA code is used to calibrate the statistical model parameters and to make predictions from the model. Before involving GPMSA, the user needs to read in the data, transform the inputs and outputs, compute basis functions for transforming the standardized outputs and the discrepancy term, and package the data into MATLAB structures that can be passed to GPMSA. These aspects are performed by the user because they fundamentally involve choices in the analysis. This will now be illustrated for the tower example.

3.2.1 Reading the Data

For this example, there are three data files for the observations and three for the simulator runs: one with the measured R_{obs} for the observations and corresponding inputs R_{sim} and C_{sim} for the simulator runs, one with the observations and corresponding simulator outputs (t_{obs} and t_{sim}), and one with the heights (\mathbf{h}_{obs} and \mathbf{h}_{sim}).

```
% read in the field (observed) data
>> Robs = textread('field.radius'); % radii R

Robs =
0.1000    0.2000    0.4000

>> hobs = textread('field.height'); % heights h
% hobs has all the tower heights;
% we only use the lowest 3 for the largest ball
hobs =
5      10      15      20

>> tobs = textread([dirstr 'field.dat']); % times t
% tobs has one column per experiment, one row per tower height.
% The NaN in experiment 3 indicates we didn't drop the largest
% ball from the highest tower.
tobs =
1.2180    1.1129    1.0611
2.0126    1.7225    1.5740
2.7942    2.2898    2.0186
3.5747    2.8462      NaN

>> tstd = textread([dirstr 'field.sd']); % sd of measured
times
```

```
tstd =
0.1000    0.1000    0.1000
0.1000    0.1000    0.1000
0.1000    0.1000    0.1000
0.1000    0.1000      NaN

% read in the design and the simulator output
>> [Rsim Csim] = textread('sim.design'); % design (R and C)
>> tsim = textread('sim.dat'); % times t
>> hsim = textread('sim.height'); % heights h

>> n = size(tobs, 2); % number of experiments
>> m = size(tsim, 2); % number of simulation runs
```

3.2.2 Transforming x and θ

The GPMSA code requires that the inputs x and θ lie in the interval $[0, 1]^{p+q}$ and responses that are $N(0,1)$. These transformations allow the selection of default prior distributions and MCMC proposal distributions. First the inputs to the simulator (R_{sim} and C_{sim}) are transformed, so they lie in $[0, 1]$; then the minimum and range of R_{sim} are used to transform the corresponding experiment's measurements (R_{obs}).

```
% transform the simulator inputs so each dimension lies in
[0, 1]
>> Rsimmin = min(Rsim);
>> Rsrang = range(Rsim);
>> Rsim01 = (Rsim - Rsimmin) / Rsrang; % transformed R

>> Csimmin = min(Csim);
>> Csrang = range(Csim);
>> Csim01 = (Csim - Csimmin) / Csrang; % transformed C

% transform the field experiment input the same way
>> Robs01 = (Robs - Rsimmin) / Rsrang; % transformed R
```

3.2.3 Transforming y^{sim} and y^{obs}

The GPMSA code requires that the outputs y have mean zero and variance one. As above, the output from the simulator (\mathbf{t}_{sim}) is transformed and then those values are used to transform the observations (\mathbf{t}_{obs}). Here the simulator output should have mean zero at each height h and an overall variance of one.

```
% standardize the simulator output
>> tsimmean = repmat(mean(tsim, 2), [1 m]); % the mean
simulator run
>> tsimStd = tsim - tsimmean; % make mean at each height zero
>> tsimsd = std(tsimStd(:)); % standard deviation of ALL
elements of tsimStd
>> tsimStd = tsimStd / tsimsd; % make overall variance one
```

Transformed observations should use the distribution of the simulator runs (`tsimmean` above) at each experimental height, but the output grid of the simulator doesn't match the experimental observation grid; i.e., the value of the mean simulator run at all the experimental heights is unknown. Instead, `tsimmean` will be interpolated in order to estimate the value of an assumed underlying mean function at each experimental height. This interpolated mean and the overall standard deviation of all elements of the simulator runs will be used `tsimsd`, to transform the observations.

Each multivariate observation may have its elements on a different grid (in this example, different number of heights at which the ball was dropped), so the observations cannot be in a matrix. Instead, the observation data are collected into a Matlab *struct* array called `yobs`.

```
>> for ii = 1:n
    % number of heights with measurements for experiment ii
    numhts = sum(~isnan(tobs(:, ii)));

    % do the interpolation and get the interpolated values at
    % the experimental heights
    yobs(ii).tobsmean = ...
        interp1(hsim, tsimmean(:, 1), hobs(1:numhts),
        'linear', 'extrap');

    % do the standardization
    yobs(ii).tobsStd = (tobs(1:numhts, ii) - yobs(ii)
        .tobsmean') / tsimsd;

    % for convenience, record some extra information in yobs
    yobs(ii).hobs = hobs(1:numhts); % the heights where
        measurements were taken
    yobs(ii).tobs = tobs(1:numhts, ii); % the untransformed
        output

    % now record the observation covariance matrix for the
    % measured times
    yobs(ii).Sigy = diag(tstd(1:numhts, ii).^2);
    % now the observation covariance for the standardized
    % observations
    yobs(ii).SigyStd = yobs(ii).Sigy ./ (tsimsd.^2);
end
```

`yobs(ii).Sigy` holds the covariance matrix for the observations of experiment `ii`. If not specified, it is given a default constant value. `Sigy` is scaled by a parameter calibrated in the GPMSA model that by default is free to vary. The prior specification for this measurement precision scale factor can be changed to ensure that measurement error stays close to the specified value.

3.2.4 Computing the K Matrix for Transforming \mathbf{y}^{sim} and \mathbf{y}^{obs}

As discussed in the model overview, multivariate observations and responses are modeled with a linear basis. The use of *principal components*, or scaled

eigenvectors, computed by the singular value decomposition of the simulator output, is demonstrated. While principal components are commonly used for this, any orthogonal linear transformation will work. For a compact representation, $p_u < m$ basis functions that capture most of the variation in the simulation runs are retained. The choice of how many principal components to use is a trade-off, considering the variability represented by the projection and emulator performance. Note that p_u , the number of basis elements, should not be confused with p , the dimension of the input x .

```
>> pu = 2; % number of basis components to keep
>> [U, S, V] = svd(tsimStd, 0); % compute the SVD
>> Ksim = U(:, 1:pu) * S(1:pu, 1:pu) ./ sqrt(m); % construct
    the basis components
```

This K_{sim} matrix has $n_\eta = 16$ rows (one for each height in the grid used by the simulator) and $p_u = 2$ columns. A corresponding matrix K_{obs} for each experiment in the field data is computed by interpolating the K_{sim} components onto the observation data locations.

```
>> for ii = 1:n
    yobs(ii).Kobs = zeros(length(yobs(ii).tobsStd), pu); %
    allocate space

    % compute each basis component
    for jj = 1:pu
        % do the interpolation and get the interpolated values
        % at the experimental heights
        yobs(ii).Kobs(:, jj) = ...
            interp1(hsim, Ksim(:, jj), yobs(ii).hobs,
            'linear', 'extrap');
    end
end
```

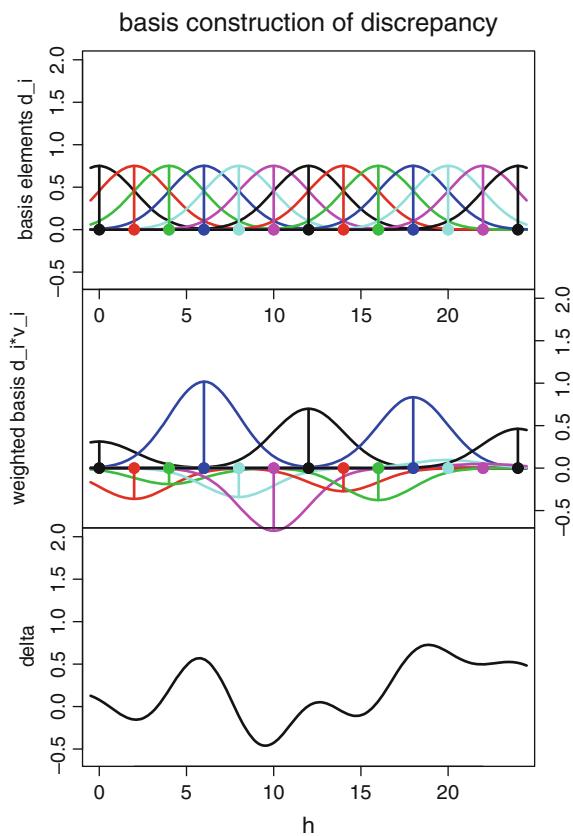

3.2.5 Specifying the D Matrix for Modeling the Discrepancy Term

The discrepancy term $\delta(x)$ models a systematic bias between the simulator (at the best setting for the calibration parameter θ) and is represented as a GP over the x space. In the example, for a given ball radius x , $\delta(x)$ is a function over the possible drop heights $1.5 \leq h \leq 24$ m. The discrepancy is approximated by a linear basis with similar motivation to the emulator response. The discrepancy basis is selected to allow a prior estimated required flexibility. Its form is ultimately problem dependent, but in many problems a reasonable form is the smooth constraint of a normal kernel basis.

Over $h \in [1.5, 24]$, $\delta(x)$ is represented as a linear combination of basis functions

$$\delta(x) = \sum_{i=1}^{p_v} \mathbf{d}_i v_i(x)$$

Fig. 55.2 Basis construction of $\delta(x)$ for the ball dropping example. Here a model for $\delta(x)$ – the discrepancy between the calibrated simulator and experimental observations at x – is modeled by a linear combination of normal kernels. *Top:* 13 normal kernels with $sd = 2$ are placed at heights $h = 0, 2, \dots, 24$. Each of the 13 columns in D corresponds to one of these basis kernels. *Middle:* each basis kernel is multiplied by a random normal variate $v_i(x)$ which is estimated in GPMSA, with dependence over the x -space, using the simulation output and experimental data. *Bottom:* the discrepancy is set to the sum of these weighted kernels, producing a prior realization for $\delta(x)$. In vector form, this is given by $Dv(x)$, where $v(x)$ is the 13 element vector of weights corresponding to input condition x

where \mathbf{d}_i are vectors over the output support h . For this example, the $d_i(\cdot)$'s are taken to be normal kernels with an sd of 2. The kernels are centered at a grid of 13 heights equally spaced between 0 and 24. This model is depicted in Fig. 55.2.

For each experiment, we construct the matrix D_{obs} whose rows correspond to the observed drop heights in the experiment, and whose columns correspond to the $p_v = 13$ basis elements. For analysis purposes, the matrix D_{sim} which has rows corresponding to the h -space is also constructed:

```
% -- D basis --
>> Dgrid = 0:2:max(hsim); % locations on which the kernels
    are centered
>> Dwidth = 2; % width of each kernel
>> pv = length(Dgrid); % number of kernels

% Compute the kernel function map, for each kernel
% Designate space for the Dsim matrix,
% one row per simulated height, one column per kernel
% (consider making the grid of heights much denser for
    plotting)
```

```

>> Dsim = zeros(length(hsim), pv);

% designate space for the Dobs matrix for each experiment,
% one row per experimental height, one column per kernel
>> for ii = 1:n
    yobs(ii).Dobs = zeros(length(yobs(ii).tobsStd), pv);
end

% create each kernel
>> for jj = 1:pv
    % first create kernel jj for each experiment
    for ii = 1:n
        % normpdf computes the value of a Gaussian with mean
        % Dgrid(jj) and variance Dwidth at each element of hobs
        yobs(ii).Dobs(:, jj) = normpdf(yobs(ii).hobs,
            Dgrid(jj), Dwidth);
    end
    % now create kernel jj for the simulations
    Dsim(:, jj) = normpdf(hsim, Dgrid(jj), Dwidth);
end

% normalize the basis elements of D so that the marginal
% variance of delta is about 1
>> Dmax = max(max(Dsim * Dsim'));
>> Dsim = Dsim / sqrt(Dmax);
>> for ii = 1:n
    yobs(ii).Dobs = yobs(ii).Dobs / sqrt(Dmax);
end

```

The D matrices are normalized so that the prior marginal variance for $\delta(x)$ is approximately one when $\lambda_v = 1$.

For normal basis kernels, a rule of thumb is to make the spacing one standard deviation between adjacent kernels to ensure that no sparsity effects appear, while limiting the number of parameters [2].

3.2.6 Package all the Pieces

Having now completed the specification and transformation of required data, it can be collected into a single Matlab structure to be given to GPMSA for model setup. This structure, here called `data`, will contain a field for the simulated data (`simData`) and another for the field data (`obsData`). For both fields, we'll include information that's required by the model as well as extra information (stored in a subfield called `orig`) that will later make it easier for us to return the output to the native scale and to perform analysis and plotting.

```

% required fields
>> simData.x = [Rsim01 Csim01]; % our design (standardized)
>> simData.yStd = tsimStd; % output, standardized
>> simData.Ksim = Ksim;

% extra fields: original data and transform stuff
>> simData.orig.y = tsim;
>> simData.orig.ymean = tsimmmean;

```

```
>> simData.orig.ysd = tsimsd;
>> simData.orig.Dsim = Dsim;
>> simData.orig.t = hsim;
>> simData.orig.xorig = [Rsim Csim]; % original scale for
simulated R, C
```

For the observed data, each experiment is packaged separately since each could have a different length.

```
% loop over experiments
>> for ii = 1:n
    % required fields
    obsData(ii).x = Robs01(ii);
    obsData(ii).yStd = yobs(ii).tobsStd;
    obsData(ii).Kobs = yobs(ii).Kobs;
    obsData(ii).Dobs = yobs(ii).Dobs;
    obsData(ii).Sigy = yobs(ii).Sigy./(tsimsd.^2);

    % extra fields: original data
    obsData(ii).orig.y = yobs(ii).tobs;
    obsData(ii).orig.ymean = yobs(ii).tobsmean;
    obsData(ii).orig.t = yobs(ii).hobs;
end
```

Now we'll put `simData` and `obsData` in a structure called `data` that can be passed to GPMSA.

```
>> data.simData = simData;
>> data.obsData = obsData;
```

3.3 Model Initialization and MCMC

Now that the user setup of data has been completed, the model can be initialized and the posterior distributions of parameters sampled via Markov chain Monte Carlo (MCMC). The code in this section is in the MATLAB file `runmcmc.m`.

`readdata.m` implements the code previously detailed.

```
>> towerdat = readdata()

towerdat =

    simData: [1x1 struct]
    obsData: [1x3 struct]
```

`setupModel()` performs the initial setup of the model, taking the `obsData` and `simData` fields from `towerdat` and returning a structure `pout` (for ‘parameter output’).

```
>> pout = setupModel(towerdat.obsData, towerdat.simData)
SetupModel: Determined data sizes as follows:
```

```

SetupModel: n= 3 (number of observed data)
SetupModel: m= 25 (number of simulated data)
SetupModel: p= 1 (number of parameters known for
observations)
SetupModel: q= 1 (number of additional simulation inputs
(to calibrate))
SetupModel: pu= 2 (response dimension (transformed))
SetupModel: pv= 13 (discrepancy dimension (transformed))

pout =

```

data:	[1x1 struct]

simData:	[1x1 struct]
pvals:	[]

Fields of `pout` include the simulated and observed data transformed by the K and D matrices (`data`), initial values for the parameters of the posterior induced by the model in GPMSA (`model`), priors on the model parameters (`priors`), MCMC controls (e.g., step sizes) in (`mcmc`), and the `obsData` and `simData` structures that were given in the call to `setupModel()`. It also includes a placeholder for the `pvals` field which will hold the MCMC draws. MCMC will be used to get draws from the parameters' posterior distribution with the GPMSA function `gpmmcmc()`.

1. Before performing MCMC, and as an optional step, GPMSA includes a utility `stepsize()` to optimize the MCMC proposal widths, or “step sizes.” Default settings may provide reasonable, although not optimal, performance. The step size estimation procedure is taken from Graves [1].

Computation of the step size starts by collecting MCMC proposal acceptance statistics at a number of possible values (`levels`), using estimates constructed from a number of MCMC draws.

```

>> nsamp = 100; % number of draws to sample

>> nlev = 13; % number of candidate levels used for step
size estimation

>> pout=stepsize(pout,nsamp,nlev)
Setting up structures for stepsize statistics collect ...
Collecting stepsize acceptance stats ...
Drawing 100 samples (nBurn) over 13 levels (nLev)
Started timed counter, vals 1 -> 1300
963..20.29sec
Computing optimal step sizes ...
Step size assignment complete.

```

```
pout =
    data: [1x1 struct]
    model: [1x1 struct]
    priors: [1x1 struct]
    mcmc: [1x1 struct]
    obsData: [1x3 struct]
    simData: [1x1 struct]
    pvals: [1x1300 struct]
```

The `pvals` object holds the result of the MCMC. Here it records the 1300 draws from the posterior distribution for each parameter produced by the MCMC updates carried out so far. In addition to the parameter values at each of the 1300 MCMC steps, the corresponding values for the log likelihood, the log prior, and the log posterior are also recorded. The draws used for step size estimation are not valid samples of the posterior distribution and should not be used in prediction or analysis; they could be discarded at this point, setting `pout.pvals` to an empty matrix.

Here are the updated MCMC settings:

```
>> pout.mcmc

ans =
    thetaWidth: 0.2668
    rhoUWidth: [0.5341 0.4523 2.6462 1.7655]
    rhoVWidth: 0.4656
    lamVzWidth: 433.1763
    lamUzWidth: [0.8726 1.9799]
    lamWsWidth: [1.6396e+03 4.0254e+03]
    lamWosWidth: 2.0908e+04
    lamOsWidth: 3.1539e+04
    pvars: {1x11 cell}
    svars: {'theta' 'betaV' 'betaU' 'lamVz' 'lamUz'
            'lamWs' 'lamWos' 'lamOs'}
    svarSize: [1 1 4 1 2 2 1 1]
    wvars: {1x8 cell}
```

Note that like any MCMC procedure, the values presented here are subject to random variability and will not replicate exactly.

2. Now MCMC draws (realizations) can be generated efficiently from the parameters' joint posterior distribution. These will be added to the `pvals` field of `pout`.

```
>> nmcmc = 10000; % number of draws we want
>> pout = gpmmcmc(pout, nmcmc,'step',1)
Started timed counter, vals 1 -> 10000
    787..1577..2363..3158..3923..4675..5409..6152..6877..
    7614.. 1.7 min, 0.5 min remain
    8344..9077..9817..2min:12.57sec
```

```
>> pout =
    data: [1x1 struct]
    model: [1x1 struct]
    priors: [1x1 struct]
    mcmc: [1x1 struct]
    obsData: [1x3 struct]
    simData: [1x1 struct]
    pvals: [1x11300 struct]
```

There are now 10,000 additional values recorded for each parameter in the `pout` object. These were produced by the 10,000 MCMC iterations carried out by the last call to `gpmmcmc()`.

At this point, the system model parameters and the GPMSA parameters have been calibrated by sampling the joint posterior distribution.

3.4 Examining the Estimated Parameters' Posterior Distribution

Since the model inputs and data are transformed, the posterior sampling carried out in GPMSA corresponds to this transformed scale. Some model diagnostics (e.g., the GP's $u(x, t)$, $v(x)$, precision parameters λ) are more interpretable on their transformed scale, while others (e.g., predictions, model parameters) are more usefully viewed on their original, or native, scale. Hence some of the plotting routines covered here use the transformed scale for showing output, while others use the native scale.

3.4.1 Traces of the MCMC Draws

The GPMSA code function `showPvals()` will produce traces of the MCMC draws for the parameters in the model as shown in Fig. 55.3.

```
>> showPvals(pout.pvals);
Processing pval struct from index 1 to 11300
    theta:   mean           s.d.
      1:       0.3513        0.04313
    betaV:   mean           s.d.
      1:       0.767          0.9483
    betaU:   mean           s.d.
      1:       8.628          2.38
      2:       0.6311         0.3162
      3:       4.365          2.52
      4:       3.466          2.473
    lamVz:   mean           s.d.
      1:       72.42          63.21
    lamUz:   mean           s.d.
      1:       0.4518          0.1354
      2:       0.8458          0.3108
    lamWs:   mean           s.d.
```

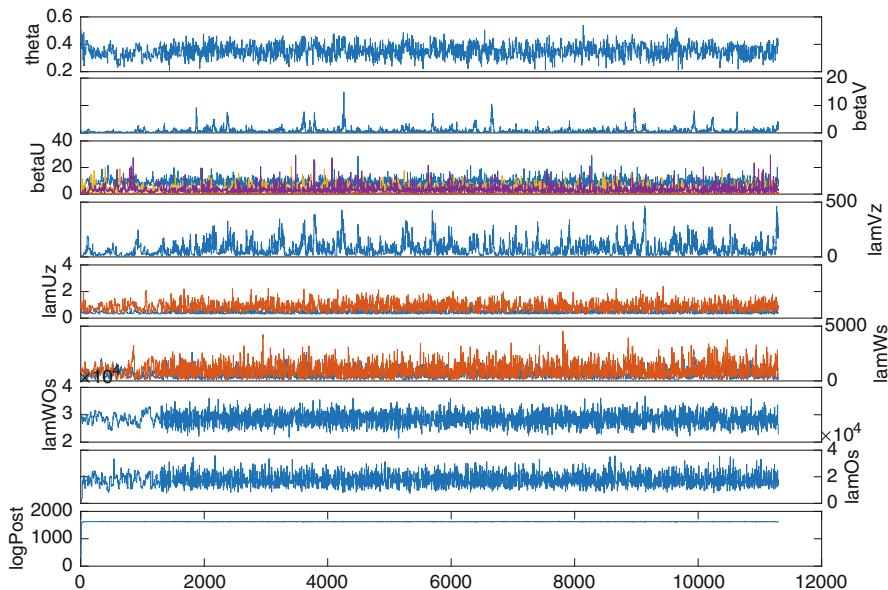

Fig. 55.3 Traces of the MCMC draws of the parameters in `pout.pvals` as generated by the `showPvals()` function

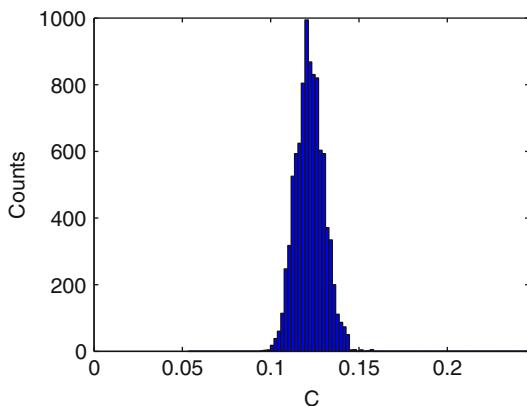

1:	546.2	326.6
2:	963.7	572.3
lamWo:	mean	s.d.
1:	2.846e+04	2095
lamOs:	mean	s.d.
1:	1.779e+04	4275
logPost:	mean	s.d.
1:	1624	28.9

Note that we're calling `showPvals()` with *all* the draws in `pout.pvals`, not just the ones specified by the index `ip` defined above. This includes the draws used for burn in and step size estimation. The resulting plot is shown in Fig. 55.3. The figure shows qualitatively that the MCMC chains of all the parameters after 2000 draws, skipping the step size data collection phase and allowing for a transient, appear mixed and stationary. Note that a rerunning of this MCMC chain will give slightly different values.

3.4.2 Posterior Distribution of C

Figure 55.4 shows the histogram of the MCMC draws from the posterior distribution of the object of calibration C . Because all 10,000 posterior draws may be excessive for plotting or further computation, a subset of 500 equally spaced draws are taken.

Fig. 55.4 Histogram of draws from the posterior distribution of C , on the native scale

```
>> from = 2000; % start getting realizations at this index
>> to = length(pout.pvals); % continue to the last realization
>> thismany = 500; % grab this many evenly spaced realizations
>> ip = round(linspace(from, to, thismany)); % indices of the
pvals to use
```

With the exception of the `showPvals()` function, the plotting functions in this section are not part of the core GPMSA code package, but the example `.m` files used are available as associated examples to GPMSA. The posterior distribution of the target model parameters is θ in the output from `showPvals`.

```
>> thetaphisthist(pout, 2000:11300);
```

Note that the realizations of the standardized parameter θ were scaled and shifted to give realizations of C on its native scale.

3.5 Assessing Emulator Adequacy

It is important to examine diagnostics to understand the quality of the emulator in reproducing the simulator output at new, untried settings. The GPMSA code produces several diagnostic plots, a few of which are displayed here. The following plots are useful in assessing the quality of the emulator fit.

3.5.1 Principal Components

Figure 55.5 shows the $p_u = 2$ principal components used in this example. Note that the vertical scale for the second principal component is much smaller than that of the first; this confirms that most of the variation in the data is being captured by the first principal component. The left graphic on this plot was made as follows:

```
>> plot(pout.simData.orig.h,pout.simData.Ksim);
```

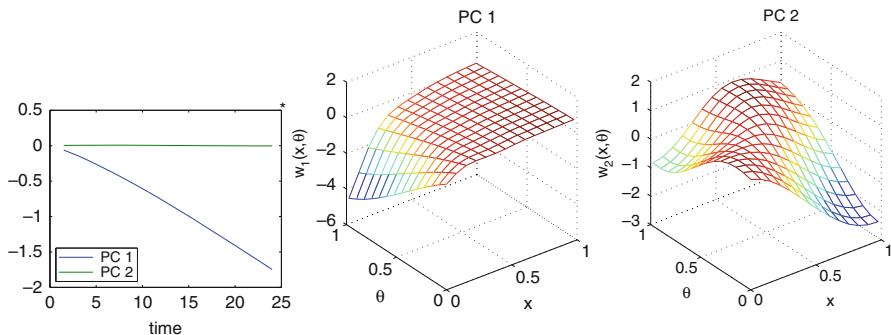

Fig. 55.5 *Left:* The $p_u = 2$ principal components used in modeling this example. *Middle and right:* posterior mean of the Gaussian processes of the weight functions for the two principal components. The weights $w(x, \theta)$ are used to make the predictions

The right two graphs on Fig. 55.5 show the posterior mean of the Gaussian process of the weight functions for the two principal component for the domain of (x, θ) . The weight $w(x, \theta)$ at each (x, θ) pair is used to make the predictions from the model. The code `PCresponsesurf.m` calls the function `gPred()` to make predictions at each grid point and generates the plot as follows:

```
>> PCresponsesurf(pout, ip);
```

3.5.2 Parameters in the Gaussian Process Fit

Using the MCMC draws of the spatial dependence parameters β , $\rho = \exp\{-\beta/4\}$ can be calculated to show the values on a bounded scale. The value of ρ gives us information about the dependence of the simulation output on each input parameter x and θ . Figure 55.6 shows box plots of the posterior draws for the ρ for each x and θ and for each principal component. The figure was generated using a subset of the realizations:

```
>> rhoboxplots(pout, ip);
```

When ρ is near 1 for a particular x or θ principal component, it suggests that particular component of the simulator output is linear in that dimension (the case of exactly 1 is degenerate; theoretically it would be constant). As ρ goes smaller, nonlinear activity is associated with that input. The outputs will vary smoothly with the inputs, with smaller values of ρ indicating less smoothness.

As ρ becomes smaller, the modeled response is increasingly flexible. Eventually, this indicates that the emulator is overfitting the data, interpolating each point instead of fitting a trend. This suggests predictions from the model are suspect. Thus if any of the box plots in Fig. 55.6 shows values that are all close to zero, the model is suspect. Cross-validation diagnostics should be considered before accepting predictions from the model, especially in that case. Correlation parameter(s) for the discrepancy process can be similarly assessed.

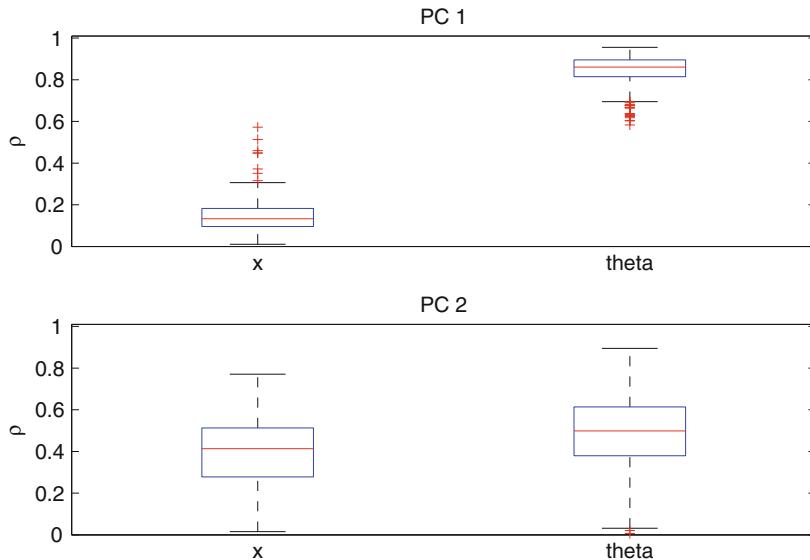

Fig. 55.6 Box plots of $\rho = \exp\{-\beta/4\}$ for the draws of β associated with x and θ for each principal component

3.5.3 Cross-Validation of Simulation Response

The most direct test of the emulator's ability to reproduce the results of the simulator is to compare the emulator predictions with actual simulations for a relevant holdout set. If available, such tests will be very informative. If a holdout test set is not available, one option is to take a cross-validation approach [4].

For each run i of the simulator, a model excluding run i is constructed and then run i predicted as holdout. This allows us to look for trends in the quality of predictions as a function of the inputs R_{sim} and C_{sim} . Figure 55.7 shows the results sorted by R_{sim} . This plot, among others, was produced by the function call `holdoutpreds(pout, ip)`. One could also plot the residuals for a closer look. Here the cross-validated holdout predictions are less accurate when R is small. As expected, larger errors are associated with design points at the edge of the design (see Fig. 55.1) where there is lower neighborhood constraint. Holding out data from the design in a cross-validation fashion will be an overestimate of the expected error of predictions using all constraints.

3.5.4 Conditional Response Sensitivity

An alternative way to understand how the simulator responds to changes in the inputs is to plot the output while varying each input over its range from high to low, at fixed settings of the other parameters. Figure 55.8 shows how the drop time as a function of height varies as x and θ are varied from their low to high values. Here the other input is held at its midpoint to produce this plot. This plot

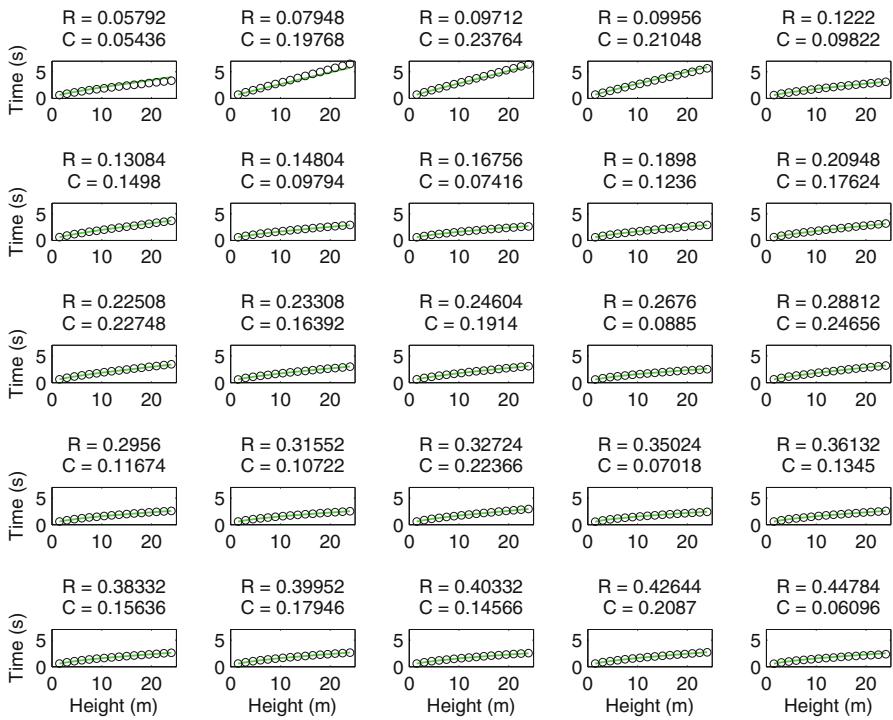

Fig. 55.7 Holdout predictions, sorted by the value of R_{sim} . The black circles are actual simulations and the green lines are emulations

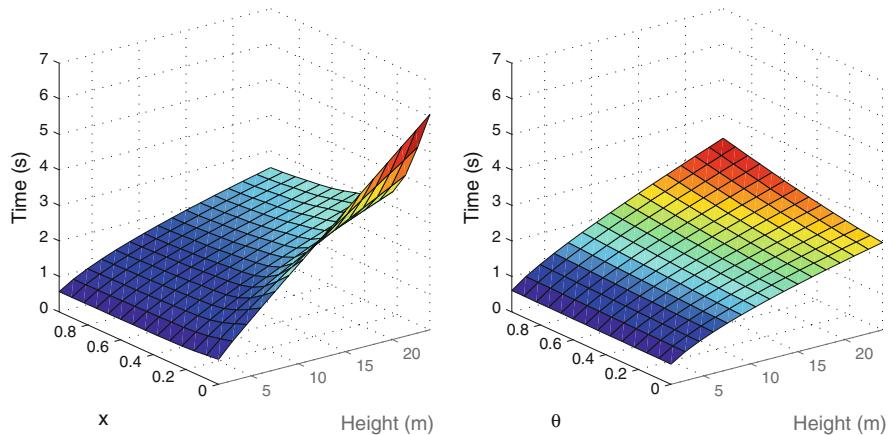

Fig. 55.8 Surface plots showing sensitivity to x (left) and to θ (right)

also highlights the sensitivity of the simulator response to very low values of the standardized ball radius x . Figure 55.8 is generated by the following function call `sensitivities(pout, ip)`.

3.6 System Predictions

Once we're satisfied that the emulator is adequately reproducing the simulator output, GPMSA can produce predictions for the actual system at new experimental conditions \mathbf{x} . Below, the MCMC samples are used to produce predictions with uncertainty.

The system prediction uses the posterior uncertainty for θ , along with the additional GPMSA model parameters, to produce uncertainties for a new experimental outcome \mathbf{y}^* at experimental conditions \mathbf{x}^*

$$\mathbf{y}^* = \eta(\mathbf{x}^*, \theta) + \delta(\mathbf{x}^*) + \mathbf{e}^*.$$

Uncertainties in this prediction come partly from variation in the posterior samples collected. Posterior draws of \mathbf{y}^* use the samples in `pout`. This is carried out in the function `etasdeltas.m`. This produces realizations of the calibrated simulator $\eta(\mathbf{x}^*, \theta)$, the discrepancy $\delta(\mathbf{x}^*)$, which compose the predicted drop time \mathbf{y}^* as a function of height. Making many predictions, for three different balls denoted whose

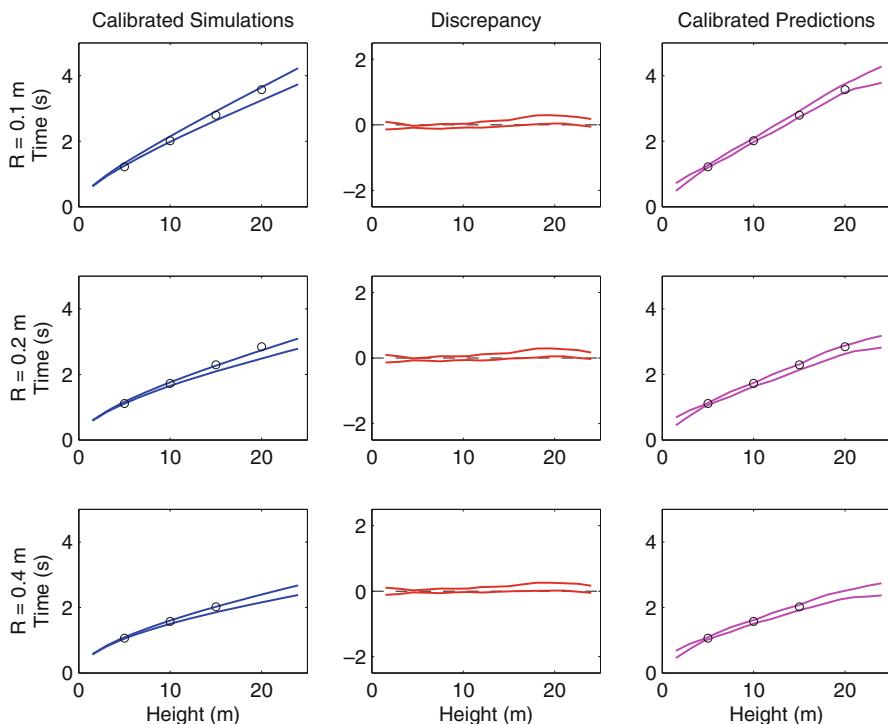

Fig. 55.9 Circles show the field data, and colored lines indicate the 5th and 95th percentiles. Each row is a different ball size. *Left column:* Calibrated simulations. *Center:* Discrepancy term (dashed line shows where zero discrepancy would be). *Right:* Calibrated predictions = calibrated simulations + the discrepancy term

radii are denoted by \mathbf{x}^* , allows the estimate of mean and quantile statistics, as shown in Fig. 55.9. The left column shows the calibrated simulations; the center column shows the discrepancy between the experimental data (circles) and the calibrated simulations; and the right column shows the calibrated predictions made after adding the discrepancy term to the calibrated simulation.

3.7 The pout Object

The ball dropping example has produced `pout` which holds a variety of data, which may in some cases be useful for diagnostics, to follow through the function of calibrating the GPMSA statistical model. The preprocessing function `readdata()` constructs `obsData` and `simData`. `obsData` holds information regarding the physical observation data, while `simData` holds information regarding the simulation output, including the basis representations for the multivariate simulation output and the discrepancy basis.

The function `setupModel()` creates `data`, `model`, `priors`, and `mcmc`. It also creates an empty object `pvals`, which will later hold the MCMC output produced by `gpmcmc()`. Hence the posterior samples for the various parameters will be kept in the `pvals` object. The `data` object holds transformations of the simulation and observed data that are required for likelihood evaluations used in the MCMC algorithm. There should be no need to modify this data, although if unexpected behavior occurs, it may be useful to validate the problem setup by verifying the expected transformations are in place. The `model` object holds all of the additional objects required to evaluate the likelihood and prior, as well as saved partial computations to speed computation. The current value of the MCMC chain is stored here. The `prior` object holds the prior specification for each of the model parameters. This includes upper and lower bounds for each parameter, the name of the log-prior evaluation function, and the parameters. Nonstandard or user-defined priors can be implemented by changing the prior functions and parameters. Finally, the `MCMC` object holds information required to carry out the MCMC sampling, including step sizes used in the Metropolis-Hastings updates for each parameter, indicators for sampling, and the parameters to be logged in `pvals`. These values are modified when the step size estimation is carried out in `gpmcmc()`.

Further descriptions of these fields are provided in the reference manual.

4 Example 2: Ball Drop with Different Radii and Densities

The second example follows a similar framework to Example 1; however, now consider different types of balls that have different densities. In this scenario, three different types of balls, bowling ball, basketball, and a baseball, are again dropped from a tower. Each type of ball has a unique radius R and density ρ . The heights that the balls are dropped range from 10 to 60 m; however, the basketball and baseball are only dropped from 20, 40, and 60 m. The bowling ball is dropped from 10, 20, 30, 40, 50, and 60 m.

The experiments are not actually performed, but the system observations are generated as noisy realizations from

$$\frac{d^2h}{dt^2} = g - \frac{C}{2} \frac{3\rho_{\text{air}}}{4R_{\text{ball}}\rho_{\text{ball}}} \left(\frac{dh}{dt} \right)^2, \quad (55.13)$$

where ρ_{air} is the density of air, R_{ball} is the radius of the ball, ρ_{ball} is the density of the ball, and g and C are the coefficient of gravity and the coefficient of drag as defined in Eq. 55.11. The system model for this example is given by Eq. 55.13. In this example, the acceleration due to gravity, g , and the coefficient of drag, C , are both considered unknown and the goal is to jointly estimate these parameters.

Again the emulator is prepared to collect system observations via a computational simulator representing the system model. In this framework, 20 simulations are conducted for each ball type, which corresponds to a radius-density pair. The radius-density pairs are selected using a space filling Latin hypercube design.

Here is a summary of the data used in this example:

- There are n_i field experiments for each ball. The baseball, $R = 0.0380 \text{ m}$, $\rho_{\text{ball}} = 626 \text{ kg/m}^3$, is dropped from three heights $\{20, 40, 60\} \text{ m}$. The basketball, $R = 0.1200 \text{ m}$, $\rho_{\text{ball}} = 84 \text{ kg/m}^3$, is dropped from three heights $\{20, 40, 60\} \text{ m}$. The bowling ball, $R = 0.1100$ and $\rho_{\text{ball}} = 1304 \text{ kg/m}^3$, is dropped from six heights $\{10, 20, 30, 40, 50, 60\} \text{ m}$.
- A space filling Latin hypercube design selects the $m = 20$ (C, g) pairs, shown in Fig. 55.10, at which to run the computer model. For each (C, g) pair in the design, the simulator produces a curve of $n = 100$ height-time pairs, where the simulation heights are evenly spaced in $[0, 99] \text{ m}$. Each of these 20 parameter settings are run for each of the three balls described above and a softball with $R = 0.0485$ and $\rho_{\text{ball}} = 380.9$.

4.1 How We Use the Gaussian Process Model

1. $\mathbf{x} = (x_1, x_2, \dots, x_p)$ denotes inputs that are under the control of (or are observable by) the experimenter in both the field experiments and the simulator runs. In this example, there are $p = 2$ inputs of this type: $\mathbf{x} = \{R, \rho\}$, the radius and density of the ball being dropped.
2. $\boldsymbol{\theta} = (\theta_1, \theta_2, \dots, \theta_q)$ denotes inputs to the simulator to be estimated using the experimental data. In this example, there are $q = 2$ inputs of this type: $\boldsymbol{\theta} = \{C, g\}$, the coefficients of drag and gravity.

There are also the two types of output from system observations and the system model simulation:

run	C	g
1	1.3368	10.9474
2	0.4842	9.4737
3	0.7684	12.0000
4	0.6737	8.2105
5	0.9579	10.3158
6	1.1474	8.4211
7	0.3895	11.3684
8	1.9053	11.1579
9	2.0000	9.8947
10	1.6211	9.2632
11	0.5789	10.7368
12	0.2000	10.1053
13	0.2947	8.8421
14	1.8105	8.6316
15	1.0526	11.5790
16	1.2421	9.6842
17	1.5263	11.7895
18	1.4316	8.0000
19	1.7158	10.5263
20	0.8632	9.0526

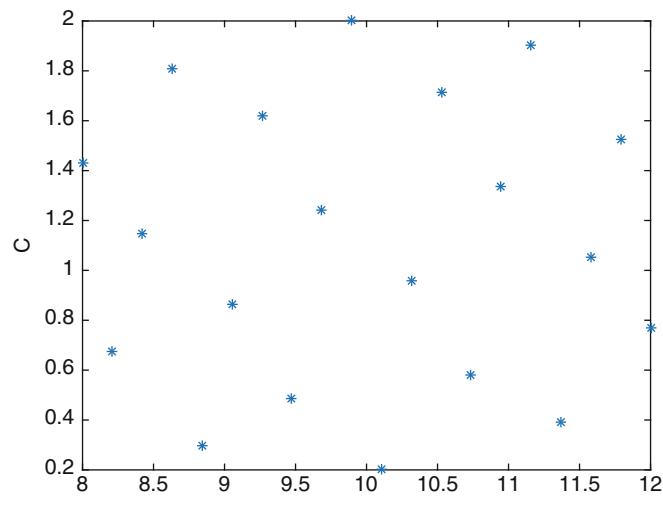

Fig. 55.10 Left: Scaled Latin hypercube design with $m = 20$ rows of (C, g) pairs. Right: A plot of the design

1. $\mathbf{y}^{\text{obs}}(\mathbf{x})$, the system observations. For the synthetic tower experiments, \mathbf{y}^{obs} is a 3- or 6-element vector of times, one time for each corresponding drop height for a given ball.

Not all experiments produce output of the same size; in the tower experiment, there are six recorded times for the bowling ball, but only three for the baseball and basketball.

2. $\mathbf{y}^{\text{sim}}(\mathbf{x}, \boldsymbol{\theta})$, the output of the simulation runs. For the tower example, the simulator uses an evenly spaced grid of $n_\eta = 100$ heights (up to 100 m) and computes a time for each height on the grid, so $\mathbf{y}^{\text{sim}} = \mathbf{t}_{\text{sim}}$.

Unlike the observed data, the simulator output will always have the same size, i.e., the same number of computed times. The grid of 100 equally spaced heights between 0 and 100 m will be the same from run to run.

4.2 Preparing the Data for Use by GPMSA

Before using the GPMSA code, the data are read and transformed. Much of the material here overlaps with Example 1 and will not be explained here in as much detail.

4.2.1 Reading the Data

This example uses one dataset for the tower experiments and three datasets for the simulated data. Note the dataset corresponding the tower experiments includes softball drops, but this information is not used in this experiment.

```
>> % read in the field data
>> fielddat = textread([dirstr 'fieldDat15x6gparam.txt']);
% R_ball rho_air rho_ball height time sd(time); 1st 3 are
    basketball drops,
% 2nd 3 are baseball drops, 3rd 3 are bowling ball drops.
>> fielddat

fielddat =
    .1200    1.1840    84.0000    20    2.2903    0.10
    .1200    1.1840    84.0000    40    3.2610    0.10
    .1200    1.1840    84.0000    60    4.3482    0.10
    .0380    1.1840   626.0000    20    2.0149    0.10
    .0380    1.1840   626.0000    40    2.7790    0.10
    .0380    1.1840   626.0000    60    4.0438    0.10
    .1100    1.1840  1304.0000    10    1.4650    0.10
    .1100    1.1840  1304.0000    20    1.9566    0.10
    .1100    1.1840  1304.0000    30    2.6336    0.10
    .1100    1.1840  1304.0000    40    2.7205    0.10
    .1100    1.1840  1304.0000    50    3.2327    0.10
    .1100    1.1840  1304.0000    60    3.5393    0.10

>> % read in the simulated data and the design
>> tsim = textread([dirstr 'sims101x80Cg.txt']); % times
>> hsim = textread([dirstr 'simHeights101x1']); % heights
>> % design (x=R, rho_ball and theta=C g)
>> designNative = textread([dirstr 'desNative80x4Cg.txt']);
>> designNative(1:5,:)

ans =
    0.1200    84.0000    1.3368    10.9474
    0.1200    84.0000    0.4842     9.4737
    0.1200    84.0000    0.7684    12.0000
    0.1200    84.0000    0.6737     8.2105
    0.1200    84.0000    0.9579    10.3158

>> m = size(tsim, 2); % number of simulation runs
>> n = 3;
>> iball = [1 1 1 2 2 2 3 3 3 3 3]; % index of balls for
    field data
>> nmeas = [3 3 6]; % number of measurements per ball
>> cumnmeas = [0 cumsum(nmeas)];
```

4.2.2 Transforming $x, \theta, y^{\text{sim}}$; and y^{obs}

Again the inputs \mathbf{x} and $\boldsymbol{\theta}$ as well as y^{sim} and y^{obs} need to be standardized according to the same procedure as Experiment 1.

```
>> simData.orig.designNative = designNative;
>> simData.orig.colmax = max(designNative);
```

```

>> simData.orig.colmin = min(designNative);

>> % standardize the inputs to the simulator (x and theta) to
    lie in [0, 1]
>> dmin = simData.orig.colmin;
>> dmax = simData.orig.colmax;
>> drange = dmax-dmin;

>> % standardize the simulator output to have mean zero at
    each height and an
>> % overall variance of one
>> tsimmean = repmat(mean(tsim,2), [1 m]);
>> tsimStd = tsim - tsimmean; % makes mean at each height zero
>> tsimsd = std(tsimStd(:));
>> tsimStd = tsimStd / tsimsd; % makes overall variance one
    (but not at each height)

% standardize the field data.
>> for ii = 1:n
    numhts = nmeas(ii); % how many heights have measurements
    for experiment ii
        yobs(ii).y = fielddat((1+cumnmeas(ii)): (cumnmeas(ii+1)),5);
        yobs(ii).h = fielddat((1+cumnmeas(ii)): (cumnmeas(ii+1)),4);
        yobs(ii).xnative = fielddat(cumnmeas(ii+1), [1 3]);
        yobs(ii).x = (yobs(ii).xnative - dmin(1:2))./drange(1:2);
        yobs(ii).ymean = interp1(hsim, tsimmean(:,1), yobs(ii).h,
            'linear', 'extrap');
        yobs(ii).Sigm = diag(fielddat((1+cumnmeas(ii)):
            (cumnmeas(ii+1)),6).^2);
        yobs(ii).yStd = (yobs(ii).y - yobs(ii).ymean)/tsimsd;
    end

```

4.2.3 Computing the K Basis for Transforming y^{sim} and y^{obs}

Again the multivariate observations and responses are modeled with a linear basis using the K basis. For a compact representation, $p_u < m$ basis functions capture most of the variation in the simulation runs. The choice of how many principal components to use is an issue of experimentation with the variability captured and emulator performance. In this example, three basis functions are used.

```

>> pu = 3; % number of basis components to keep
>> [U, S, V] = svd(tsimStd, 0);
>> Ksim = U(:, 1:pu) * S(1:pu, 1:pu) ./ sqrt(m);
% the pu curves capture variation across simulation runs

```

This K_{sim} matrix of basis elements has $n_\eta = 101$ rows (one for each height in the grid used by the simulator) and $p_u = 3$ columns. A corresponding basis matrix K_{obs} for each experiment in the field data is computed by interpolating the K_{sim} components onto the observation data locations.

```

% now interpolate between height grids to produce a
    corresponding Kobs
>> for ii = 1:n

```

```

yobs(ii).Kobs = zeros(length(yobs(ii).yStd), pu);
for jj = 1:pu % compute for each basis component
    yobs(ii).Kobs(:, jj) = interp1(hsim, Ksim(:, jj),
        yobs(ii).h, 'linear', 'extrap');
end
end

```

4.2.4 Specifying the D Basis for Modeling the Discrepancy Term

The discrepancy term $\delta(x)$ models a systematic bias between the simulator and the experimental observations. A common procedure for fitting the discrepancy is using a normal kernel basis as in Example 1. Here a simple linear discrepancy is used.

```

>> % let's just use a simple linear discrepancy delta(h) = a*h;
>> Dsim = hsim;
>> pv = size(Dsim,2);
>> Dmax = max(max(Dsim * Dsim'));
>> Dsim = Dsim / sqrt(Dmax);
>> for ii = 1:n
    nyobsii = length(yobs(ii).yStd);
    hobsii = yobs(ii).h;
    yobs(ii).Dobs = zeros([nyobsii pv]);
    for jj = 1:pv
        yobs(ii).Dobs(:,jj) = interp1(hsim,Dsim(:,jj),hobsii,
            'linear');
    end
end

```

4.2.5 Package All the Pieces

Having now completed the specification and transformation of required data, it can be collected into a single Matlab structure to be given to GPMSA for model setup. This structure, here called `data`, will contain a field for the simulated data (`simData`) and another for the field data (`obsData`). For both fields, we'll include information that's required by the model as well as extra information (stored in a subfield called `orig`) that will later make it easier for us to return the output to the original scale and to do plots.

```

>> simData.x = design; % our design, standardized
>> simData.yStd = tsimStd; % output, standardized
>> simData.Ksim = Ksim;

% extra fields: original data and transform stuff
>> simData.orig.y = tsim;
>> simData.orig.ymean = tsimmmean;
>> simData.orig.ysd = tsimsd;
>> simData.orig.Dsim = Dsim;
>> simData.orig.h = hsim;
>> simData.orig.xNative = designNative; % original scale
    for simulated R, C

```

For the observed data, each experiment is created separately since each could have a different length.

```
% -- obsData --
>> for ii = 1:n
    % required fields
    obsData(ii).x = yobs(ii).x;
    obsData(ii).yStd = yobs(ii).yStd;
    obsData(ii).Kobs = yobs(ii).Kobs;
    obsData(ii).Dobs = yobs(ii).Dobs;
    obsData(ii).Sigy = yobs(ii).Sigy./ (tsimsd.^2);

    % extra fields
    obsData(ii).orig.y = yobs(ii).y;
    obsData(ii).orig.ymean = yobs(ii).ymean;
    obsData(ii).orig.h = yobs(ii).h;
    obsData(ii).orig.xNative = yobs(ii).xnative;
end
```

4.3 Model Initialization and MCMC

Now that the user setup of data has been completed, we can initialize the model, use the data to compute the posterior distribution of the parameters, and then sample from this distribution via Markov chain Monte Carlo (MCMC). The code in this section is in the MATLAB file `runmcmc.m`.

First we'll call `readdata.m`, which implements the code previously detailed, in order to get the data structure created there; we'll store it in a variable called `towerdat`.

```
>> % read data
>> towerdat = towerreg(1);
```

The initial setup of the model is performed using the GPMSA code function `setupModel()`. The function `setupModel()` takes the `obsData` and `simData` fields from `towerdat`, makes all the structures needed to do MCMC, and returns a structure which we'll call `pout` for “**parameter output**”.

```
>> params = setupModel(towerdat.obsData, towerdat.simData);
SetupModel: Determined data sizes as follows:
SetupModel: n= 3 (number of observed data)
SetupModel: m= 80 (number of simulated data)
SetupModel: p= 2 (number of parameters known for observations)
SetupModel: q= 2 (number of additional simulation inputs
(to calibrate))
SetupModel: pu= 3 (response dimension (transformed))
SetupModel: pv= 1 (discrepancy dimension (transformed))

>> params
params =
    data: [1x1 struct]
    model: [1x1 struct]
    priors: [1x1 struct]
    mcmc: [1x1 struct]
```

```

obsData: [1x4 struct]
simData: [1x1 struct]
optParms: []
pvals: []

```

Fields of `params` include the simulated and observed data transformed by the K and D matrices (`data`), initial values for the parameters of the posterior induced by the model in GPMSA (`model`), priors on the model parameters (`priors`), details (like step sizes) of the MCMC routine for getting draws from the posterior distribution of the parameters (`mcmc`), and the `obsData` and `simData` structures given in the call to `setupModel()`. It also includes a placeholder for the `pvals` field which will hold the MCMC draws.

Next the prior distribution parameters are specified.

```

% require the model stays close to the obs sd of .1 seconds
params.priors.lamOs.params = [10 10];
% allow the white noise component of the W's to get small
params.priors.lamWs.params = repmat([1 .00001],
    [params.model.pu 1]);
% initialize with a small discrepancy error
params.model.lamVz=10000;
% start with the observation precision mulitplier at 1
params.model.lamOs=1.0;
% allow the precision for the discrepancy to get big
params.priors.lamVz.priors = [1 .00001];
params.mcmc.lamVzwidth = 200.0;

```

1. Again as in Example 1, and as an optional step, GPMSA includes a utility `stepsize()` to optimize the MCMC proposal widths, or “step sizes.” Default settings may provide reasonable, although not optimal, performance. Computation of the step size starts by collecting MCMC proposal acceptance statistics at a number of possible values (levels), using estimates constructed from a number of MCMC draws. The code is the same as Example 1 and will not be replicated here.
2. After running the `stepsize()` function, MCMC samples are generated efficiently from the parameters’ joint posterior distribution. Again the code here is the same as Example 1.

4.4 Examining the Estimated Parameter’s Posterior Distribution

All of the diagnostic plots presented in Example 1 can be performed, but here the focus is on a different set from those in the first example.

4.4.1 Joint Posterior Distribution of C and g

In this example, the aim is to learn the joint distribution of the coefficient of drag, C , and the coefficient of gravity, g . The function call `t1Plots(pout, ip, 23)` creates a joint posterior distribution of C and g which can be seen in Fig. 55.11.

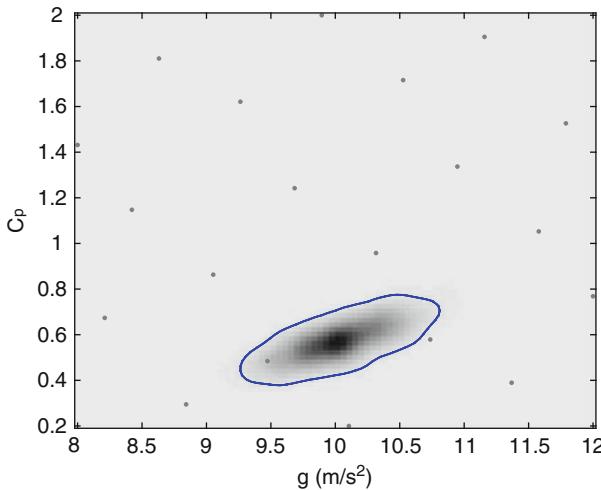

Fig. 55.11 The joint posterior distribution of coefficient of drag, C , and coefficient of gravity, g . The points represent C, g pairs selected in the space filling Latin hypercube design, and the dark contours form the joint posterior of C and g

4.4.2 Parameters Controlling the Gaussian Process Fit

Using the MCMC draws of the spatial dependence parameters $\beta, \rho = \exp\{-\beta/4\}$ is computed. The value of ρ gives information about the dependence of the simulation output on each input parameter \mathbf{x} and $\boldsymbol{\theta}$. Figure 55.12 shows box plots of the posterior draws for the ρ s for each \mathbf{x} and $\boldsymbol{\theta}$ and for each principal component. As above, the figure was generated using a subset of the realizations:

```
>> t1Plots(pout, ip, 1);
```

When ρ is exactly 1 for a particular x or θ principal component, it means that particular component of the simulator output is constant along that dimension. That is, the simulation is not sensitive to that input, and knowing the value of the input gives no information about the value of the output. As ρ goes smaller than 1, this indicates activity associated with that input. The outputs will vary smoothly with the inputs, with smaller values of ρ indicating less smoothness.

4.5 System Predictions

Finally in this experiment, the model is used to predict drop times for each ball type across the heights specified in the emulator. This figure is generated using the following code:

```
>> t1Plots(pout, ip, 3)
```

Note that the estimated discrepancy is nearly zero, so that the prediction uncertainty is accounted for by the model parameters, as well as in uncertainty regarding the

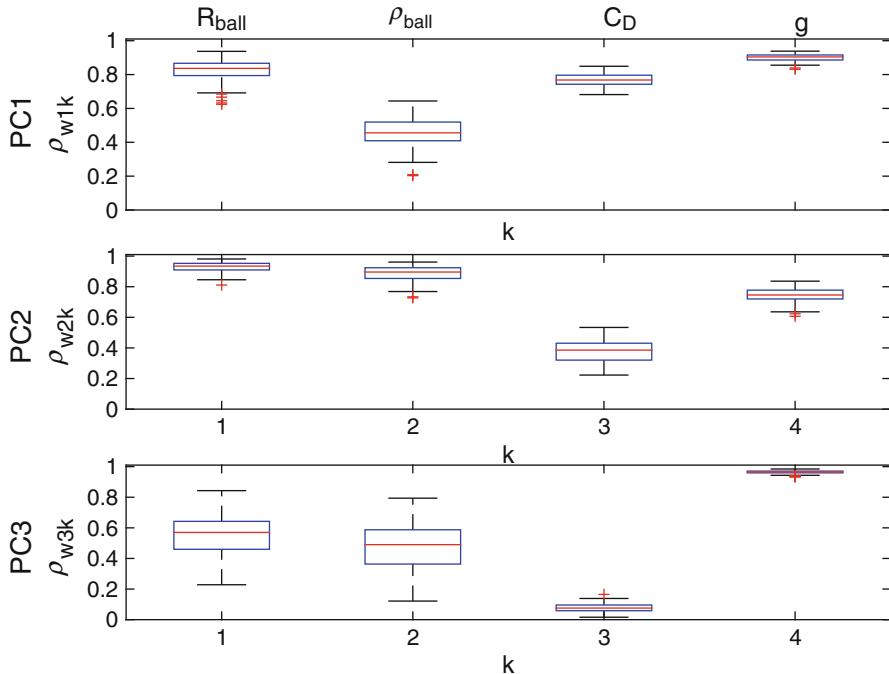

Fig. 55.12 Box plots of $\rho = \exp\{-\beta/4\}$ for the draws of β associated with \mathbf{x} and $\boldsymbol{\theta}$ for each principal component

GP-based response surface. Also, the fact that the design for the simulation runs uses the exact values of R_{ball} and ρ_{ball} for the softball means that the GP interpolation is only over the model parameters $\boldsymbol{\theta} = (C, \theta)$. Hence there will be very little uncertainty due to interpolation, even though the ρ s for the radius and density dimensions can be rather far from 1.

5 Example 3: Ball Drop Exploiting Kronecker-Separable Design

The third example follows the same experimental conditions as Example 2, but takes advantage of the structure present in the input parameters for the emulator. Recall the emulator inputs used a space filling Latin hyper cube to select the twenty pairs for the coefficient of drag and the coefficient of gravity. This dataset was imported directly as a 80×4 matrix with the twenty (C, g) pairs applied to the radius and density of each of the four balls used in the emulator: baseball, basketball, softball, and bowling ball. In this example, two separate datasets are imported, one for the twenty (C, g) and the other with the radius and density for each ball.

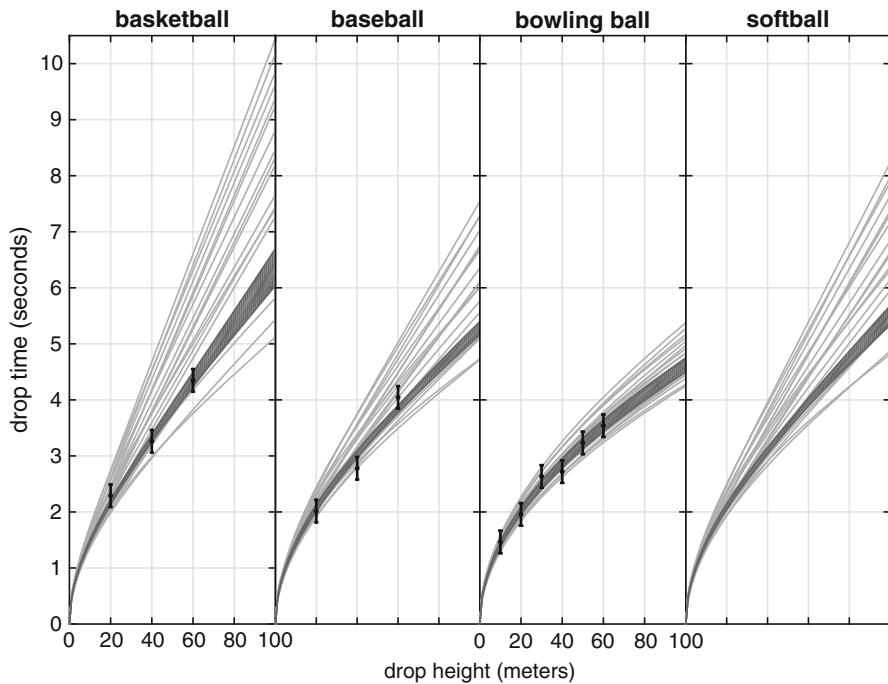

Fig. 55.13 The gray lines represent the emulator runs. The black points represent the experimental observations with uncertainty. The dark bands give a 90% prediction interval produced by propagating the posterior parameter realizations shown in Fig. 55.11 through the emulator

```

>> des1 = textread([dirstr 'desNative4x2Rrho.txt']); % design
    (x=R, rho_ball)
>> des1

des1 =
    0.1200      84
    0.0380     626
    0.1100    1304
    0.0485    380.9
>> des2 = textread([dirstr 'desNative20x2Cg.txt']);
    % design (theta=C,g)
>> des2

des2 =
    1.3368    10.9474
    0.4842     9.4737
    0.7684    12.0000
    0.6737     8.2105
    0.9579    10.3158
    1.1474     8.4211
    0.3895    11.3684

```

```

1.9053    11.1579
2.0000    9.8947
1.6211    9.2632
0.5789    10.7368
0.2000    10.1053
0.2947    8.8421
1.8105    8.6316
1.0526    11.5790
1.2421    9.6842
1.5263    11.7895
1.4316    8.0000
1.7158    10.5263
0.8632    9.0526
>> simData.orig.colmax = [max(des1) max(des2)];
>> simData.orig.colmin = [min(des1) min(des2)];
>> designNative = {des1,des2};

```

The above code is packaged into the `toweregKron.m` Matlab function. By specifying the separable structure, the Matlab function `setupModel.m` recognizes the Kronecker structure.

```

>> % initial set-up
>> params = setupModel(towerdat.obsData, towerdat.simData);
SetupModel: Determined data sizes as follows:
SetupModel: n= 3 (number of observed data)
SetupModel: m= 80 (number of simulated data)
SetupModel: p= 2 (number of parameters known for observations)
SetupModel: q= 2 (number of additional simulation inputs
                 (to calibrate))
SetupModel: pu= 3 (response dimension (transformed))
SetupModel: pv= 1 (discrepancy dimension (transformed))
SetupModel: Kronecker separable design specified

```

After setting up the model, the MCMC algorithm can be initialized using the Matlab function call `gpmcmc.m` just as in Example 2. By specifying the Kronecker-separable design, more efficient matrix algebra techniques can be used to solve the quadratic forms of the matrices, speeding up the log-likelihood evaluations required within the MCMC computations. Note that the `gPredict.m` function does not make use of this structure when producing posterior realizations from the emulator. In the likelihood computation, the computation is usually limited by the number of either observations or simulations, where the computation is $O(n^3)$, quickly dominated by the larger. With a Kronecker-separable design, the computation is $O(n^3)$ dominated by the largest n in the component designs. A design of 10^4 may be intractable to evaluate, but a design of two Kronecker sub-designs each of size 100 will be relatively quick to sample.

6 Example 4: Specifying Priors on C and g

This section extends Example 2, further illustrating how to specify a user-specified prior for the model parameters $\theta = (C, g)$. The “observed” data continues to be noisy realizations from the following ODE:

$$\frac{d^2h}{dt^2} = g - \frac{C}{2} \frac{3\rho_{\text{air}}}{4R_{\text{ball}}\rho_{\text{ball}}} \left(\frac{dh}{dt} \right)^2. \quad (55.14)$$

The experimental design continues to be the same Latin hypercube, which could be decomposed by exploiting its Kronecker structure.

6.1 Prior Specification for g and C

One way to modify priors is to modify their parameters in the `priors` structure, if the prior family does not change. In this example, changing the function that evaluates the log prior to a user-defined function is demonstrated. The prior is specified by defining a function called `logThetaPrior`, which takes as input the parameter $\theta = (C, g)$ and returns the log of the prior density up to an additive constant. For this example, we would like to use the fact that we have very good knowledge about g prior to carrying out this analysis. This is specified by a normal prior distribution for g centered at the gravitational acceleration in Vancouver (9.8134 m/s^2) and with a moderate standard deviation (0.02 m/s^2). A flat, uninformative prior is chosen for the coefficient of drag C . Since $\theta = (C, g)$ is transformed (scaled and shifted according to the min and max of the design range) to reside on the unit interval $[0, 1]^2$, the prior mean and standard deviation are similarly transformed for g to be 0.4533 and 0.005.

GPMSA takes as an argument the name of a function corresponding to this prior with the following line:

```
params.priors.theta.fname='logThetaPrior';
```

This log-prior function is defined in a file called `logThetaPrior.m` with the following code:

```
function lp = logThetaPrior(x,~)
% uniform for C, N(9.8134,.02^2) for g in Vancouver
% on the standardized scale 0 is 8.0, 1 is 12.0
meang = (9.8134 - 8.0)/(12.0 - 8.0);
sdg = .02/(12.0 - 8.0);
lp = - .5/(sdg^2)*(x(2)-meang)^2;
end
```

It requires that the parameter vector be passed to the function. If this function is not provided, GPMSA defaults to specifying independent normal priors $N(0.5, 10)$ for each component of θ , which is very flat over the domain of study in $[0,1]$.

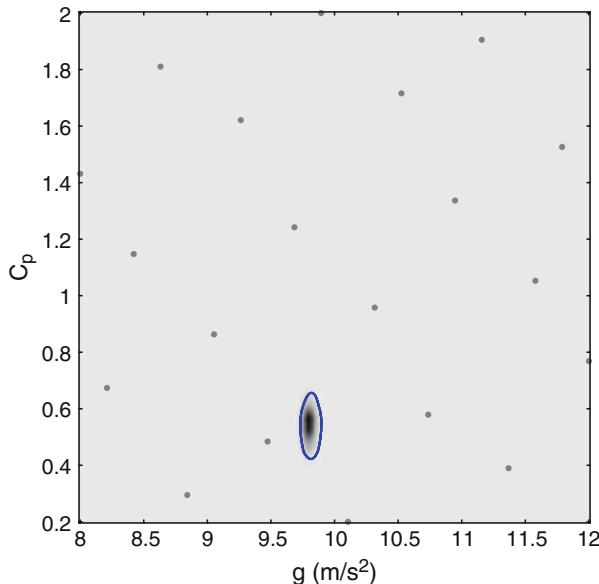

Fig. 55.14 Posterior distribution from Example 4 for the parameter vector θ . Notice that the contours are much narrower after supplying information through the customized prior

By introducing an informative prior, improvements can in principle be made in estimation of the parameters of interest $\theta = (C, g)$. Figure 55.14 shows how doing so results in a tighter posterior distribution, not only for the parameter given a strong prior but also its covariate.

7 Example 5: Inferring the Type of Ball Dropped

In this example, the potential of GPMSA to infer the type of ball dropped (basketball, baseball, bowling ball, or softball) from a new set of drop time data is explored. The general approach is to pose the question as a calibration problem; the unknown example has a category that is to be inferred, with uncertainty, by the GPMSA model. This follows on from the analysis in Example 2, producing a posterior distribution for $\theta = (C, g)$. For this new analysis, the posterior from Example 2 is taken as the prior, specifying a custom prior for (C, g) . This prior is well approximated by the following distribution:

$$\begin{pmatrix} C \\ g \end{pmatrix} \sim N \left(\begin{pmatrix} 0.125 \\ 0.5214 \end{pmatrix}, \begin{pmatrix} 0.0020504 & 0.00283 \\ 0.00283 & 0.007363 \end{pmatrix} \right) \quad (55.15)$$

Given this information, there is a new set of three drop times at heights 20, 40, and 60 m (see Table 55.1).

Table 55.1 Field data for Example 5 with unknown ball type

Height (m)	Time (s)	σ
20	2.1502001	0.1
40	3.1681314	0.1
60	3.9311893	0.1

The aim is to infer which ball was used in these experiments. Thus a categorical latent parameter (ball type) is estimated from these data. Technically, the strong prior for (C, g) expressed above is also updated. Thus, there now is a three-dimensional parameter $\theta = (C, g, \text{balltype})$, where the third component of θ is categorical, taking on values 1, 2, 3, or 4.

7.1 Specifying a Categorical Ball-Type Parameter in GPMSA

The indicator for ball category ranges from 1 to 4, corresponding to basketball, baseball, bowling ball, and softball, respectively. In GPMSA, categorical parameters are specified using the `optParms.catInd` (optional parameters category indicators) argument when calling the function `setupModel`.

In this example, the argument is set to `optParms.catInd = (0, 0, 0, 4)`, a four-dimensional vector with zeros in the first three entries corresponding to the first three entries of (x, θ) which are not categorical. The last entry of `optParms` is 4, indicating that there are four possible categories in the final unknown parameter of (x, θ) . It is worth noting that the first dimension of `optParms.catInd` is a “dummy” variable relating to x , which is set to a constant 0.5 for all instances in the observed and simulated data. GPMSA requires that the length of `optParms.catInd` equals $p + q$, the dimension of (x, θ) . In this case, this is 4, since the dimension of the dummy variable x is 1, while that of $\theta = (C, g, \text{balltype})$ is 3.

For categorical parameters, each iteration of the MCMC algorithm proposes a new category by uniformly randomly sampling from the set of possible categories $\{1, 2, 3, 4\}$, but excluding the current state. That is, if the current state of the sampler is k , the proposal is uniformly generated from $\{1, 2, \dots, k-1, k+1, \dots, K\}$, where in this case $K = 4$. Then the proposal is accepted or rejected according to the usual Metropolis decision rule.

Figure 55.15 shows the posterior distribution of ball type, clearly identifying the fourth category – softball – as the most probable candidate. The estimated posterior probability of the observed data being generated by a softball is 0.67, demonstrating that GPMSA can successfully identify the true underlying ball type. Note that a prediction can also be produced, just as before, but now accounting for the uncertainty regarding the ball type with the call `t1Plots(pout, ip, 32)` as given in the file `runmcmcBallEst.m`.

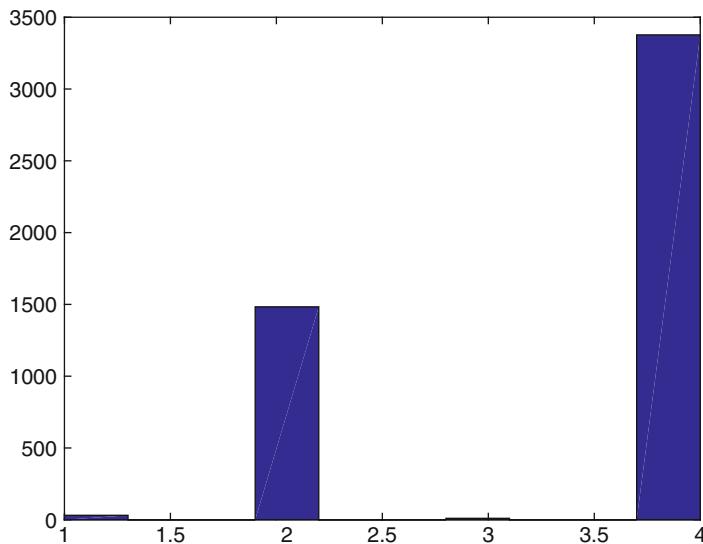

Fig. 55.15 Posterior draws of ball-type category

8 Conclusion

This chapter has discussed the nature of multivariate Bayesian model calibration using a Gaussian process emulator and how this has been implemented in the GPMSA code. This methodology and software have been applied successfully to a number of different examples, where complex scientific phenomena are studied using complex computer models.

COSSAN: A Multidisciplinary Software Suite for Uncertainty Quantification and Risk Management

56

Edoardo Patelli

Abstract

Computer-aided modeling and simulation is now widely recognized as the third “leg” of scientific method, alongside theory and experimentation. Many phenomena can be studied only by using computational processes such as complex simulations or analysis of experimental data. In addition, in many engineering fields computational approaches and virtual prototypes are used to support and drive the design of new components, structures, and systems. One of the greatest challenges of virtual prototyping is to improve the fidelity of the computational analysis. This can only be achieved by explicitly including variability and uncertainties from different sources. Variability is inherent in many natural systems and therefore cannot be reduced. Uncertainty is also always present since it is not possible to perfectly model or predict future events for which no real-world data is available.

Although stochastic methods offer a much more realistic approach for analysis and design, their utilization in practical applications remains quite limited. One of the reasons is that the developments of software for stochastic analysis have received considerably less attention than their deterministic counterparts. Another common limitation is that the computational cost of stochastic analysis is often by orders of magnitude higher than the deterministic analysis. Hence, robust, efficient, and scalable computational tools are necessary, i.e., by making use of the computational power of a cluster and grid computing.

This chapter presents the COSSAN project: a developed multidisciplinary general-purpose software suite for uncertainty quantification and risk analysis. The computational tools satisfy the industry requirements regarding usability, numerical efficiency, flexibility, and scalability. The software can be used to solve a wide range of engineering and scientific problems. The availability of such software is particularly important for the analysis and design of resilient

structures and systems. In fact, despite the different levels of uncertainty, decision makers still need to take clear choices based on the available information. They need to trust the methodology adopted to propagate the uncertainties through multidisciplinary analysis, in order to quantify the risk with the current level of information and to avoid wrong decisions due to artificial restrictions introduced by the modeling.

1 Introduction

Knowledge about the future behavior of engineered systems is the basis for reaching economical and safety relevant decisions in our society and appears in different fields (e.g., automotive and aerospace industry, financial, environmental science, mechanical and energy sector). Together with observed responses, it provides the basis to broaden the understanding between action and reaction. In order to predict accurately the behavior of such systems and/or structures, mathematical models must be constructed and then evaluated. In an increasingly competitive market, engineers are asked to design products faster with rapid prototyping that can be achieved only through computational models and numerical simulations. In fact, nowadays, in many engineering fields computational approaches and virtual prototypes are used to characterize, predict, and simulate complex systems (see

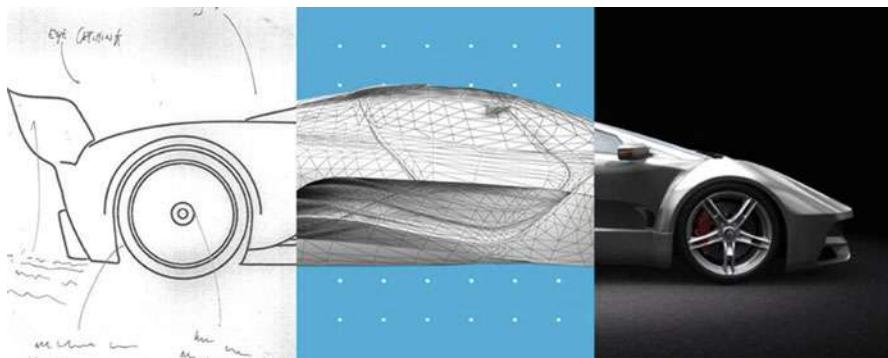

Fig. 56.1 Example of a development strategy by means of virtual prototypes (Courtesy of the Virtual Engineering Centre)

Fig. 56.1). These advancements have allowed engineering practitioners to reduce the number of expensive and destructive tests necessary to qualify new products. In fact, the performance of these products can be tested in a simulated environment and the necessary changes introduced before producing a physical item, reducing the overall development cost and time. Generally any product, component, or system is designed and optimized, in other words engineered, to fulfill requirements and codes, to improve its performance, and to reduce production and maintenance costs.

Since the industrial designs are subject to strict safety, reliability, environmental, and service requirements, the quantification of uncertainties and risks is a necessity and a challenge, needing for innovative software that allows the inclusion of nondeterministic analysis as a practice standard routing in the virtual prototyping.

1.1 Background and Motivations

The continuous advancements in modeling tools allow for very accurate reproduction of the behavior of components and systems at multiple scales. In addition, the exponential growth of computational power allows the analysis for a level of detail and precision that could have not been reached previously. However, even with very advanced models and accurate analysis, a comparison of response predictions with measured data can show an incomplete agreement. The reasons for these discrepancies are the uncertainties in model parameters and in the model itself (see Fig. 56.2). Parameter uncertainty denotes input data in the computational model which are not precisely known and are expected to deviate from the assumed deterministic values. Model uncertainty denotes the fidelity of the mathematical models, which usually involves some abstractions, simplifications, or assumptions to represent with sufficient accuracy the actual mechanical/physical responses. Nowadays, it is widely recognized that essential progress in model prediction can only be accomplished when different sources of uncertainty are explicitly included in the analysis [13, 44, 80].

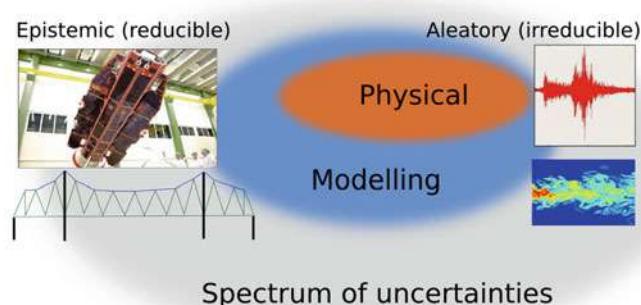

Fig. 56.2 Spectrum of the uncertainties: aleatory (irreducible) uncertainty and epistemic (reducible) uncertainties

Uncertainties are generally classified in two categories: *aleatory* and *epistemic*. Aleatory uncertainty represents the variability of true random or uncontrollable processes (e.g., earthquakes, wind loads, climate change, etc). This kind of uncertainty is irreducible because it is inherent of the system or process (e.g., it is not possible to predict the occurrence and intensity of an earthquake). Epistemic uncertainty represents limited data, limited knowledge, as well as model imprecision due to assumption and simplification. Epistemic uncertainty can be reduced, at least theoretically by collecting new data or using more detailed models. In practice, such new data is either very scarce or impossible to collect and detailed models are difficult to calibrate and validate. These two unavoidable sources of uncertainties (Fig. 56.2) must be appropriately accounted for to guarantee that the components or systems will continue to perform satisfactory despite fluctuations, i.e., the design has to be “robust” (see, e.g., [79]). Ignoring the effects of the uncertainties and/or not including them at the design stage might lead to a poor or unsatisfactory design. For instance, a product may perform well in the laboratory tests but perform unsatisfactory under realistic conditions.

In addition, recent reports have clearly shown that the risk assumed by the decision maker is often wrongly estimated due to inadequate assessment of uncertainties (see, e.g., [50]). Modeling and simulation standards require estimates of uncertainty (and descriptions of any processes used to obtain these estimates) in order to increase confidence and consistency in safety predictions and encourage the development of improved methods for quantifying and managing uncertainty. Hence, uncertainty management is necessary to provide support to the decision makers through a series of different and interconnected analyses. For instance, estimating the importance of collecting additional information allows to characterize and reduce uncertainty; by performing sensitivity analysis, it is possible to identify the parameters that contribute the most to the variability of the output; uncertainty propagation allows to study the effects of uncertainty on the performance of the

system and to identify extreme-case scenarios. Finally, optimizing the design explicitly taking into account the effect of uncertainties allows to design a robust system.

1.2 Importance of Stochastic Analysis

It is quite well accepted that deterministic analyses provide insufficient information to capture the variability of the quantity of interest, while stochastic analysis has been proved to provide a more realistic description taking explicitly into account the effect of uncertainties (see, e.g., [84]).

The merits of considering uncertainties are manifold: it allows for assessing the reliability and variability of the responses, and most importantly, it provides more realistic predictions and information to improve the design. For instance, sensitivity analyses reveal the quantities which are mainly responsible for the variability of the quantity of interest. In case the uncertainty is due to the lack of knowledge (epistemic type) and therefore reducible, the fidelity of the prediction can be improved by gathering additional data for those quantities which cause the most uncertainty in the response(s). On the other hand, irreducible (aleatory) uncertainties lead to irreducible uncertainties in the response and the design must be robust such that adverse events do not jeopardize safe operation.

Similarly, uncertainty quantification and propagation are important aspects when trying to optimize a system or a component. Optimal solutions obtained in a deterministic setting might not perform as expected and can even be dangerous in cases where ignored uncertainties influence the performance considerably. On the other hand, robust design procedures take into account all relevant uncertainties and provide robust and sound solutions, e.g., the failure probability is constrained to be less than an acceptable value [33, 36, 64, 86]. Furthermore, decisions within life cycle management for important infrastructures and investments must be made based on incomplete and generally insufficient data, where a probabilistic Bayesian approach, imprecise probability, and fuzzy methods could provide valuable information [6, 10, 11, 28].

The most widely accepted method to deal rationally with uncertainties is the stochastic approach that includes Bayes and Laplace's subjective interpretation of probability as a state of information [26, 42]. In the stochastic approaches, uncertainties are represented mathematically by random quantities and by suitable probability distributions. However, many of the uncertain phenomena are non-repeatable events. In this case, uncertainty is not embodied by intrinsic or aleatory randomness, but by the lack of knowledge or epistemic uncertainty about the phenomenon. The insight in the underlying physics can also be limited or vague. In other words, the knowledge about the phenomena is not in a complete form that allows the construction of the probability distribution or relevant quantities in the context of classical probability theory. Information may statistically include expert assessments, opinions, or team consensus. Bayesian statistics allows for a rational and systematic treatment of this kind of uncertainty, interpreting probability as a degree of belief, which is by nature subjective. Alternative approaches are

valid options, e.g., fuzzy logic [48], imprecise probability, and possibility theory, which are not so far developed as the theory of probability. To avoid the inclusion of subjective and often unjustified hypothesis, the imprecision and vagueness of the data can be treated by using concepts of imprecise probabilities. Imprecise probability combines probabilistic and set theoretical components in a unified construct (see, e.g., [1]). It allows a rational treatment of the information of possibly different forms without ignoring significant information and without introducing unwarranted assumptions. In the analysis, imprecise probabilities combine, without mixing, randomness and imprecision. Randomness and imprecision are considered simultaneously but viewed separately at any time during the analysis and in the results. The probabilistic analysis is carried out conditional on the elements from the sets, which leads eventually to sets of probabilistic results. This can support economical and safety relevant decisions in many different fields that must be done based on incomplete and generally insufficient data. For instance, interval analysis is a useful tool to explore a variety of set-valued descriptions (nested set of sets), for example, in design problems. These options can be combined with one another to suit the problem. In any case, no assumption is made regarding a distribution of probability over a set. Instead, each and every element from a set is considered as plausible with no weighting with respect to one another.

1.3 Needs of an Innovative Software

The quantification of uncertainties and risks is a key requirement and challenge across various disciplines in order to operate systems of diverse nature safely under the evolutionary dynamics of inputs and boundary conditions. These systems include engineering, infrastructural, and financial systems among others. Industry is fully aware of the truly significant potential of nondeterministic analysis and advanced simulation-based tools for many application fields with large-scale benefits. In fact, in industrial designs that are subject to strict safety, reliability, environmental, and service requirements, the quantification of uncertainties and risks is a necessity and a challenge. Although powerful mathematical basis for comprehensive uncertainty and risk quantification does exist, in practice, expertise in uncertainty quantification is generally not present in industrial design offices. A key issue for this delay in transfer of knowledge and computational technologies into industry on a large scale is the lack of proper software. Consequently, industrial design methods are still predominantly deterministic.

Software for stochastic analysis have received considerably less attention than their deterministic counterparts, and in addition, the computational cost of stochastic analysis is often by orders of magnitude higher than the deterministic analysis. This is because instead of performing the deterministic analysis once by running a detailed model (e.g., FE or CFD model), multiple runs of the deterministic model are required as shown in Fig. 56.3. In general, deterministic analysis provides a map between a single point in the input space (i.e., the model parameters) and a point in the output space (i.e., component or system performance). Stochastic analysis

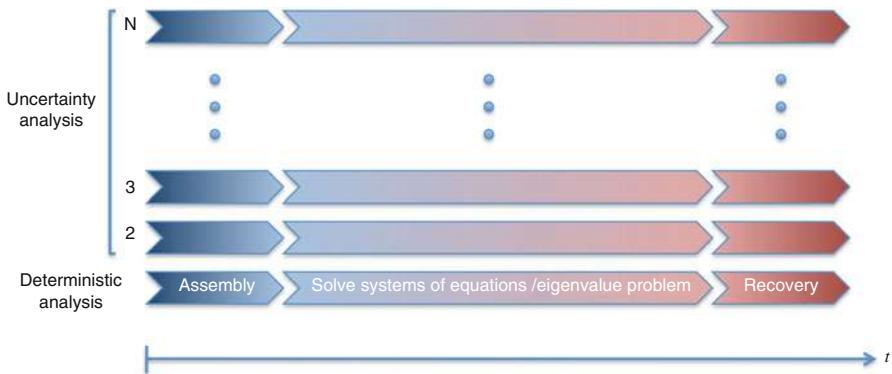

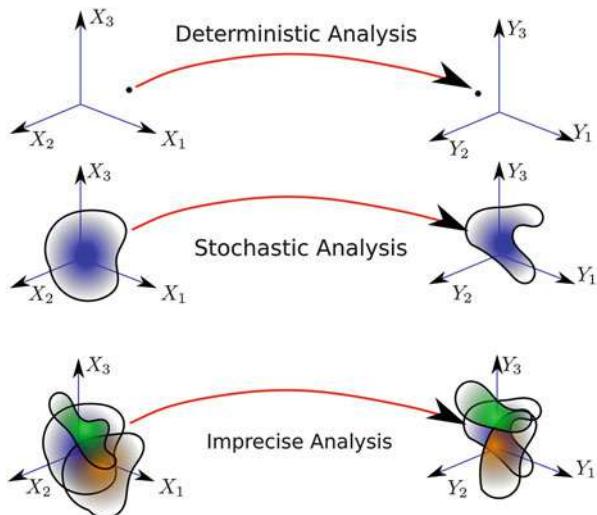

Fig. 56.3 Computational cost of the stochastic analysis versus deterministic analysis. Deterministic analysis requires assembling the model, solving a set of system equations, and then computing the quantity of interest. Uncertainty analysis requires N deterministic analysis

Fig. 56.4 Schematic representation of the different analyses: deterministic analysis provides a map between a point in the input variable space and a point into the output variable space; stochastic analysis maps an area in the input space with an area in the output space and imprecise analysis maps sets in the input space with sets in the output space

extends this map to a region in the input space and a corresponding region in the output space by repeating the deterministic analysis many times as represented in Fig. 56.4.

Recent emerging techniques to deal rationally with uncertainties, such as generalized probabilistic methods, including Bayesian approach fuzzy logic and possibility theory, introduce another layer of computational complexity [14]. These generalized probabilistic models require the evaluation of sets of possible probabilistic models (see Fig. 56.4) with even higher computational costs which might lead to impractical computational costs especially for detailed models. A comparison and details of these techniques can be found in Ref. [73].

In order to include stochastic analysis as standard procedure in engineering practice, it is of paramount importance the availability of innovative software that allows considering explicitly the effects of uncertainties. This software needs also to implement efficient simulation and parallelization strategies allowing a significant reduction of the computational costs of the nondeterministic analyses. Finally, such software should allow the analyst to perform stochastic analyses using the same software and tools used for the *deterministic* design in order to reduce the learning curve. The lack of easy-to-use nondeterministic analysis software, for solving large-scale problems, has motivated the COSSAN project. The current version of the COSSAN software meets these requirements as it will be shown in the next sections.

2 The COSSAN Project

2.1 Overview

The COSSAN project aims at developing a new generation of a general-purpose software for nondeterministic analysis that can be used by industry, academics, and researchers and for teaching purpose as well. The software incorporates the knowledge, understanding, and intellectual property from more than 30 years of research in the field of computational stochastic analysis. The COSSAN software is based on the original development by the group of Prof. Schuëller at the Institute for Engineering Mechanics, University of Innsbruck, Austria [85]. Originally, it was designed to perform stochastic structural analysis only [81] as the software name was indicating (COmputation Stochastic Structural ANalysis).

Starting from 2006, the next-generation software referred to as COSSAN-X is under continuous development, and it is intended for a wider range of applications in different fields, which includes optimization analysis, life cycle management, reliability and risk analysis, sensitivity, optimization, and robust design [65]. The current version of the software is hosted at the Institute for Risk and Uncertainty at the University of Liverpool, UK, and led by Edoardo Patelli. In addition, since 2012, an open-source version of COSSAN-X, called OPENCOSSAN, is available under the GNU Lesser General Public License [30]. This means that the program can be used for free, redistributed, and modified under the terms of the GNU Lesser General Public License. The OPENCOSSAN aims to promote learning and understanding of nondeterministic analysis through the distribution of an intuitive, flexible, powerful, and open computational toolbox in Matlab environment [67]. Recently, COSSAN-X has been integrated into the Engineering Cloud developed and led by the Virtual Engineering Centre (www.virtualengineeringcentre.com). Engineering Cloud is offering *Stochastic Analysis on Demand*, enabling small and medium enterprises to access high-performance computing resources and software capabilities and to cut capital investment requirements for hardware and software purchase.

2.1.1 General-Purpose Software

A framework is a software which provides generic functionalities and can be changed and expanded through user-defined routines and additional codes. In this optic, COSSAN is a *general-purpose computational framework*. Generally highly specialized software are developed to solve very specific problems. These tools can be very efficient and compact, but their applicability remains very limited and the solution for a different problem will require the redevelopment of the entire computational framework. The term *general purpose* means that a reasonably wide range of engineering and scientific problems can be treated by a single software. Such software packages are much more flexible than specialized software, which are developed to solve a specific type of problem within a particular discipline. The complexity of the general-purpose software packages in terms of number of lines of code, structure, and time required for developing and testing represents the major drawback of this kind of software when compared with dedicated software. However, they are developed in a single effort and then they can be used to solve a broad variety of problems. In addition, general-purpose software are usually much simpler to use and thus they can be adopted by less skilled users, resulting in a drastic reduction of analysts' training time required to familiarize with the software.

2.1.2 Historical Developments

Historically, the first developments toward a stand-alone software led to the package ISPUD, an acronym for “Importance Sampling Procedure Using Design Points” (see Fig. 56.5). ISPUD was a multipurpose program package for performing structural reliability analysis. The failure probability was calculated by integrating the joint probability density function using numerical procedures, such as Monte Carlo simulation, and in particular importance sampling around design points [15, 83].

At the beginning of the year 1990, the development of the stand-alone toolbox for structural analysis started, providing a data management system and a command interpreter [17]. The first release of COSSAN is referred to as the COSSAN-A in the development line (see Fig. 56.5). COSSAN-A was an open system, designed to be easily adjustable and expandable to include new computational tasks. Each problem solution was broken down into a set of specific commands, each performing a uniquely defined computational task, denoted as a module. The need to operate

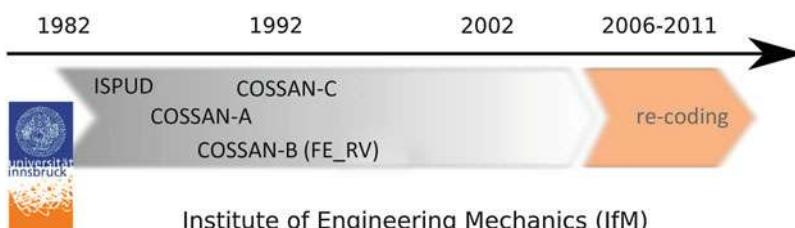

Fig. 56.5 Historical development of the COSSAN software led by Prof. Schuëller at Institute for Engineering Mechanics, University of Innsbruck, Austria

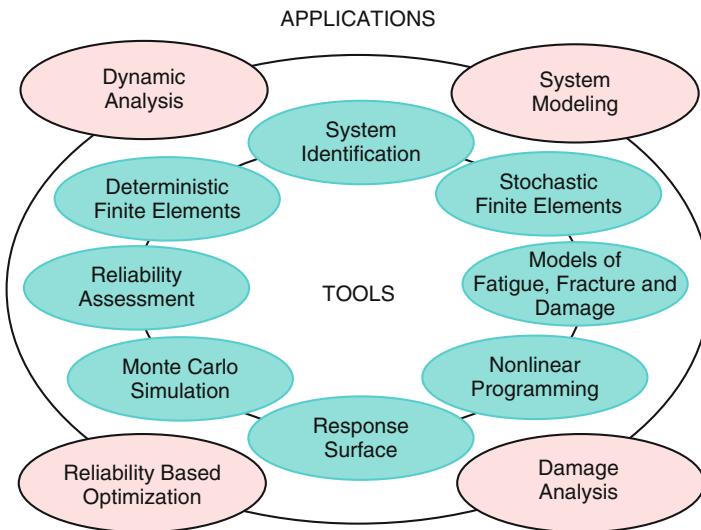

Fig. 56.6 Range of analysis capabilities featured by COSSAN-A: a stand-alone software for computational structural analysis developed in the early 1990s

directly with modules aimed to give the user explicit control over the sequence of specific tasks to be performed. Such extensive control provided substantial advantages to developers who want to expand available capabilities to solve their specific problems. The structure of COSSAN-A is as follows. On the very top of the stand-alone toolbox, there is an event-driven loop of the graphical user interface (GUI). This administration package provides all interactive capabilities of COSSAN-A. The next layer of the toolbox is the command interpreter, which translates and executes a sequence of COSSAN-A commands. The sequence of commands read by the COSSAN-A input file can be controlled by conditional and unconditional jumps, allowing for loops and repeated calls of command sequences. The stand-alone toolbox was composed by 32 module groups and 218 modules. These modules include a library of the most common finite elements, which are needed to perform Monte Carlo simulation. Figure 56.6 shows an overview of the analysis tasks and applications which can be treated within the stand-alone toolbox.

Starting in the mid-1990s, a novel approach to software development in stochastic structural analysis was undertaken: in order to capitalize on existing, widespread general-purpose FE solvers, communication tools started to be developed. These tools were collected in the so-called COSSAN-B development line and merged in the currently operational code FE_RV [18]. The modus operandi of FE_RV is depicted schematically in Fig. 56.7. The central portion (in blue) relates to the user interface; it mainly represents the user-defined specification of the probabilistic model. On the left side, the set of routines implementing the actual probabilistic methods are indicated in green. These routines may be coded in the preferred programming environment, such as PERL, Matlab, C++, etc. As shown in the figure, these engine

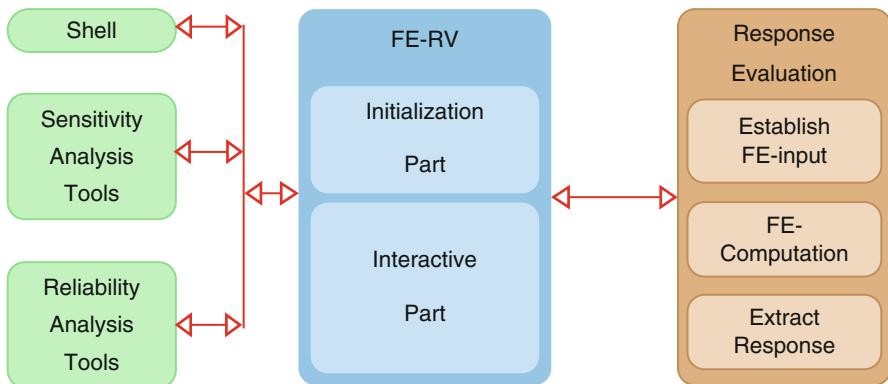

Fig. 56.7 Modus operandi of COSSAN-B, a software for communication with third-party software

Fig. 56.8 Current development of the COSSAN software at the Institute for Risk and Uncertainty at the University of Liverpool, UK

routines encompass sensitivity analysis and, most importantly, reliability analysis methods such as Monte Carlo simulation and advanced simulation methods. The numerical data obtained by these procedures are then transferred to third-party FE codes, represented by the rightmost box (in brown).

2.1.3 Development of the Next-Generation Software

The redevelopment of the COSSAN software started in 2006, in order to merge all previous versions in a more sustainable single software called COSSAN-X (see Fig. 56.5). The associated development efforts aimed at capitalizing on the highly developed, third-party codes for the computational analysis, while using advanced communication tools to interact with the commercial third-party programs and to create a general-purpose software able to solve a number of different problems. The developments aim to create a multidisciplinary software that satisfies industry requirements regarding numerical efficiency and analysis of detailed models.

Since 2011 the development of the COSSAN software is hosted at the Institute for Risk and Uncertainty at the University of Liverpool, UK (see Fig. 56.8). The current

development of COSSAN at the University of Liverpool is led by Edoardo Patelli and supported by Matteo Broggi. The current version of the software implements innovative developments in the computational algorithms, emerging concepts in stochastic mechanics and robust design to cope with model uncertainties, errors in modeling and measurements, and noise in signals [57, 72, 95]. A key element of the software is a comprehensive risk management and uncertainty quantification based on different representations of the uncertainties based on probabilistic approaches, interval and fuzzy methods, imprecise probabilities, and any combination thereof [14].

2.2 COSSAN-X

COSSAN-X represents the latest generation of the COSSAN software. It has been designed to meet the requirements of industry and academics, providing an easy access to the state-of-the-art methodologies and algorithms for stochastic analysis. In fact, it comes with a powerful and easy-to-use interface, allowing a straightforward interaction with third-party (deterministic) software (e.g., finite element solvers), and high-performance computing and data management.

The structure of the software is composed by three main blocks: user interfaces, core components, and the interaction with external code (i.e., third-party software). Each of these main blocks can be formed by a number of additional subcomponents. A scheme of the general-purpose software is shown in Fig. 56.9.

2.2.1 User Interface

COSSAN-X provides a very powerful, interactive, and user-friendly interface (Fig. 56.10). Developed in Eclipse RCP, the user interface provides the state-of-the-art wizards and graphical tools, which construct a comfortable platform to perform the various analyses and applications offered by the program, without excessive training. Available in all operating systems (i.e., Windows, Linux, and Mac OSX), COSSAN-X is designed to provide guidance to its users at every step of the analysis and to assist the inexperienced users in the selection of the most appropriate tools required for the analysis of the problem at hand (Fig. 56.11). In this regard, the user is provided with the necessary warning/error messages, as well as help icons, which enables an easy access to the associated user manual pages (Fig. 56.12).

2.2.2 Interaction with Third-Party Software

The ability to interact with (deterministic) third-party software is a critical point, since the analyst aims to solve the stochastic problem using the same models that they are already familiar with. COSSAN-X interacts with external solvers using a nonintrusive approach derived from the FE_RV code [18]. As shown in Fig. 56.13, the numerical data produced by COSSAN-X are transferred to the external solver by manipulating an ASCII input files. Then, the solver is executed and the output files are generated. Finally, the quantities of interest are from the solver output files (*extracting* data) and passed back to COSSAN-X.

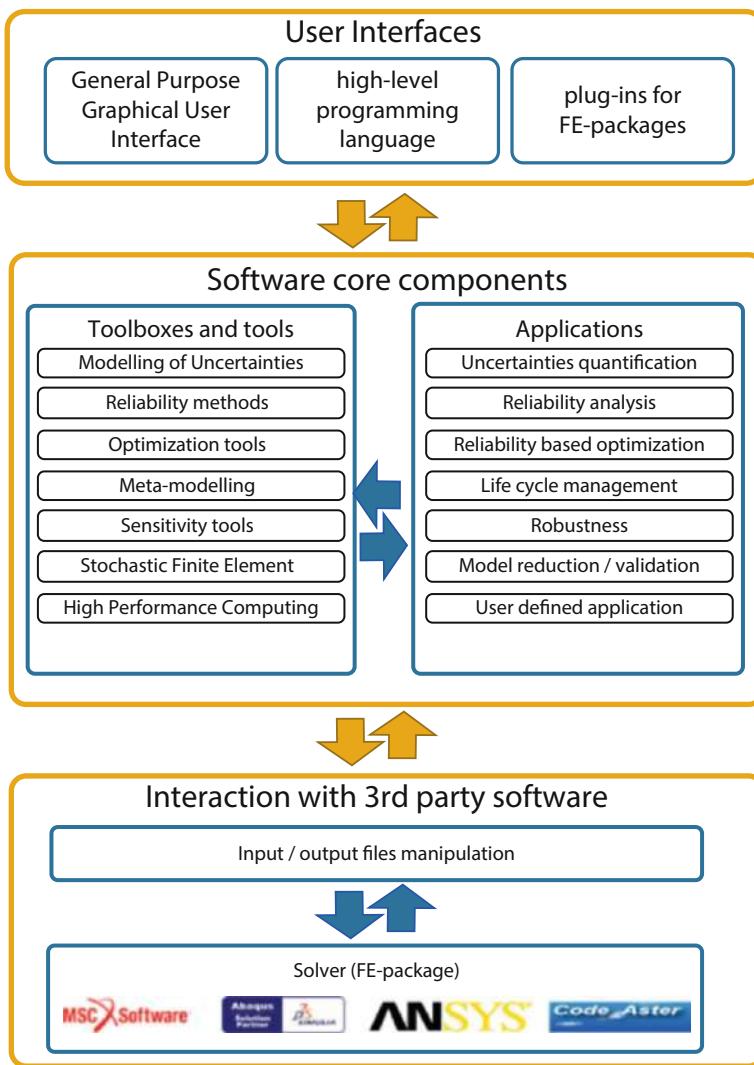

Fig. 56.9 Schematic representation of general-purpose software for computational stochastic analysis

For each realization of random variables, parameters and design variables, etc., the solver input files are modified (i.e., *injecting* data). This approach is very convenient as it allows interaction with any external software without the necessity to write dedicated interfaces. Quantities defined in COSSAN-X are linked with input parameters of the solver by means of XML tags included in the ASCII input file. XML stands for EXtensible Markup Language and it is a software- and hardware-

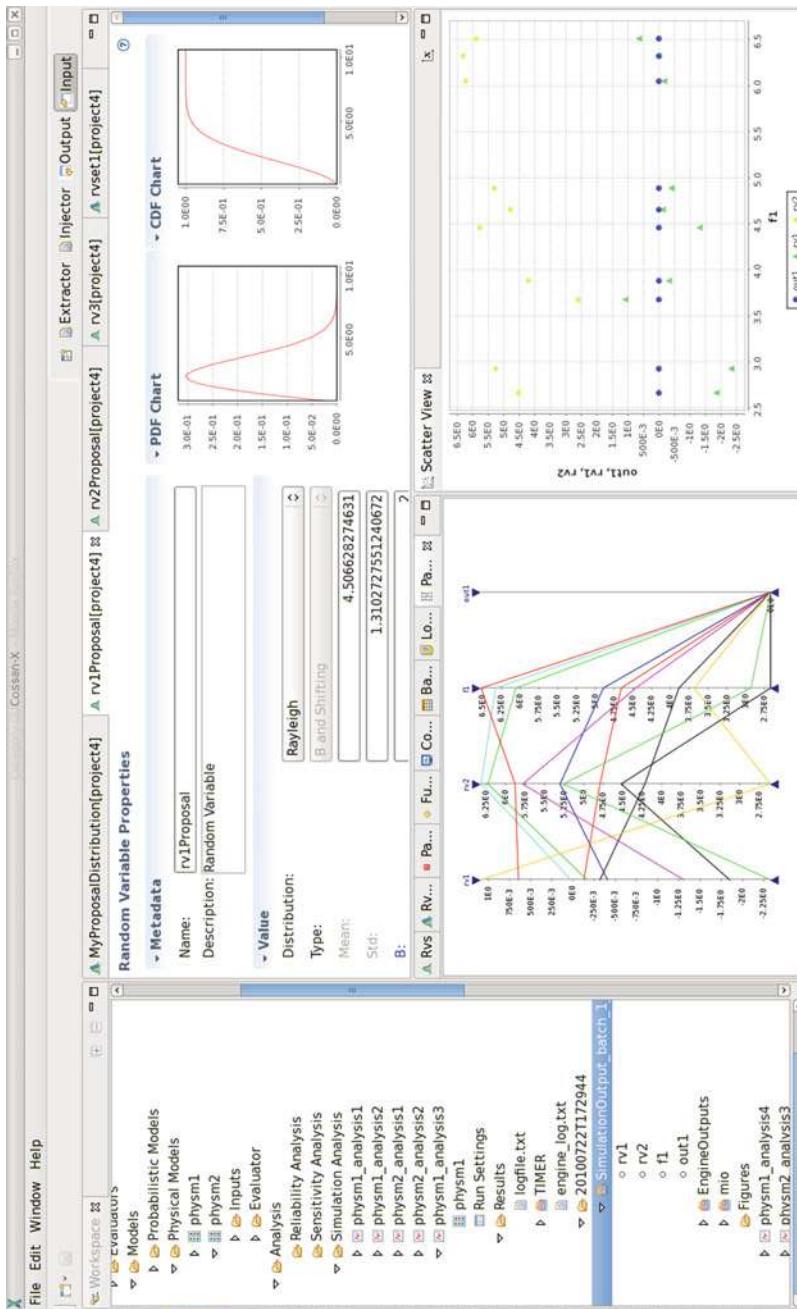

Fig. 56.10 COSSAN-X user interface. The screenshot shows the workbench of COSSAN-X that contains editors to define objects (to define objects, input, and models), wizards to define analysis, visualization tools to show the results, and a workspace to manage and organize the different parts of the analyses

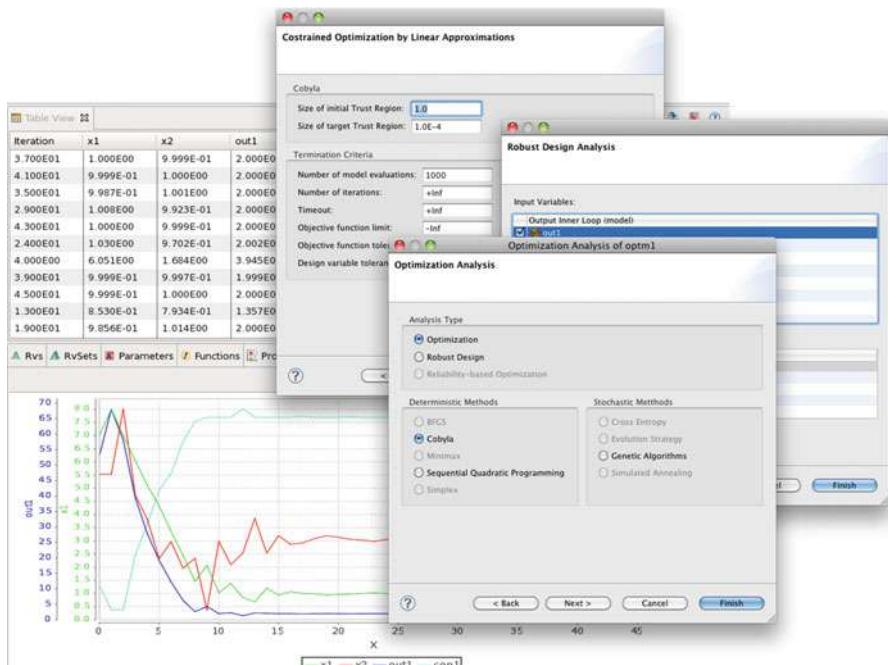

Fig. 56.11 COSSAN-X user interface: wizards and visualization tools. Example of optimization wizard where the available optimization methods are suggested together with the optimization settings. The plot on the *bottom* shows the evolution of the design variables and objective functions during an optimization analysis

independent tool designed for carrying information. The COSSAN-XML tag is self-descriptive and contains the attributes shown in Table 56.1.

The quantity of interest of the analysis is imported in COSSAN by reading ASCII output files generated by the third-party solver. This is done by defining the position of the quantities of interest in the output files. The position can be absolute or relative to some string (called anchor).

The user interface of COSSAN-X offers a very powerful editor, which makes the manipulation of the input/output files for third-party solvers an easy task. It allows to create and include the XLM tag in the input files without the necessity to manually edit the input files as shown in Fig. 56.14. The definition of the position of the quantity of interest can also be defined by means of the user interface as shown in Fig. 56.15.

2.2.3 Core Components

The core components of COSSAN-X are provided by OPENCOSSAN that represents the computational engine of the software. OPENCOSSAN offers the most advanced and recent algorithms for the rational quantification and propagation of uncertainties that have been shown to represent a robust and efficient approach for the uncertainty

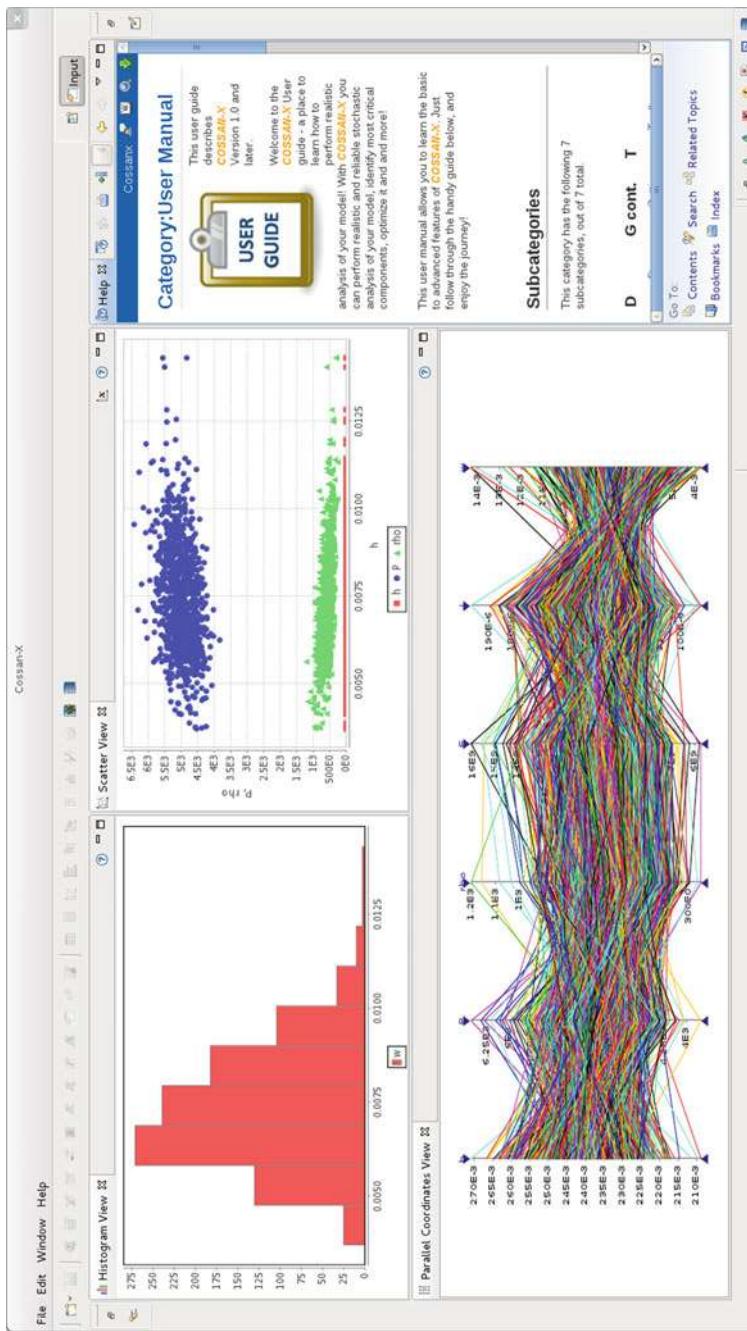

Fig. 56.12 COSSAN-X user interface: visualization tools and embedded help available via the user interface. Example of a histogram (*upper-left window*), scatterplot (*upper-right window*), and parallel coordinate view (*bottom window*). The *right-hand side column* shows the embedded help

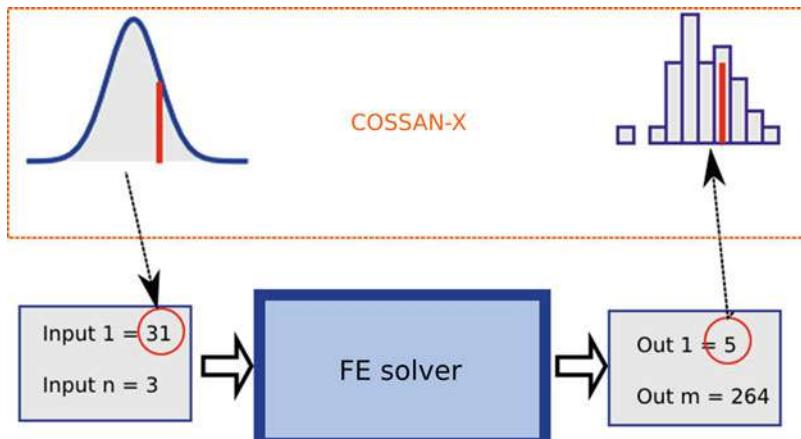

Fig. 56.13 COSSAN-X: interaction with external solvers. Realizations of input variables generated by COSSAN (e.g., Input 1=31) are written into the input file of the FE solver. Then, the FE analysis is performed and the quantity of interest (out 1=5) is retrieved from the output file and returned to COSSAN

Table 56.1 COSSAN-XLM tag used to carry transfer information from COSSAN-X and third-party software

Attribute Name	Description
Name	Name of the variable defined in COSSAN
Index	Indices of variable. The index is used to inject values defined in a vector
Format	Format of the written variable, specified as a string containing formatting operators. A formatting operator starts with a percent sign, %, and ends with a conversion character. Standard formatting string is used
Original	Original text (value) that needs to be replaced

management (see, e.g., [11, 12, 82]). The combination of various algorithms with specific solution sequences permits the analysis of engineering problems. Eventually, these algorithms form the application layer, such as uncertainty quantification, reliability analysis, life cycle management, sensitivity analysis, modal updating, etc.

2.3 Technical Features

The purpose of this section is to summarize the features of COSSAN-X. The reader is referred to the “case studies” session where the techniques and algorithms are used to solve problem of practical interest.

2.3.1 Uncertainty Characterization

Uncertainties can be described within the framework of probability. Probabilistic analysis can be a very powerful tool for the rational treatment of uncertainties.

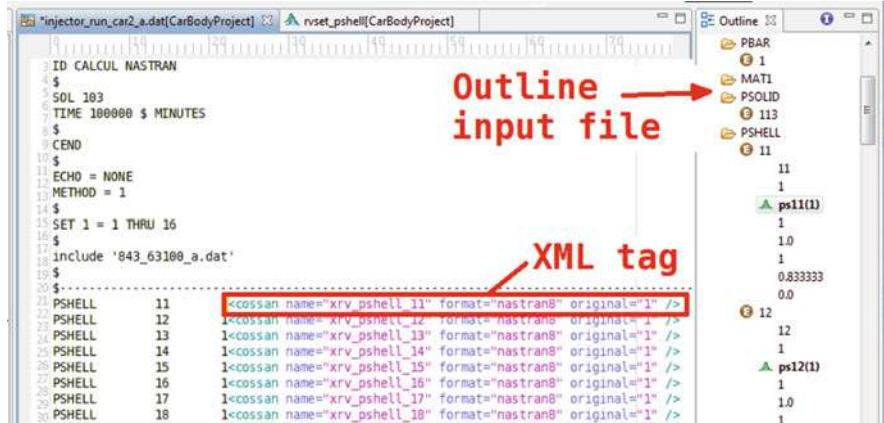

Fig. 56.14 COSSAN-X: manipulation of input file of a commercial FE software. Example of NASTRAN input file, the XLM tags are included in the input file to connect COSSAN variables to FE input parameters

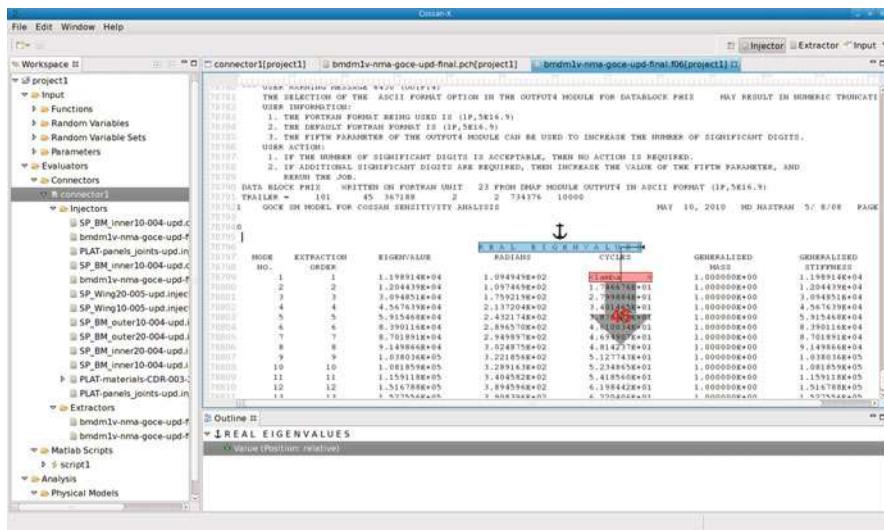

Fig. 56.15 COSSAN-X: definition of the quantities of interest in the output file of a commercial FE software. Example of NASTRAN output file where the quantity of interest is the first 45 values of the eigenvalues

However, traditional probabilistic methods require the representations of uncertainty based on probability density function (PDF) or cumulative density function (CDF). PDF and CDF can be obtained from data sets and used to describe aleatory uncertainties. Scalar values can be modeled using random variables, e.g., static load; time variant quantities can be represented using stochastic processes, e.g.,

wind speed or earthquake excitation; space variant quantities can be described using random fields, e.g., material properties in a solid.

A random variable can be defined by specifying the distribution type, e.g., normal, log-normal, uniform, etc., together with either the parameters of the distribution or its moment(s) (see Fig. 56.16). Multivariate distributions are defined by means of marginal distributions and correlations among them. Alternatively, random variable and multivariate distributions can be constructed starting from a set of realizations. The parameters leading to the best fit are automatically computed using different strategies such as the maximum likelihood estimation, kernel density estimation, and a mixture of one or more multivariate Gaussian distribution components [33] (see Fig. 56.16). Stochastic processes and random fields can be also defined and modeled by defining a functional dependence in a multidimensional continuous space or time dependence (see, e.g., [78, 96]).

When only a very limited number of samples are available, it is not possible to characterize the aleatory uncertainty, and a significant epistemic contribution needs to be taken into account. The epistemic contribution can be so large that an accurate estimation of the PDF/CDF is not possible. In such cases, a more rational treatment of the uncertainty would be, for instance, to use sets or families of PDFs/CDFs that are in agreement with the experimental evidence (i.e., the data set), with a reasonable reliability and robustness. There are different approaches to deal with such scarce data, including statistical tolerance intervals, fitting normal PDF, kernel density estimation techniques, and using nonparametric distribution to fit data samples. A comparison and further details about these techniques can be found in [14, 73].

2.3.2 Uncertainty Quantification and Reliability Analysis

Uncertainty quantification and reliability analysis aim to simulate and ensure the performance of a system or component, i.e., that the envisioned tasks are efficiently performed by the design over its lifetime. In principle, uncertainty quantification can be performed by direct Monte Carlo simulation. In practical cases, such approach is infeasible, due to the number of simulations required. In addition, generalized probabilistic approaches can be extremely demanding in terms of computational costs, and the availability of efficient and flexible computational framework is of paramount importance [12, 58, 79].

COSSAN-X contains the most recent and advanced simulation methods, as summarized in Table 56.2. Approximated methods such as FORM and SORM [27] are available as well. Since the selection of the most appropriate simulation tool and the corresponding settings is in general not an easy task for a nonexpert in stochastic analysis, COSSAN-X provides wizards and predefined setting for supporting users in the selection of the approach for performing efficiently nondeterministic analysis as shown in Fig. 56.17.

2.3.3 Optimization Tools

In today's engineering practice, optimization is an indispensable step of the design cycle of a product. By means of optimization, engineers can reach significant reductions in terms of the manufacturing and operating costs, as well as the

improvement in the performance. The optimization toolbox provides a set of widely used gradient-based and gradient-free algorithms both for small- and large-scale analysis, which can be adopted to solve real-life problems involving continuous or discrete design variables, multiple constraints, and objective functions. Again, the toolbox also provides the necessary guidance and assistance to the users for the selection of the most appropriate optimization method (see wizard in Fig. 56.18).

A wide choice of algorithms for dealing with different types of optimization problems is available and summarized in Table 56.3. Specialized strategies to deal explicitly with uncertainties are available as well (see, e.g., [8, 37, 46, 60, 86, 92, 94]).

2.3.4 Meta-modeling

In applications where a costly numerical model is to be evaluated multiple times (such as in the case of stochastic analysis). One way to reduce the analysis time is to use meta-models which approximate the quantities of interest at low computational costs. In other words, meta-models mimic the behavior of the original model (e.g., FE analysis), by means of a mathematical model with negligible computational cost. Using the features of this toolbox, the user can interactively train meta-models to replace their complex models and calibrate them to a desired accuracy. Then,

the constructed meta-model can be used for performing uncertainty quantification, sensitivity analysis, optimization, etc. Figure 56.19 shows an example of meta-model in COSSAN-X. The meta-model is created using a set of training (calibration) points and validated using a different set of points.

A number of different meta-modeling techniques are implemented as shown in Table 56.4.

2.3.5 Stochastic Finite Element Toolbox

Stochastic finite element methods (SFEM) extend the capabilities of the classical deterministic finite element analysis, in order to take the structural uncertainties into account and to propagate the unavoidable uncertainties in the structural responses (see e.g., [31, 78, 90]).

Intrusive implementations of SFEM are available for NASTRAN, ABAQUS, and ANSYS, and different and widely used formulations such as perturbation, Neumann expansion, and polynomial chaos expansion are provided.

The main capabilities of the SFEM toolbox are summarized in Table 56.5.

Analysis Types	Linear static, modal

2.3.6 Sensitivity Analysis

Sensitivity toolbox allows to study the relationship between the input and output quantities in a model and to identify the most significant variables affecting the response. Consequently, sensitivity analysis is particularly used for model calibration, model validation, and decision-making process purposes, i.e., where it is crucial to identify the parameters which contribute mostly to the output variability.

Sensitivity analysis may be divided into three broad categories: local sensitivity analysis, screening methods, and global sensitivity analysis. Local sensitivity analysis provides information about the system behavior around a selected point in

Table 56.6 Overview of the sensitivity approaches available in COSSAN-X

Sensitivity tool	References
Monte Carlo gradient estimation	[45, 59, 97]

Nonspecificity technique	[2]

the input domain, while global sensitivity analysis techniques consider the entire range of the input parameters into account. Screening techniques (or one factor at a time) simply vary one factor at a time and measure the variation in the output.

When epistemic uncertainty is present, the sensitivity analysis can be performed constructing an equivalent model that takes as inputs the values of epistemic uncertainties and returns a scalar quantity. Alternatively, the Hartley-like measure of nonspecificity can be used which does not require the calculation of the probability box associated to the output Dempster-Shafer structure. More details about the approaches to deal with epistemic uncertainty are available in Ref. [68].

COSSAN-X offers various algorithms for the sensitivity analysis, which are summarized in Table 56.6.

2.3.7 High-Performance Computing and Data Management

The computational framework provides transparent access to high-performance computing with any algorithms implemented into the framework.

The analysis of complex systems usually requires the evaluation of different solvers that should run in a specific order. For instance, one solver is preparing the mesh for the FE analysis and another solver is used for post-processing the analysis. The execution of the solvers in the specific order is dealt by COSSAN creating tasks that contain all the commands required to run the solver and some specific commands to copy files among the working directories of the solvers (see Fig. 56.20). Stochastic analyses can also be split in batches (Fig. 56.20). A batch represents a full independent analysis (i.e., execution of tasks). This allows to perform checking the convergence of the analysis or adding more samples in order to refine the analysis.

COSSAN-X performs the parallelization of the stochastic analyses by splitting the analysis on subtasks or jobs and interfacing with industry standard job schedulers, such as GridEngine, Platform/LSF, or OpenLava. These jobs are distributed among the available (remote) resources on a computer cluster and/or grid. The software allows to maximize the use of the available licenses while reducing the execution time (wall clock time) of the analysis task. The software provides different execution and parallelization strategies summarized in Fig. 56.21. In the first parallelization strategy (vertical parallelization), each task (job) performs the analysis of one realization of the input parameters and executes all solvers. Using this strategy, all the solvers run on the same machine (host) selected by the Job Manager. In the second parallelization strategy (horizontal parallelization), first all the executions of

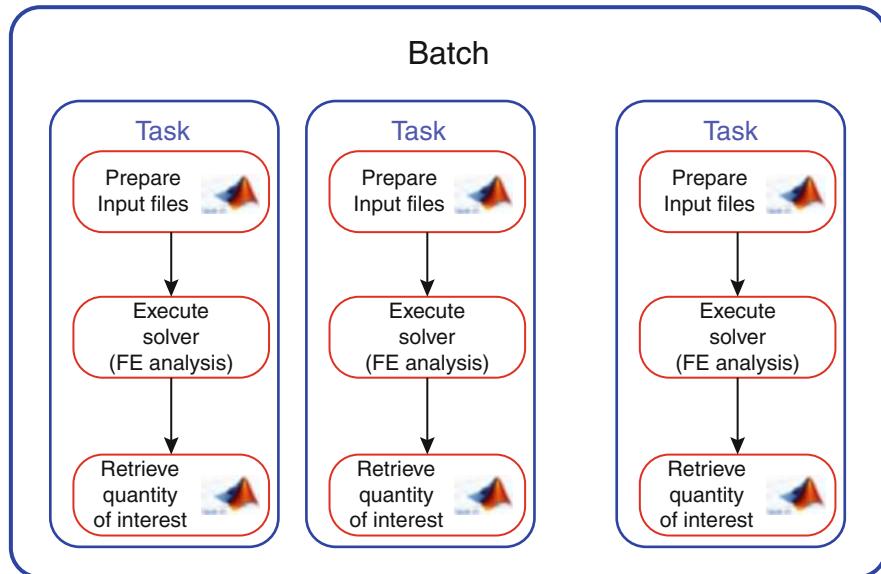

Fig. 56.20 COSSAN-X High-performance computing: splitting of the analysis batches and tasks. The task represents an execution of the solver and it involves the preparation of input files and the collection of the quantity of interest. A batch is a collection of tasks

the first solver are performed, then the second one, and so on. This allows to run each solver on specific machines (hosts) by selecting different queues for different jobs. The third parallelization strategy (granular parallelization) combines the first two methods. Using this approach, dependent jobs are submitted to the Job Manager (e.g., job involving the execution of the second solver starts after the completion of the job involving the first solver).

COSSAN-X High-Performance Computing: Parallelization Strategies. In the vertical parallelization, each job is formed by a full (deterministic) analysis and multiple jobs form the stochastic analysis. In the horizontal parallelization, a job runs only one solver with a specific number of analyses. Then when all the executions of the first solver are completed, job for the analysis of the next solver is submitted. In a granular parallelization, each solver and each (deterministic) analysis form a job. Dependent jobs are submitted to the Job Manager (i.e., a job involving a solver number j is running only after the completion of the corresponding job for the solver $j - 1$).

An important feature is the possibility to use high-performance computing (HPC) resources from machines running different operating systems (i.e., MS Windows, MacOS, and different Linux distributions). COSSAN-X allows the user to define a connection to the head node of a cluster through a secured connection over the Internet (SSH) as shown in Fig. 56.22. By doing so, the user interface is running locally and submits jobs on the HPC when needed. After the jobs are completed, the results are retrieved on the local machine.

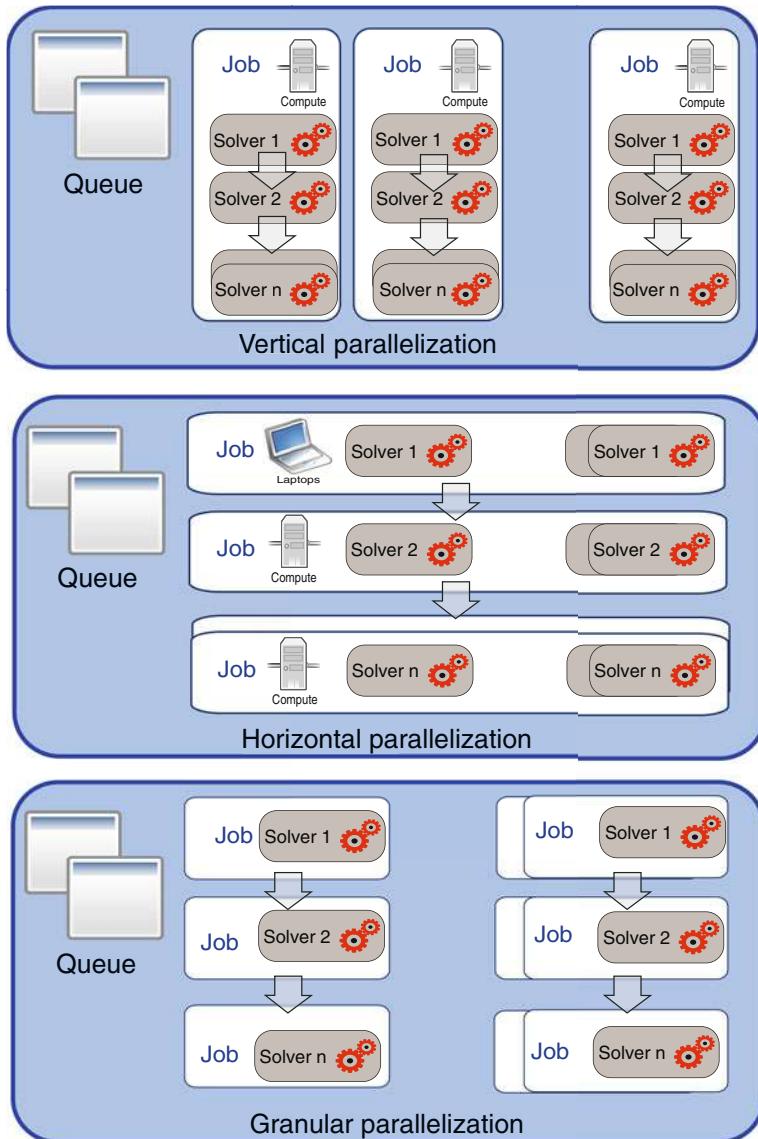

Fig. 56.21 COSSAN-X high-performance computing: parallelization strategies. In the vertical parallelization, each job is formed by a full (deterministic) analysis and multiple jobs form the stochastic analysis. In the horizontal parallelization, a job runs only one solver with a specific number of analyses. Then when all the executions of the first solver are completed, job for the analysis of the next solver is submitted. In a granular parallelization, each solver and each (deterministic) analysis form a job. Dependent jobs are submitted to the Job Manager (i.e., a job involving a solver number j is running only after the completion of the corresponding job for the solver $j - 1$)

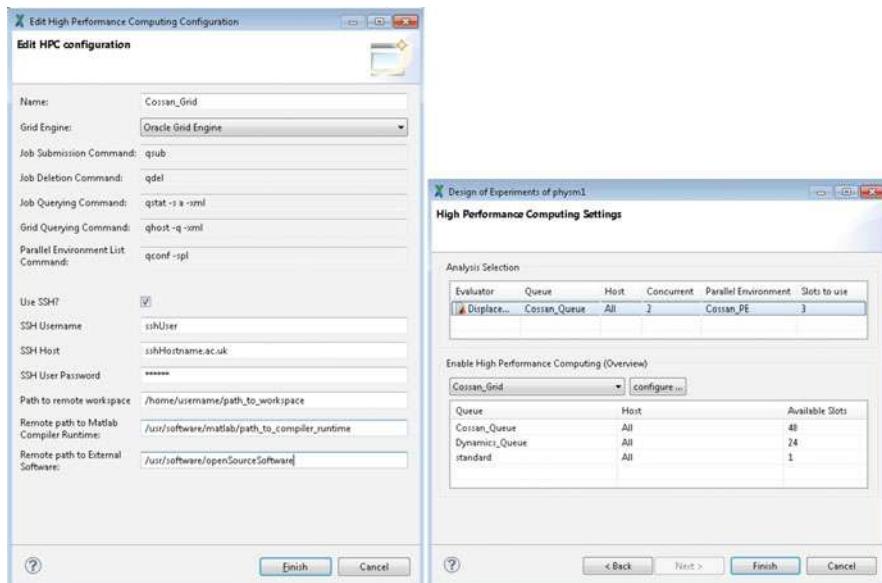

Fig. 56.22 COSSAN-X high-performance computing: definition of setting to access the cluster-/grid computing via Secure Shell (on the *left panel*). Screenshot of the interface for the definition of jobs (i.e., solution of solvers, queues, host, machine, and number of slots (e.g., processors) to be used (on the *right panel*)

Performing a stochastic analysis requires the multiple executions of the solvers. Hence a huge amount of data are generated and they need to be easily accessible to the analyst and properly stored. COSSAN-X allows to store the results of the analysis locally (using an auto-configured SQLite database) or remotely (in a centralized MySQL-like database). The database management is completely transparent to users and data are automatically stored in the user-preferred location that can be accessed directly from COSSAN-X using a dedicated interface shown in Fig. 56.23.

2.3.8 Open and Collaborative Documentation

The availability of an extended documentation, tutorials, and examples is of paramount importance for the usability of a software. Often, such documentation is written in the form of relatively long pages/tutorials. Typically users do not have the inclination/time to read long help articles. Instead, they simply want to know how to get to the next step of whatever process they are carrying out. For this reason the documentation of COSSAN-X is context sensitive. Tooltips and direct access to specific documentation related to the current task performed by the user (e.g., defining random variable, selecting solution strategy, visualizing results) are available without overwhelming the user with unnecessary information.

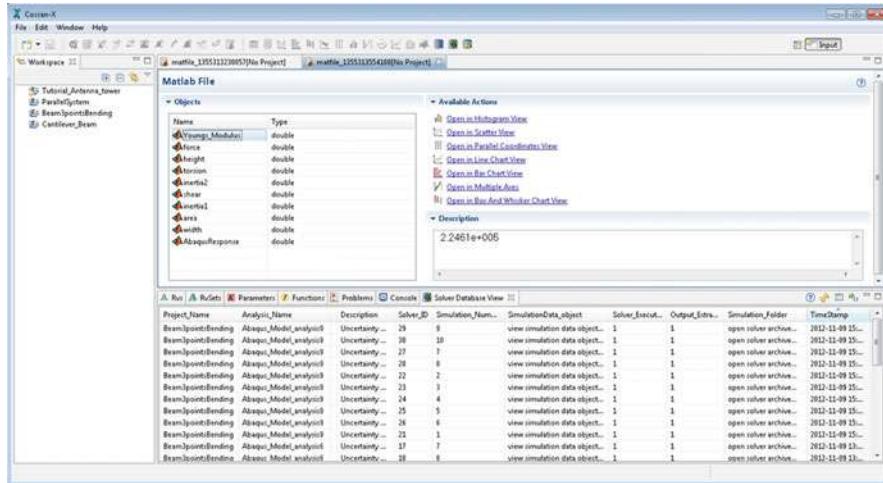

Fig. 56.23 COSSAN-X data management: the analyses can be stored in a local (e.g., SQLite) or centralized (e.g., SQL) database and all the analyses are accessible using the provided interface

In addition, theory manual, tutorial, and examples are maintained using MediaWiki tool to provide open access allowing collaborative development of the documentation (see Fig. 56.24). In addition, industrial users need to create private extensions to the help system, specific to their requirements and work processes.

2.4 OPENCOSSAN: An Open-Source Matlab Toolbox

OPENCOSSAN represents the computational core of the COSSAN project and contains a collection of open-source algorithms, methods, and tools under continuous development at the Institute for Risk and Uncertainty, University of Liverpool, UK [67]. Released under the terms of the GNU Lesser General Public License [30], OPENCOSSAN can be used for free, redistributed, and/or modified. The source code is available upon request at the web address <http://www.cossan.co.uk> or it can be downloaded automatically via the OPENCOSSAN Matlab App (as shown in the following section).

OPENCOSSAN is coded exploiting the object-oriented Matlab® programming environment, where it is possible to define specialized solution sequences, which include reliability methods, sensitivity analysis, optimization strategies, surrogate models, and parallel computing strategies. The computational framework is organized in packages. A package is a namespace for organizing classes and interfaces in a logical manner, which makes large software project OPENCOSSAN easier to manage. A class describes a set of objects with common characteristics such as data structures and methods. Objects that are instances of classes can be aggregated

Category:Getting Started

This section provides the links to basic step-by-step guides, detailing the processes required to install **COSSAN-X** and **OpenCOSSAN** onto your computer. The OpenCOSSAN Engine is an invaluable tool for uncertainty quantification and management representing the core of the COSSAN software, while COSSAN-X is a software package developed to make the concepts and technologies of uncertainty quantification and risk analysis available. The below guides offer a walk through guide to get the software up and running on your computer, and provides detailed guides on installation for operating systems: **Windows**, **Linux** and **MacOS**.

At the bottom of the page, users can also find the links to several further pages detailing information on the running of the software, known bugs within the software packages and some basic information on the importing of tutorials. The below pages provide users with the basic information needed to get started using the software packages.

COSSAN-X [edit]

The page [Installation of COSSAN-X](#) describes how to install a version of **COSSAN-X** on your machine. To access **COSSAN-X** from a remote machine using **NoMachine** connection tools, see [Run COSSAN-X remotely](#). Users are able to access an easy to follow guide, providing links to the required downloads, and screenshots to take users through the download process.

More information can be found for Cossan-X through the following link: [Category:COSSAN-X](#)

OpenCOSSAN [edit]

The page [Installation of OpenCOSSAN Engine](#) provides users with an easy to follow guide, taking you through, in detail, the steps required to get **OpenCOSSAN** installed and up and running on your computer.

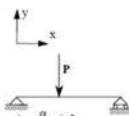

Beam 3-point bending (overview)

This tutorial is also available for OpenCossan in:

- echodemo TutorialBeam3PointBendingMatlab
- echodemo TutorialBeam3PointBendingNastran
- echodemo TutorialBeam3PointBendingAnsys
- echodemo TutorialBeam3PointBendingAbaqus

Tutorial for COSSAN-X
File -> New -> Tutorial -> Tutorial 2: Beam 3-point bending (see also Import tutorial)

This example considers a beam in three points bending. It will be studied using several third-party software and various toolboxes from COSSAN-X.

The presentation of the mechanical model and its implementation in the different toolboxes are in the pages linked below. The model is analysed using either a [Matlab script](#) or using a third party finite element software ([Nastran](#), [Abaqus](#) and [Ansys](#)). Then simulation analysis is performed to investigate the effects of the uncertainties on the mid-span displacement. Finally the tutorial shows how to perform [reliability analysis](#) using this example. Both the uncertainty quantification and the reliability analysis can be executed on the grid using [High Performance Computing](#).

forming more complex objects and proving solutions for practical problem in a compact, organized, and manageable format. The structure of OPENCOSSAN allows for extensive modularity and efficient code reutilization. Objects (instances of a class) can be aggregated forming more complex objects with methods providing solutions for practical problem in a compact, organized, and manageable format. Hence, different objects and methods can be combined by the users to solve specific problems, including uncertainty quantification, sensitivity analysis, reliability analysis, and robust design. Such problems can be solved by adopting traditional probabilistic approaches as well as by generalized probabilistic methods. Thanks to the modular nature of OPENCOSSAN, it is possible to define specialized solution sequences including any reliability method, optimization strategy, and surrogate model or parallel computing strategy to reduce the overall cost of the computation without loss of accuracy. Figure 56.25 shows a simplified representation of the computational framework and the dependencies among the different toolboxes.

OPENCOSSAN does not provide a dedicated user interface, but it relies on Matlab Desktop framework that provides a high-level language and interactive environment for numerical computation, visualization, and programming as shown in Fig. 56.26. In particular the *current folder* panel is used to access files, while the command windows is used to enter commands and interact with OPENCOSSAN (see Fig. 56.27). Finally, the Matlab editor allows to visualize, debug, extend, or modify any part of OPENCOSSAN.

```

Fig. 56.28 Example of a OPENCOSSAN script. The script shows the procedure to instantiate objects by calling the corresponding constructors (e.g., an object MonteCarlo is created as follows: “Xmc=MonteCarlo”). Then, the objects can be used accessing their methods (e.g., the failure probability is computed invoking the method computeFailureProbability of the object “Xmc”) and providing a ProbabilisticModel object (e.g., “Xpf=Xmc.computeFailureProbability(XprobModel)”).

OPENCOSSAN provides intuitive, clear, well-documented, and human readable interfaces to the classes. Hence, the OPENCOSSAN code can also be used by users not familiar with Matlab environment. Figure 56.28 shows a Matlab script based on OPENCOSSAN toolbox for solving a reliability problem. The approach adopted

to solve a user-defined problem depends on the representation of the uncertain quantities. In fact, uncertainties can be defined as distributional or free p-boxes, random variables, intervals, fuzzy, etc. Hence, if the uncertain quantities are defined by means of random variables, the framework will estimate the failure probability using Monte Carlo simulation or advanced Monte Carlo methods (subset simulation [4, 5, 56] in the example of Fig. 56.28). On the other hand, if uncertain quantities are defined as intervals or p-boxes, the framework will estimate the bounds of the failure probability. The user can freely control the computational strategies: as an example it is possible to estimate the bounds of the failure probability by means of a double loop Monte Carlo simulation, or by means of tailored solution strategies, e.g., combining an optimization strategy with the line sampling method [24]. Furthermore, the developed numerical methods are highly scalable and parallelizable, thanks to its integration with distributed resource management, such as openlava and GridEngine. These job management tools allow to take advantages of high-performance computing resources.

2.4.1 OPENCOSSAN Matlab App

OPENCOSSAN Matlab App is an interactive application design to assist the end user to obtain easily the OPENCOSSAN source files, access the documentation (help, tutorials, and reference manual), assist the installation phase, and initialize the OPENCOSSAN toolbox. It allows to keep the local version synchronized with the upstream version of the software without the need to configure or install any software versioning and revision control system.

OPENCOSSAN Matlab App is available in www.cossan.co.uk and in Matlab File Exchange and it can be installed in just one click. Then, it will be accessible in the Apps tab of the MATLAB Toolstrip. Figure 56.29 shows an example of the Matlab application tab with the installed OPENCOSSAN Matlab App and a screenshot of the App.

2.5 Engineering Cloud

It is recognized that the application of virtual engineering/prototyping for reducing engineering risks is fundamental to the future success of high-value manufacturing and engineering to bring the most sophisticated technology to market as quickly and cheaply as possible. To meet these challenges, the industry (and in particular aerospace industry) is making increasing use of the so-called virtual prototyping with the aim of physical testing to be eliminated until the final verification phases. However, simulations of virtual prototypes are becoming more comprehensive involving the investigation of multiple variants using different disciplines, thus requiring multi-physics solutions, multidisciplinary optimization, design of experiments, and robustness analyses. This, combined with the need for real-time simulation to support business decision making, is driving the requirement for a new cloud structure which not only requires on-demand computational power but more importantly needs ease of use and tailored application-driven capabilities.

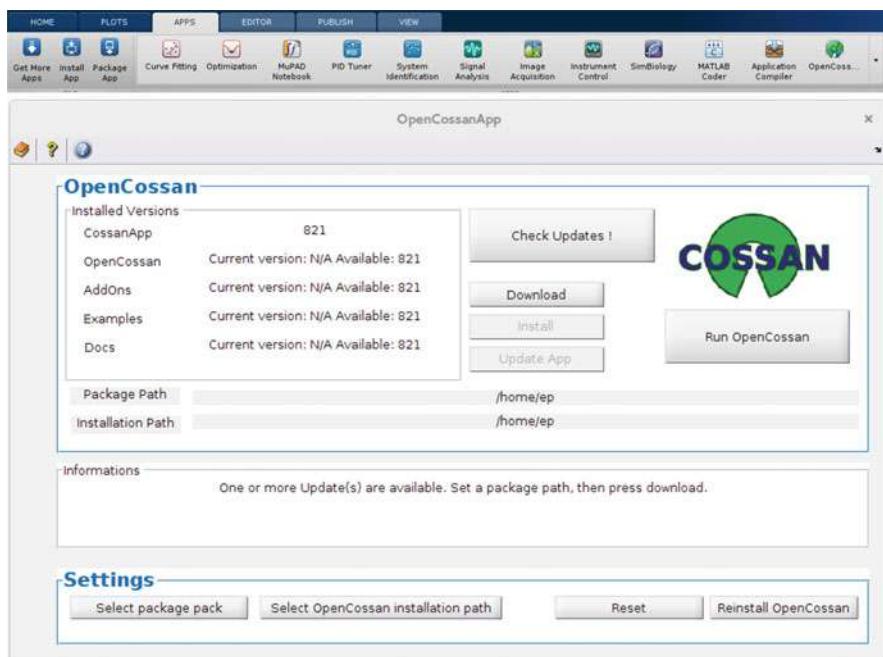

Fig. 56.29 OPENCOSSAN Matlab App. In the upper part of the figure, the Matlab application bar is shown

A combination of technological, social, and economic barriers, including lack of skills, knowledge, flexibility, and affordability of software licensing models and initial costs for computer facilities (including setting up costs and maintenance), is preventing companies from adopting modern software solutions. Hence, in order to meet these needs, COSSAN-X has been integrated into the “Engineering Cloud” project led by the Virtual Engineering Centre (Virtual Engineering Centre, STFC Daresbury Laboratory, Daresbury Science & Innovation Campus, Warrington, WA4 4AD, www.virtualengineeringcentre.com). The “Engineering Cloud” offers “virtual prototypes on demand,” promoting a culture to develop and host “engineering apps,” enabling front-end users to develop locally complex multidisciplinary workflows and upload them in the cloud through a secure web-based interface and perform, e.g., stochastic analysis, robust design, etc. In order to perform such analyses, a range of (deterministic) software tools are combined with COSSAN software and in-house solutions. Thereafter, the execution of the analyses is handled by the cloud taking advantage of the HPC facilities as well as the pool of integrated software as shown schematically in Fig. 56.30.

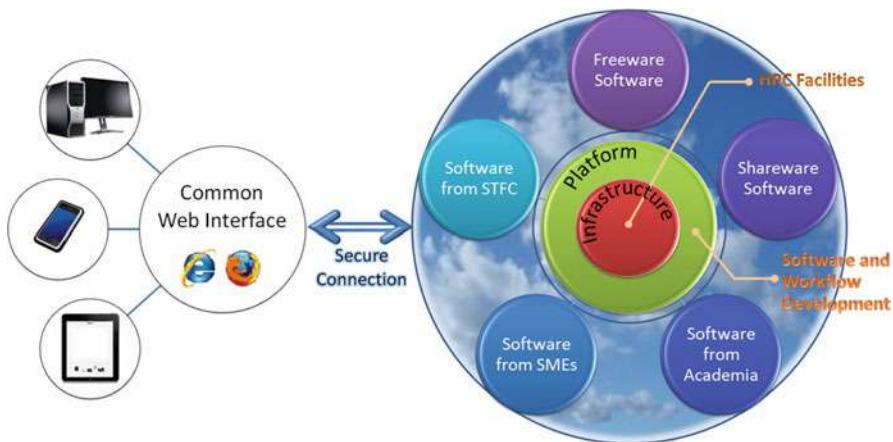

Fig. 56.30 Schematic concept of the Engineering Cloud developed and led by the Virtual Engineering Centre

3 Case Studies

In this section, selected challenging problems are briefly presented in order to demonstrate the applicability and flexibility of the software to solve a wide range of engineering and scientific problems. The first example presents a series of analyses and methodologies that can be used for dealing with aleatory and epistemic uncertainties in a multidisciplinary model. The second example shows the reliability analysis of a large-scale finite element model of a six-story building involving imprecision in the definition of the random variables. In the third example, the robust design of a truss roof is presented. The last example addresses the problem of designing a robust maintenance scheduling for components and systems in the presence of aleatory and epistemic uncertainty.

3.1 Application to the Robust Design of a Twin-Jet Aircraft Control System

NASA Langley Research Center has recently proposed a challenge problem in order to determine limitation and range of applicability of existing uncertainty quantification (UQ) methodologies and to advance the state of the practice in UQ problem. The reader is referred to Ref. [23] for a full description of the NASA UQ challenge problem.

OPENCOSSAN has been used to solve all the tasks proposed in the challenge problem. Here only a small selection of the main findings are reported, and results of the NASA UQ challenge problem are available in Ref. [66].

3.1.1 The Model

A multidisciplinary model that describes the dynamic of a remotely operated twin-jet aircraft has been developed by NASA Langley Research Center to provide an in-flight validation capability for high-risk flight testing beyond the normal flight envelope. The overall aim of the analysis is to identify design points that provided optimal worst-case probability performance in the presence of uncertainty of the control system for the Airborne Subscale Transport Aircraft Research (AirSTAR).

The mathematical model of the AirSTAR test aircraft, S , has been treated as a “Black Box.” The uncertain parameters in the model, p_i , $i = 1, \dots, 21$, are used to describe losses in control effectiveness and time delays resulting from telemetry and communications and to model a spectrum of flying conditions that extend beyond the normal flying envelope. The outputs of S , i.e., the requirements in g_j , $j = 1, \dots, 8$, are used to describe the vehicle stability and performance characteristics in regard to pilot command tracking and handling/riding qualities. Fourteen design parameters, d_k , $k = 1, \dots, 14$, can be tuned to optimize the robustness of the system.

The uncertain parameters are modeled accounting aleatory and epistemic uncertainty. The aleatory is modeled by the use of random variables with fixed function form and known coefficient. The epistemic uncertainty is modeled by the use of interval of fixed but unknown constants. Finally, distributional p-boxes are adopted if the parameters are affected by combined aleatory and epistemic uncertainty. The aim of the analysis is to identify a design point with improved robustness and reliability by minimizing the expectation of the maximum of the output, $J_1 = E[\max_j(g_j)]$, and minimizing the upper bound of the probability of failure $J_2 = P(g_j < 0)$. Figure 56.31 shows a schematic representation of the multidisciplinary model; the sub-models \mathbf{h} , \mathbf{f} ; intermediate variables \mathbf{x} ; and

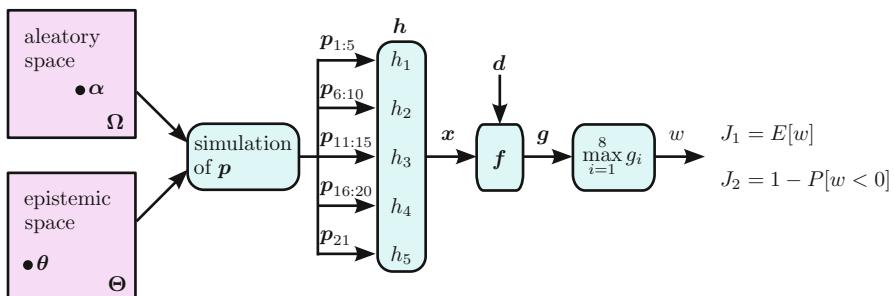

Fig. 56.31 Relationship between the variables and functions of the NASA Langley multidisciplinary uncertainty quantification challenge problem [50]

different performance function g . A detailed description of the problem can be found in [23].

3.1.2 Proposed Approach

Different tools and approaches exist for uncertainty quantification and characterization that can be potentially used in the design and safety-critical systems. Every method is based on some assumptions and hypothesis that often cannot be verified a priori. Moreover, the simulation strategies are able to produce accurate results only if the right set of parameters are selected and this often cannot be verified. Hence, different analyses have been performed using different strategies and hypothesis in order to *cross-validate* the results.

Many of the proposed solutions to the challenge problem make use of the random set theory [3, 47]. Random set theory allows to model under the same framework different representations of the uncertainty (such as cumulative distribution functions, intervals, distribution-free probability boxes, normalized fuzzy sets, and Dempster-Shafer structures) without making any implicit or explicit assumption at all.

3.1.3 Uncertainty Reduction

The aim of model updating is to reduce the epistemic uncertainty on the output of the model $x = h(\alpha; \theta)$ based on the availability of a limited set of data (observations) $\{x_k^e : k = 1, 2, \dots, n_e\}$. These observations of the “true uncertainty model” $\theta^* \in \Theta$ can be used to improve the uncertainty model, i.e., to reduce the original intervals of the epistemic uncertainties by excluding those combinations of parameters that fail to describe the observations as shown in Fig. 56.32. Different approaches can be used for model updating such as nonparametric approaches based on some statistical tests and Bayesian methods. Here, only the Bayesian method is briefly presented.

Bayesian inference is a statistical method in which Bayes’ rule is used to update the probability estimate for a hypothesis as additional information is available.

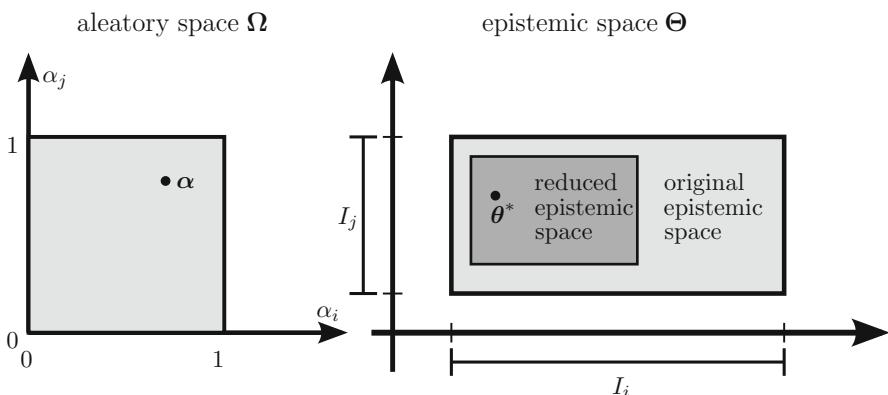

Fig. 56.32 Representation of the uncertainty reduction space for the NASA UQ challenge problem

Suppose we are given a set of observed data points $\mathcal{D}_e := \{x_k^e : k = 1, 2, \dots, n_e\}$ called the *evidence*, which are sampled from a PDF $p(\cdot; \boldsymbol{\theta}^*)$ which belongs to a certain family of PDFs $\{p(\cdot; \boldsymbol{\theta}) : \boldsymbol{\theta} \in \boldsymbol{\Theta}\}$ called the *parametric model*. The idea of Bayesian inference is to update our belief about the vector of parameters $\boldsymbol{\theta}^*$ provided that $\boldsymbol{\theta}^*$, the true set of parameters of the PDF, is unknown. Bayes' theorem updates that belief using two antecedents:

- a prior PDF $p(\boldsymbol{\theta})$ which indicates all available knowledge about $\boldsymbol{\theta}^*$ before the evidence \mathcal{D}_e is observed;
- the *likelihood function* $P(\mathcal{D}_e | \boldsymbol{\theta})$, which is a function related to the probability of observing the samples \mathcal{D}_e assuming that the true parameter underlying the model PDF $p(x; \boldsymbol{\theta})$ is $\boldsymbol{\theta}$, is defined as

$$p(\mathcal{D}_e | \boldsymbol{\theta}) = \prod_{k=1}^{n_e} p(x_k^e; \boldsymbol{\theta}), \quad (56.1)$$

when a set of independent and identically distributed observations \mathcal{D}_e is available. Please note that in practice (i.e., for the numerical implementation), the log-likelihood is used instead of the likelihood.

The updated belief about the vector of parameters $\boldsymbol{\theta}^*$ after observing the evidence \mathcal{D}_e , is modeled by the so-called posterior PDF $p(\boldsymbol{\theta} | \mathcal{D}_e)$ which is calculated by

$$p(\boldsymbol{\theta} | \mathcal{D}_e) = \frac{p(\mathcal{D}_e | \boldsymbol{\theta})p(\boldsymbol{\theta})}{P(\mathcal{D}_e)}; \quad (56.2)$$

where the probability of the evidence

$$P(\mathcal{D}_e) = \int_{\boldsymbol{\Theta}} P(\mathcal{D}_e | \boldsymbol{\theta})p(\boldsymbol{\theta}) \cdot \cdot \cdot d\boldsymbol{\theta} \quad (56.3)$$

can be understood as a normalizing constant. We hope that after using the evidence \mathcal{D}_e , the posterior PDF $p(\boldsymbol{\theta} | \mathcal{D}_e)$ is sharply peaked about the true value of $\boldsymbol{\theta}^*$. We will update our belief about the true set of parameters $\boldsymbol{\theta}^* \in \boldsymbol{\Theta}$ propagating the evidence through Bayes' equation numerically; this can be performed using an algorithm called Transitional Markov Chain Monte Carlo [21].

Using Laplace's principle of indifference (or more generally, the principle of maximum entropy), we will define a non-informative prior on the space of epistemic uncertainty $\boldsymbol{\Theta}$; in other words, a uniform PDF on $\boldsymbol{\Theta}$, that is, $\boldsymbol{\theta} \sim \text{Unif}(\boldsymbol{\Theta})$, is used to represent the epistemic uncertainty. Different likelihood functions based on different mathematical assumptions can be used. For instance, the likelihood can be estimated through kernel density or approximated using the following expression [7, 20]:

$$p(\mathcal{D}_e | \boldsymbol{\theta}_i) = \prod_{k=1}^{n_e} \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{1}{2} \left(\frac{\delta_k}{\sigma}\right)^2\right) \quad (56.4)$$

where $\delta_k = |F^i(x_k^e) - F^e(x_k^e)|$ for $k = 1, 2, \dots, n_e$ and F^i and F^e represent the empirical CDF of the $\{x_j^i : j = 1, 2, \dots, n\}$ and the experimental data \mathcal{D}_e , respectively. The values of the standard deviation are unknown and hence it represents an additional parameter that needs to be estimated during the Bayesian analysis [9].

The Bayesian updating expressed in Eq. (56.1) needs the evaluation of the normalizing factor, i.e., the denominator of Eq. (56.1). Its computation is difficult and computationally expensive. In OPENCOSSAN, to avoid the calculation of the normalizing factor, the Transitional Markov Chain Monte Carlo have been used [21]. This algorithm allows the generation of samples from the complex-shaped unknown posterior distribution through an iterative approach:

$$P_i \propto P(D|\theta, I)^{\beta_i} P(\theta|I) \quad (56.5)$$

where m intermediate distributions P_i are introduced and the contribution of the likelihood is scaled down by an exponent β_i , with $0 = \beta_0 < \dots < \beta_i < \dots < \beta_m = 1$. Thus, the first distribution is the prior distribution, and the last one is the posterior distribution. These intermediate distributions show a more gradual change in the shape from one step to the next when compared with the shape variation from the prior to the posterior.

Each realization obtained from the posterior distribution at the end of the Bayesian updating procedure identifies a possible set of input parameters (i.e., realization of the epistemic uncertainty). The aleatory uncertainty (not reduced by the Bayesian inference method) can be propagated via a Monte Carlo simulation in order to compute the empirical CDF, \hat{F} , of the quantity of interest. The collection of \hat{F}^i obtained using different realizations from the epistemic space describes the p-box of model output. Hence, it is possible to compute the quantiles for each value of the model output and identify confidence bounds of \hat{F} . Confidence bounds are then compared with the empirical distributions of the available experimental realizations, F^e , obtained using Gaussian kernel smoother function. The confidence levels allow to identify the level of refinement of the updated intervals obtained from the posterior distributions.

Figures 56.33 and 56.34 show the posterior distributions obtained for the epistemic parameters. The horizontal red lines represent the cut-off (confidence bound) using the reduced epistemic uncertainty space. For instance, the imprecision of the mean value of p_1 is reduced from $[0.6, 0.8]$ to $[0.608, 0.726]$ and $[0.626, 0.761]$ using 25 and 50 experimental observations, respectively. The results show that the experimental observations do not allow to reduce all the epistemic uncertainties. In fact the data do not contain enough information to improve the knowledge of, e.g., the correlation coefficient between p_4 and p_5 ($\rho(p_1, p_2)$).

3.1.4 Sensitivity Analysis

The aim of sensitivity analysis is to identify and rank the parameters that contribute mostly to the variability of the output of a system h_1 . Two approaches can be used:

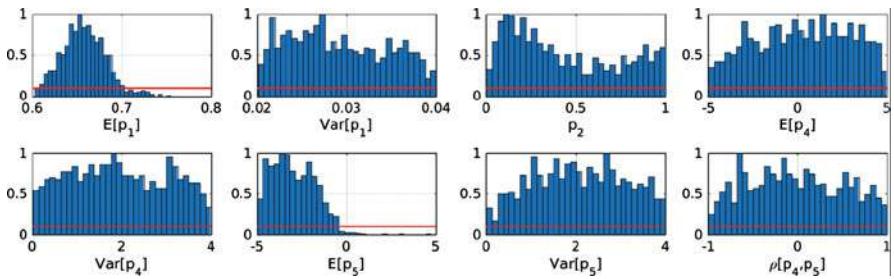

Fig. 56.33 Normalized histogram of $p(\theta | \mathcal{D}_e)$ obtained using approximate Bayesian computational method with (a) 25 experimental observations

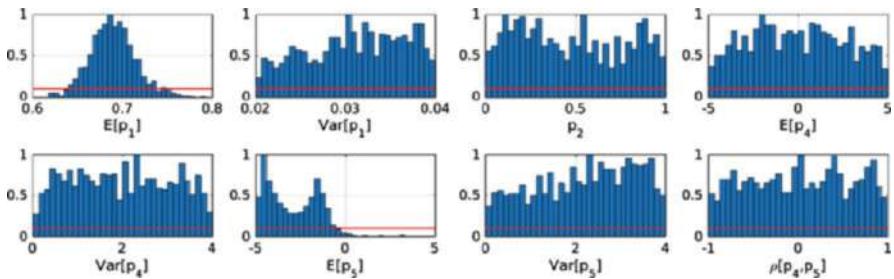

Fig. 56.34 Normalized histogram of $p(\theta | \mathcal{D}_e)$ obtained using approximate Bayesian computational method with 50 experimental observations of x_1

the Hartley-like measure of nonspecificity and the global sensitivity analysis based on the Sobol and total sensitivity measures. Both approaches can be used to deal with sensitivity analysis due to epistemic uncertainty.

The first approach is using the Hartley-like measure of nonspecificity, which is a measure of epistemic uncertainty and which does not require the calculation of the probability box associated to the output Dempster-Shafer structure after the application of the extension principle for random sets. The reader is referred to Ref. [2] for the explanation of the method. The second approach is based on global sensitivity analysis to estimate the Sobol and the total sensitivity indices [87]. The first-order Sobol indices are defined as

$$S_i = \frac{V_{X_i}[E_{X \sim i}(Y | x_i)]}{V[Y]} \quad (56.6)$$

where $V[Y]$ represents the unconditional variance of the quantity of interest and $V_{X_i}[E_{X \sim i}(Y | x_i)]$ the variance of conditional expectation. The total sensitivity index, T_i , measures the contribution to the output variance of x_i of the input factors including all interactions with any other input variables,

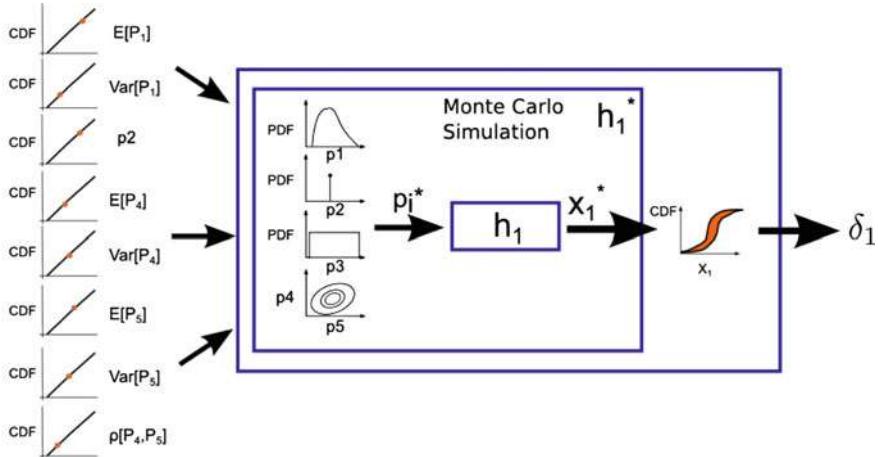

Fig. 56.35 Equivalent model used for performing global sensitivity analysis in the presence of epistemic and aleatory uncertainties. In the example shown here, the model h_1^* is used to perform the sensitivity analysis with respect to the variables x_1

$$T_i = 1 - \frac{V_{X_{\sim i}}(E_{X_i}(Y | x_{\sim i}))}{V(Y)}. \quad (56.7)$$

The global sensitivity approach cannot be applied directly to solve the problems where the uncertainty is described distributional/free p-boxes and intervals. In fact, this method requires the exact knowledge of the PDF of the input variables and the variance of a measurable model output. Global sensitivity analysis can be performed on a equivalent model (h^*), as shown in Fig. 56.35. In the model h^* , the epistemic uncertainties are represented by uniform distributions and they are the only inputs for the model. Then the model uses realizations of the input parameters to define probabilistic distribution for internal variables. The model performs an internal Monte Carlo analysis to compute a CDF of the quantity of interest. Finally, the difference between the estimated CDF and a reference CDF is computed (λ_1). Traditional algorithms (e.g., [41, 61, 77]) can be used to perform the global sensitivity analysis of the model h^* . Figure 56.36 shows an example of global sensitivity analysis obtained by adopting the equivalent model h^* and the Saltelli computational approach [77].

3.1.5 Uncertainty Propagation

For the uncertainty propagation considering aleatory and epistemic uncertainty, two main approaches exist. In the first approach, n samples from the aleatory space are drawn from the product copula $C : [0, 1]^{N_a} \rightarrow [0, 1]$ that models the aleatory dependence between the input variables. Each realization corresponds to a focal element in the theory of random set represented by α . Then using the extension principle (with the optimization method), each input focal element is

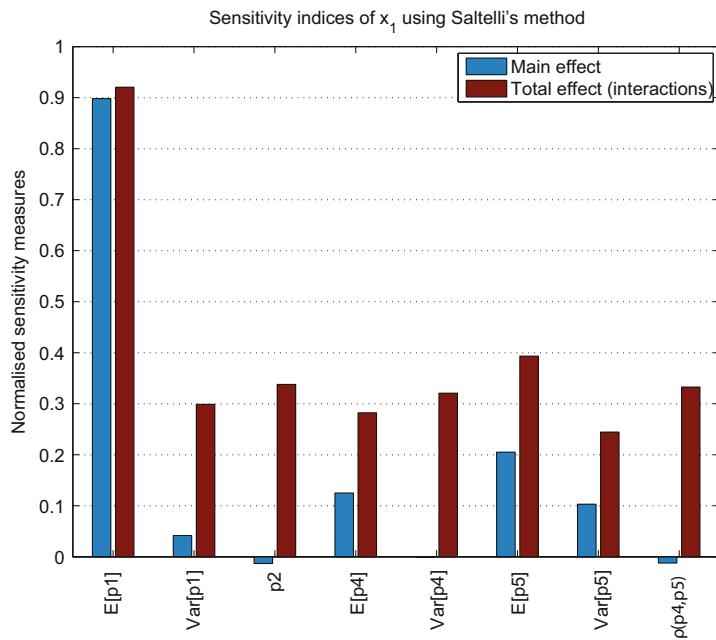

Fig. 56.36 Global sensitivity analysis with respect to the variable x_1 . The figure shows the first-order Sobol sensitivity measure and the total sensitivity indices. The results show that the first variable (mean of p_1) is the inputs that contribute the most to the variability of the output x_1

mapped through the model and a Dempster-Shafer structure with n intervals $[l_i, u_i]$ is finally obtained. Hence, each focal element has a basic mass assignment of $1/n$. It is important to point out that this approach models the probability boxes as distribution-free p-boxes. Furthermore, it requires the calculation of the image of a set through a function using the extension principle and an optimization method (Fig. 56.37).

In the second approach, the quantities of interest (e.g., mean and failure probability estimations) are used as objective functions of a global search in the epistemic space Θ . The global optimizations in the epistemic space $\Theta \equiv \times_{i=1}^{31} I_i$ are performed in order to find the set of parameters that produce the upper and lower bounds of the quantities of the interest (e.g., J_1 and J_2). Hence, for any candidate solution produced by the optimization algorithm $\theta_i \in \Theta$, a set of points $\{\alpha_j, j = 1, 2, \dots, n\}$ is randomly sampled from the aleatory space $\Omega \equiv (0, 1)^{17}$. Then, n realizations are generated according to the uncertainty models of p_1 to p_{21} and propagate to the model for computing the empirical CDF of the outputs of interest. The uncertainty propagation can be performed using simple Monte Carlo method or more advanced and efficient techniques (e.g., [25, 56, 58, 63]). Figure 56.38 shows the uncertainty quantification approach based on the global optimization in the epistemic space.

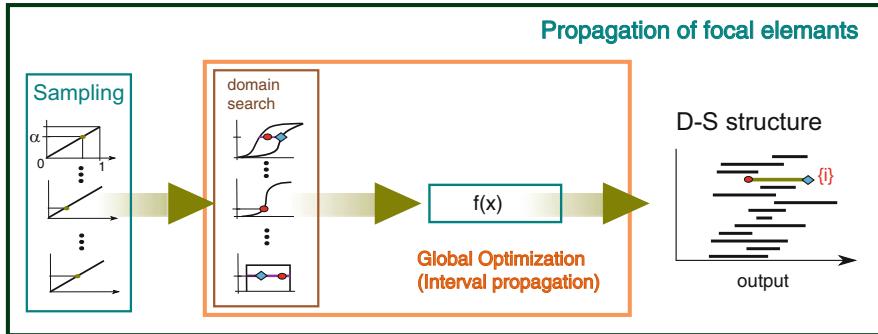

Fig. 56.37 Uncertainty quantification by means of focal element propagation. The approach requires sampling “ α -cut” and then propagates the intervals through the model and computes a Dempster-Shafer structure. The output bounds for each focal element are calculated by means of an optimization procedure

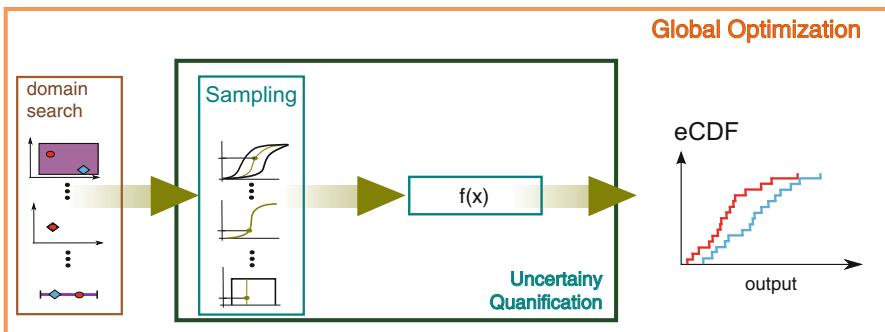

Fig. 56.38 Uncertainty quantification by means of a global optimization in the epistemic space. The inner model is a classical probabilistic problem and can be solved by adopting classical methods for uncertainty quantification

The uncertainty quantification required a double loop approach resulting in a rather challenging task in terms of computational cost. The lower and upper bound of the mean of the model response is obtained as

$$\underline{\mu} = \min_{\theta \in \Theta} \int_{\Omega} h(\alpha; \theta) dC(\alpha) \quad \bar{\mu} = \max_{\theta \in \Theta} \int_{\Omega} h(\alpha; \theta) dC(\alpha) \quad (56.8)$$

while the lower and upper bound of the probability of failure, defined as the exceedance of a critical threshold level h^{crit} of the model response, is obtained as

$$P_f = \min_{\theta \in \Theta} \int_{\Omega} \mathcal{I}[h(\alpha; \theta) > h^{crit}] dC(\alpha) \quad \overline{P_f} = \max_{\theta \in \Theta} \int_{\Omega} \mathcal{I}[h(\alpha; \theta) > h^{crit}] dC(\alpha). \quad (56.9)$$

In Eqs. 56.8–56.9 θ is a vector focal elements, C the copula, and θ the vector of aleatory uncertainty.

3.1.6 Robust Design

The final task in the design of a safety-critical system is to perform a robust design optimization. The main aim of the robust design is to consider explicitly the effects of the uncertainties in the optimization problem. This requires to repeatedly evaluate the performance of the system such as the expected values and probability of failure (the inner loop), which may require considerable numerical efforts, for each candidate solution of the optimization procedure (the outer loop).

Generally, in robust design only one bound is of interest. Nevertheless, the estimation of bounds of the system performance remains a computational challenging task. Thus, the direct solution of the robust design problem is infeasible and surrogate models need to be used. Surrogate models mimic the behavior of the original model, by means of an analytical expression with negligible computational cost. The approximation is constructed by selecting some predefined interpolation points in the design space, at which the failure probability is estimated; then, a surrogate model is adjusted to the data collected in a least square sense. OPENCOSSAN provides the access to different surrogate modes (see Table 56.4) and optimization strategies (see Table 56.3) that allow the analysis to perform efficient robust design.

3.1.7 Final Remarks

The development and design of robust safety-critical systems is a challenging problem since in general quantitative data is either very sparse or prohibitively expensive to collect. OPENCOSSAN provides numerically efficient and scalable tools that have allowed to solve each task required by the NASA Langley UQ challenge problem using two different approaches. Considering different approaches to solve the same engineering problem might be seen as a waste of resources and time. However, all the existing approaches for dealing with epistemic and aleatory uncertainty require fine-tuning of their parameters in order to be efficient and accurate. Hence, it is of paramount importance to be able to verify and cross-validate the results against a different procedure.

3.2 Large-Scale Finite Element Model of a Six-Story Building

In this example the reliability analysis of a six-story building subject to wind load is carried out. Three different models of uncertainty characterization are here considered. Firstly, a standard reliability analysis, where the inputs are modeled by precise probability distribution functions, is performed. Secondly, the structural parameters are modeled as imprecise random variables [14]. In the third analysis both imprecise random variables and intervals are considered for structural parameters.

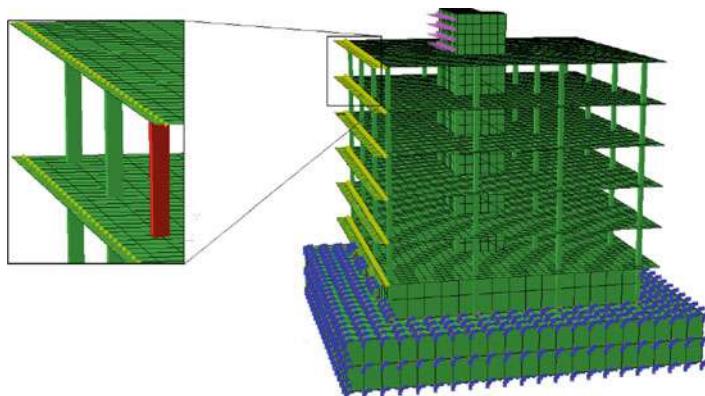

Fig. 56.39 FE model of the six-story building and selected critical component used in this analysis

Table 56.7 Distribution models for the input structural parameters for the six-story building

Parameter ID	Probability distribution	Description	Units
1	Normal (0.1, 0.001)	Column's strength	GPa
2–193	Uniform (0.36, 0.44)	Sections size	m
194–212	Log-normal (35.0, 12.25)	Young's modulus	GPa
213–231	Log-normal (2.5, 0.0625)	Material's density	kg/dm ³
232–244	Log-normal (0.25, 0.000625)	Poisson's ratio	—

3.2.1 The Finite Element Model

An ABAQUS finite element model (FEM) is built for the six-story building, as illustrated in Fig. 56.39, which includes beam, shell, and solid elements. The load is considered as combination of a (simplified) lateral wind load and the self-weight, which are both modeled by deterministic static forces acting on nodes of each floor. The magnitude of the wind load increases with the height of the building. The FEM of the structure involves approximately 8200 elements and 66,300 degrees of freedom. A total of 244 independent random variables are considered to account for the uncertainty of the structural parameters. The material strength (capacity) is represented by a normal distribution, while log-normal distributions are assigned to the Young modulus, the density, and the Poisson ratio. In addition, the cross-sectional width and height of the columns are modeled by independent uniform distributions. A summary of the distribution models is reported in Table 56.7.

Component failure for the columns of the 6th story is considered as failure criterion. The performance function is defined as the difference between the maximum Tresca stress, where $\sigma_{III} \leq \sigma_{II} \leq \sigma_I$ are the principal stresses, and the yield stress σ_y :

$$f(\boldsymbol{\theta}) = |\sigma_I(\boldsymbol{\theta}) - \sigma_{III}(\boldsymbol{\theta})| / 2 - \sigma_y, \quad (56.10)$$

3.2.2 Reliability Analysis

By using the uncertainty model reported in Table 56.7, a reliability analysis is carried out in COSSAN-X and OPENCOSSAN by means of an advanced Monte Carlo method, namely, Advanced Line Sampling [25]. The selected algorithm requires the definition of the so-called important direction. The latter is a direction that points toward the failure region. It can be provided by the analyst or it can be approximated by computing the gradient in the origin of the standard normal space. COSSAN-X can compute automatically the important direction (see Fig. 56.40), while the user needs only to define the total number of lines that will be used to estimate the failure probability.

The Advance Line Sampling procedure implemented in OPENCOSSAN and available via the graphical interface of COSSAN-X is a very efficient method. It allows to estimate accurately small values of failure probability using very limited number of samples. In fact, only 62 model evaluations (i.e., 30 lines) were necessary to estimate a failure probability of $\hat{p}_F = 1.42 \cdot 10^{-4}$ with a coefficient of variation of $CoV = 0.092$.

3.2.3 Imprecision in Distribution Parameters

In this second approach, it has been assumed that insufficient data are available to estimate exactly the parameters of the distributions in Table 56.7. Hence,

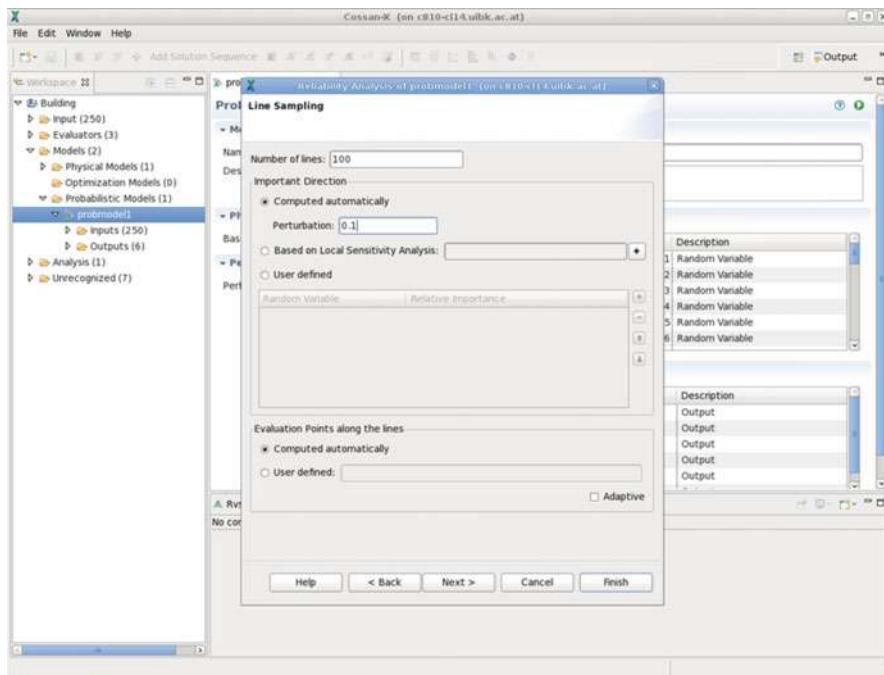

Fig. 56.40 Implementation of the reliability analysis in COSSAN-X. The screenshot shows the wizard page to define the parameters for the line sampling algorithm

intervals are used to model such indetermination. The interval parameters are represented as

$$\underline{p} = p_c (1 - \epsilon), \quad \bar{p} = p_c (1 + \epsilon) \quad (56.11)$$

using the interval center $p_c = (\underline{p} + \bar{p})/2$ and the relative radius of imprecision ϵ . These intervals $[\underline{p}, \bar{p}]$ are defined by a bounded set Q_1 of 488 parameters. In the example, all interval parameters are modeled with the same relative imprecision ϵ . In order to explore the effects of ϵ on the results, a fuzzy set is used to consider a nested set of intervals $\tilde{p} = \{\underline{p}, \bar{p}\}$ for the parameters defined by $\epsilon = \{0, 0.005, 0.01, 0.025, 0.05, 0.075\}$ as shown in Fig. 56.41. The reliability analysis with the generalized model of uncertainty is performed using the important direction determined in the physical space and then remapped in the standard normal space for each realization of the epistemic space.

Since intervals are used to characterize the uncertainty, it is not possible to estimate a single value for the failure probability. Instead, the maximum and minimum of the failure probability are computed. The failure probability is obtained as a fuzzy set, which includes the standard reliability analysis as special case with $\epsilon = 0$. Each interval for the failure probability, p_F , corresponds to the respective interval $\bar{p} = [\underline{p}, \bar{p}]$ in the input for the same membership level, and each membership level is associated with a different value ϵ . The results of the reliability analysis are shown in Fig. 56.41 (right) and summarized in Table 56.8.

OPENCOSSAN implements a very efficient algorithm to estimate the bounds of the failure probability. As shown in Table 56.8, the number of samples required to estimate the bounds of the failure probability is on average 254, which is even less than the total number of model evaluation required by two standard reliability analyses using line sampling (~ 360 samples). This is an astounding result considering that a standard approach to propagate aleatory and epistemic

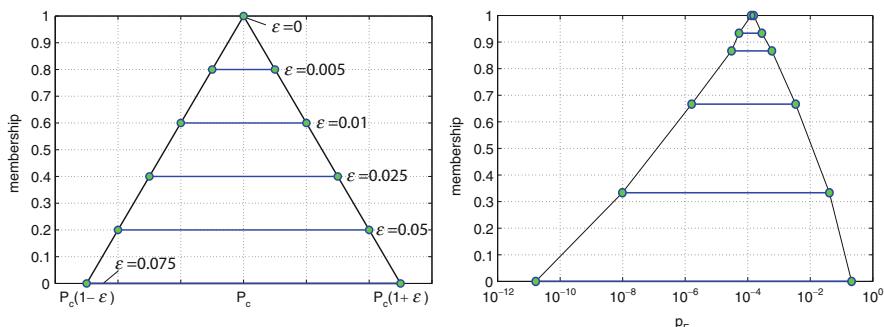

Fig. 56.41 On the left, the fuzzy parameters $\tilde{p} = \{p_c [1 - \epsilon_j, 1 + \epsilon_j]\}_{j=1}^6$ used to model the imprecision in the probabilistic model. On the right, the fuzzy failure probability obtained as a set of results for different levels of imprecision

Table 56.8 Results of the robust reliability analysis of the multistory building from model considering imprecision in distribution parameters. The results are obtained in terms of lower and upper bounds of the failure probability for different values of imprecision ϵ

Imprecision level ϵ	Lower bound		Upper bound		Number of samples N_s
	\underline{p}_F	CoV	\bar{p}_F	CoV	
0.000	$1.42 \cdot 10^{-4}$	$9.2 \cdot 10^{-2}$	$1.42 \cdot 10^{-4}$	$9.2 \cdot 10^{-2}$	126
0.005	$5.75 \cdot 10^{-5}$	$8.7 \cdot 10^{-2}$	$2.63 \cdot 10^{-4}$	$7.1 \cdot 10^{-2}$	257
0.010	$4.57 \cdot 10^{-5}$	$33.6 \cdot 10^{-2}$	$5.30 \cdot 10^{-4}$	$11.5 \cdot 10^{-2}$	250
0.025	$1.75 \cdot 10^{-6}$	$8.8 \cdot 10^{-2}$	$3.22 \cdot 10^{-3}$	$5.3 \cdot 10^{-2}$	253
0.050	$2.27 \cdot 10^{-8}$	$57.0 \cdot 10^{-2}$	$3.88 \cdot 10^{-2}$	$5.4 \cdot 10^{-2}$	255
0.075	$1.88 \cdot 10^{-11}$	$12.2 \cdot 10^{-2}$	$2.02 \cdot 10^{-1}$	$3.5 \cdot 10^{-2}$	254

Table 56.9 Input definition from uncertainty model. The relative radius of imprecision is $\epsilon = \{0, 0.01, 0.015, 0.020, 0.025, 0.03\}$

Parameter ID	Uncertainties type		$\bar{p} = p_c [1 - \epsilon, 1 + \epsilon]$, $\bar{x} = [\underline{x}, \bar{x}]$	
1	Distribution	$N(\bar{\mu}, \bar{\sigma}^2)$	$\mu_c = 0.1$	$\sigma_c^2 = 0.001$
2 – 193	Interval	\bar{x}	$\underline{x} = 0.36$	$\bar{x} = 0.44$
194 – 212	Distribution	$LN(\bar{m}, \bar{v})$	$m_c = 35$	$v_c = 12.25$
213 – 231	Distribution	$LN(\bar{m}, \bar{v})$	$m_c = 2.5$	$v_c = 0.0625$
232 – 244	Distribution	$LN(\bar{m}, \bar{v})$	$m_c = 0.25$	$v_c = 0.000625$

uncertainty, driven by two nested loops, would have required several hundreds of thousands of model evaluations (see, e.g., [69]).

3.2.4 Imprecision in Both Distribution Parameters and Structural Parameters

In this example, 192 input parameters $x \in \mathbb{R}^{192}$ are modeled as interval variables, while the 52 remaining structural parameters $\xi \in \mathbb{R}^{52}$ are considered as imprecise random variables (see Table 56.9). The imprecise distribution parameters are modeled using the radius of imprecision ϵ , as in the previous case. The relative radii of imprecision $\epsilon = \{0, 0.01, 0.015, 0.020, 0.025, 0.03\}$ are considered to construct a fuzzy model for all parameters (see Fig. 56.42 (left)).

The results of the reliability analysis are shown in Table 56.10 and in Fig. 56.42 (right). Again, the computational tool is very efficient requiring on average only 254 model evaluations for the estimation of the bounds for each level of imprecision, ϵ . The results show that the level of uncertainty is much larger compared to the previous cases. This is mainly due to the imprecision introduced in the modeling of the cross sections.

3.2.5 Final Remarks

COSSAN-X and the computational framework based on OPENCOSSAN implement very efficient strategies for reliability analysis adopting different representations of the uncertainty. The approaches couple an advanced sampling-based algorithm

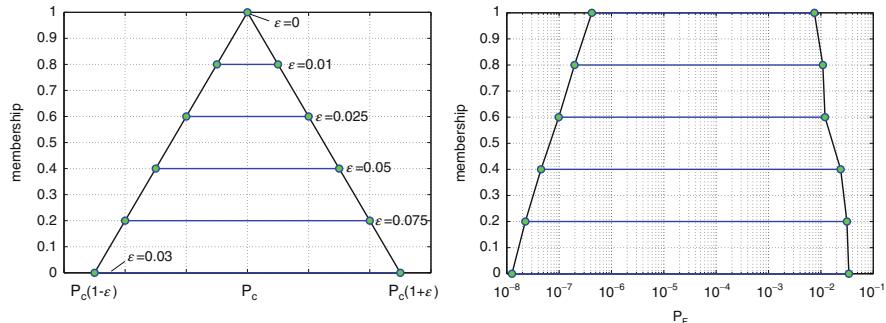

Fig. 56.42 On the left, the fuzzy distribution parameters $\tilde{p} = \{p_c [1 - \epsilon_j, 1 + \epsilon_j]\}_{j=1}^6$. On the right, the estimated fuzzy failure probability for the six-story building

Table 56.10 Results of the robust reliability analysis of the multistory building from model with imprecision in both distribution parameters and structural parameters. The results are obtained in terms of lower and upper bounds of the failure probability

Imprecision level	Lower bound		Upper bound		Number of samples
	\underline{p}_F	CoV	\overline{p}_F	CoV	
0.000	$4.70 \cdot 10^{-7}$	$10.2 \cdot 10^{-2}$	$6.73 \cdot 10^{-3}$	$11.5 \cdot 10^{-2}$	259
0.010	$2.28 \cdot 10^{-7}$	$13.4 \cdot 10^{-2}$	$9.71 \cdot 10^{-3}$	$12.2 \cdot 10^{-2}$	247
0.015	$1.10 \cdot 10^{-7}$	$10.3 \cdot 10^{-2}$	$1.11 \cdot 10^{-2}$	$7.6 \cdot 10^{-2}$	255
0.020	$5.19 \cdot 10^{-8}$	$13.1 \cdot 10^{-2}$	$2.08 \cdot 10^{-2}$	$14.6 \cdot 10^{-2}$	255
0.025	$2.51 \cdot 10^{-8}$	$9.97 \cdot 10^{-2}$	$2.72 \cdot 10^{-2}$	$15.3 \cdot 10^{-2}$	249
0.030	$1.40 \cdot 10^{-8}$	$9.94 \cdot 10^{-2}$	$3.21 \cdot 10^{-2}$	$6.5 \cdot 10^{-2}$	254

with optimization procedures. The advanced computational method dramatically reduces the computational costs of the reliability analysis without compromising the accuracy of results and allows to perform the reliability analysis adopting the real FE model without the necessity to train a surrogate model. The advantage of considering explicit imprecision can be fully appreciated in a design context. In fact, the results can be used to identify a tolerable level of imprecision for the inputs given a constraint on the maximum tolerable failure probability. For example, fixing an allowable failure probability of 10^{-3} , the maximum level of imprecision for the distribution parameters is limited to 1% (see Fig. 56.41). Moreover, the outputs show that when the level of imprecision is too large, the results become non-informative.

3.3 Robust Design of a Steel Roof Truss

In this numerical example, the linear static behavior of a steel roof truss is analyzed. The aim is to optimize the total volume of the structure, i.e., the quantity of material required for constructing the steel roof truss taking into account the effect of uncertainties.

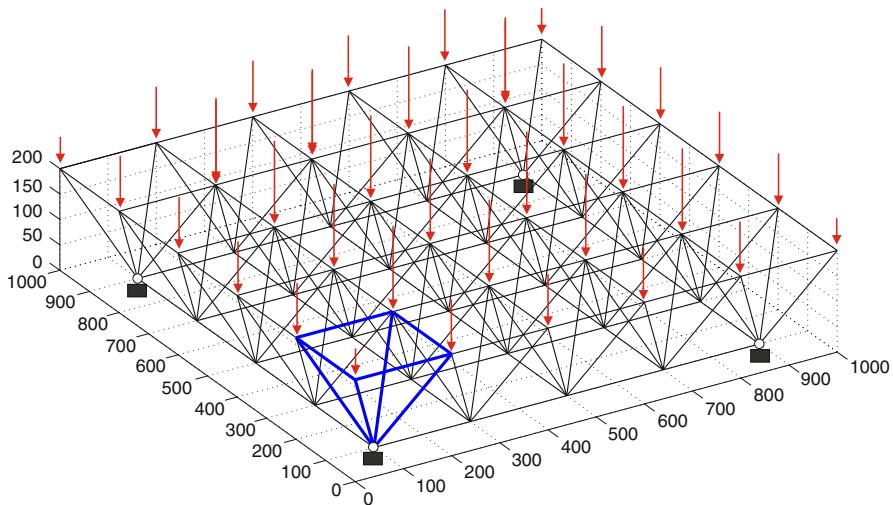

Fig. 56.43 Scheme of the steel roof truss and the load applied. The axes in the figures are expressed in centimeters

Table 56.11 Design variables and parameters of the steel roof truss

Parameter	Description
Design variable (A_1)	60 beams forming the top of the structure
Design variable (A_2)	100 beams connecting the top and the bottom of the structure
Design variable (A_3)	40 beams forming the bottom of the structure
maxDisp	Capacity of the system (10^{-3} [m])
Parameter	Distribution(μ, σ)
Load (L_1)	Normal (12000, 120) [N]
Load (L_2)	Normal (16000, 800) [N]
Load (L_3)	Normal (50000, 20000) [N]
Young's module (E)	Log-normal($2.0 \cdot 10^{11}, 1.05 \cdot 10^{10}$) [Pa]
Density (ρ)	Normal (7500, 150) [kg/m^3]

3.3.1 Description of the Problem

The steel roof truss, as shown in Fig. 56.43, is composed of 200 steel beams with different cross-sectional areas. A total number of three design variables are used to define the cross-sectional area of the structural beams according to the type and location as shown in Table 56.11. The grouping is carried out in order to make the optimization feasible, since an optimization of each single beam might not have been feasible.

It is imposed as a constraint of the optimization problem that the failure probability has to be lower than 10^{-4} . System failure is defined as the exceedance of the maximum allowable nodal displacement defining the performance function. In this context the word failure has to be intended as the occurrence of

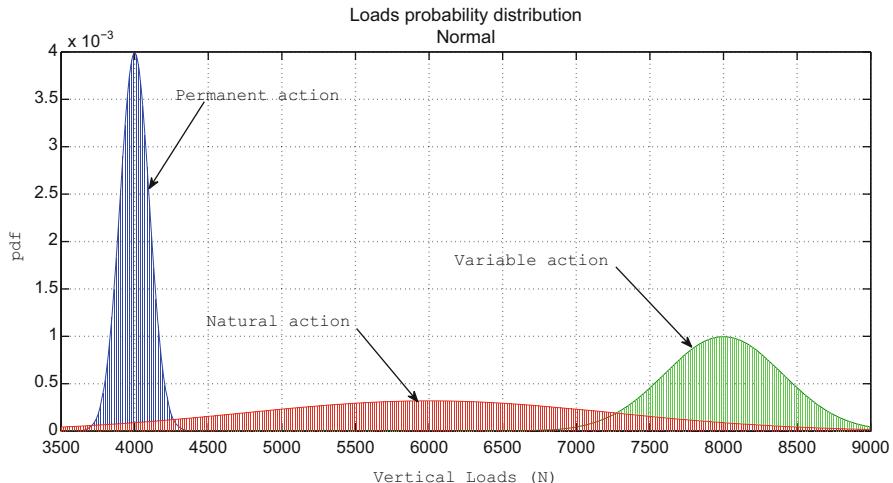

Fig. 56.44 Distribution of the nodal loads representing the permanent action, the natural action, and the variable action, respectively

structural response beyond the target assumption. The uncertainties considered in the numerical example are also summarized in Table 56.11. Nodal loads are modeled as normal independently distributed variables. Each load corresponds to different physical actions applied to the structure. The loads represent permanent, variable, and natural actions and are characterized by an increasing level of uncertainties as shown in Fig. 56.44. The density of the material is also modeled as a random variable.

Note that although the physical quantities such as load and material density are modeled using an unbounded distribution (normal distribution), the probability to sample a negative value is smaller than the maximum numerical precision available in Matlab. Hence this probability is treated as zero.

3.3.2 Analysis

The reliability-based optimization analysis is performed adopting the so-called direct approach. The COBYLA algorithm is used to drive the optimization procedure. Line sampling is used to perform the reliability analysis at each iteration step of the optimization procedure using approximately 60 model evaluations. The evolution of the design variables, objective function, and the constraint during the optimization is shown in Figs. 56.45, 56.46, and 56.47, respectively. The results of the analysis show that the total volume is decreased from the initial value of 6.3 to 5.7 [m³]. The evolution of the design variables shows that the beam section A_3 is larger than the starting design, while the design variables A_1 and A_2 were reduced. The failure probability of the system has been successfully reduced from an initial value of $1.3 \cdot 10^{-2}$ to the prescribed value lower than 10^{-4} .

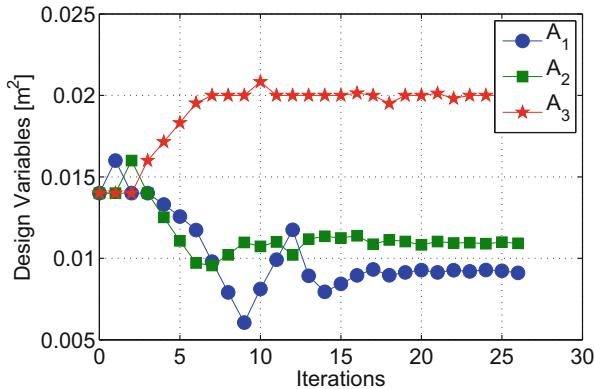

Fig. 56.45 Evolution of the design variables (A_1 , A_2 , and A_3) during the reliability-based optimization analysis

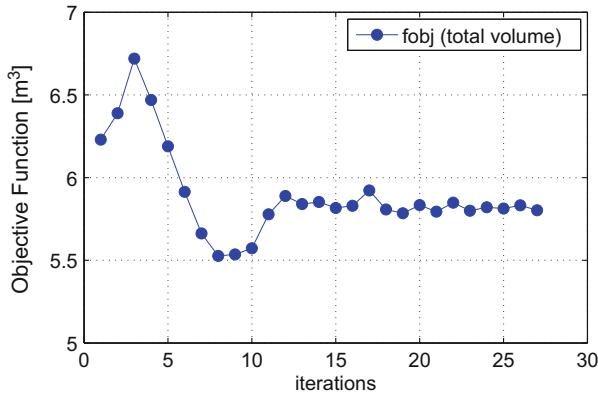

Fig. 56.46 Evolution of the objective function (i.e., total volume) during the reliability-based optimization analysis

3.3.3 Numerical Implementation

This example has been solved in OPENCOSSAN and a brief description of the script shown in Figs. 56.48, 56.49, 56.51, 56.52, and 56.53 is provided here. The script is self-commented and human readable since OPENCOSSAN does not use any acronyms or abbreviations. The script shows the combination of COSSAN objects used to perform the reliability-based optimization analysis that requires the definition of a reliability analysis (the inner loop) used to estimate the probability of failure and an optimization loop (the outer loop) used to identify the values of the design variables that minimize the objective function. First, the inputs of the models are defined. Uncertainties are modeled using *RandomVariable* objects (see lines 38–44 in Fig. 56.48), while the values of the beam sections and the maximum capacity of the system are defined by means of *Parameter* objects (see lines 52–54 and line

59 in Fig. 56.48, respectively). The total volume of the structure is calculated using a *Function* object (line 56). Finally, these objects are grouped in an *Input* object (lines 62–63).

The model of Fig. 56.43 is solved in Matlab and evaluated by a function defined in a *Mio* object (lines 67–71 of Fig. 56.49). The “solver” is included in an *Evaluator* object that allows to define the parallelization strategy (i.e., using a cluster/grid computing). The combination of the *Evaluator* and the *Input* object defines a *Model* object (line 77 of Fig. 56.49). The uncertainty quantification can be performed defining a simulation method and applied to the defined model. In this example a *MonteCarlo* simulator has been defined with 1000 samples (line 80) and used to evaluate the model (line 82). The results of the analysis are stored in a

in the input object (`displacementCapacity`) and the demand is the output computed by the solver (`MaxDisp`).

The reliability analysis is performed defining a simulation object (e.g., `LineSampling` calling the method `computeFailure` (line 94 in Fig. 56.51).

The optimization problem is defined by creating a new `Input` object containing design variables as shown in lines 123–132 in Fig. 56.52. Objective function and constraint are defined invoking the construction method for `ObjectiveFunction` and `Constraint`, respectively.

A reliability-based optimization problem is defined by combining a `ProbabilisticModel` object, a simulator object to perform the reliability analysis, and `ObjectiveFunction` and `Constraint` objects and the mapping between design variables and quantities defined in the inner loop as shown in lines 148–157 in Fig. 56.53. The COBYLA optimization approach is defined (see line 159) and the reliability-based optimization is performed invoking the method `optimize`. Finally, the results of the RBO analysis are plotted.

Finally an optimization method is selected (`MyOptimizer`) and passed to the method `optimize` of the `RBO` object to perform the analysis. Multiple optimization

Fig. 56.53 OPENCOSSAN script for the steel roof truss problem: reliability-based optimization analysis

procedures and efficient approximate algorithms can be chosen to solve the problem. COBYLA method is used in this example.

Reliability-based optimization can also be performed in COSSAN-X. The graphical user interface provides wizards and intuitive problem definition that allows the user to perform robust design and reliability-based optimization (an example of wizard that assists the user in the definition of a reliability-based optimization (RBO) is shown in Fig. 56.54).

3.3.4 Final Remarks

It is important to note that the total computational efforts required by the reliability-based optimization analysis adopting the line sampling and COBYLA (1200 model evaluations) represent only a small fraction of a single direct reliability analysis based on Monte Carlo simulation ($\approx 10^5$ model evaluations). The procedure for the robust design presented here is very general and it can be easily adopted for the robust design of different structures and systems. In addition, the user has the flexibility to select and use different optimization and reliability algorithms. For instance, subset simulation [56] can be used to estimate the failure probability in the inner loop and genetic algorithms can drive the optimization search.

3.4 Robust Maintenance Scheduling Under Aleatory and Epistemic Uncertainty

Maintenance activities are important strategies to prevent loss of serviceability or even collapse of structures. A vast amount of operational costs are associated with inspection and eventual repair, which adds up to a huge cost of failure. Due to the unavoidable uncertainties present in inspection and repair activities as well as in the

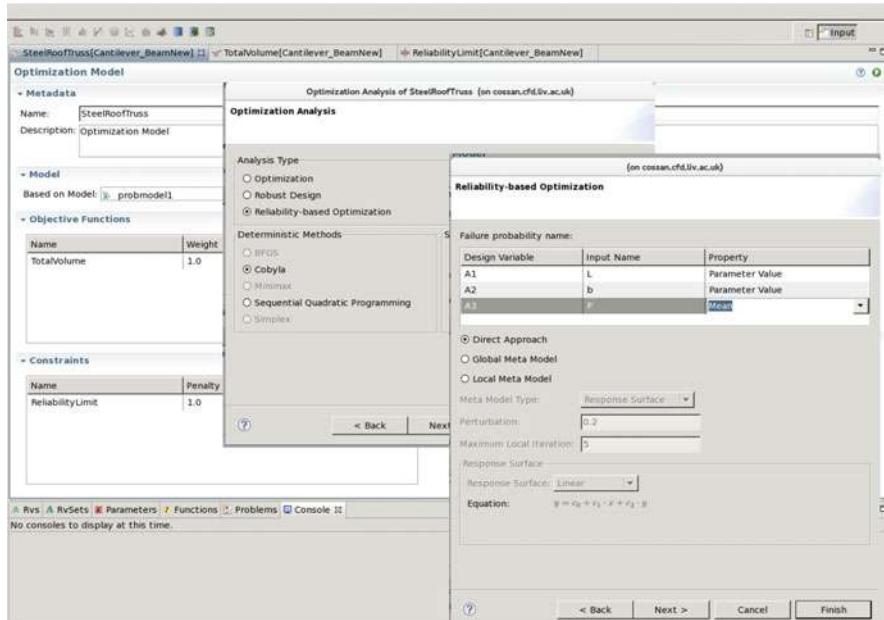

Fig. 56.54 COSSAN-X: definition of a reliability-based optimization problem, the wizard to select optimization algorithm and definition of the mapping between the inner loop (reliability analysis) and the outer loop (optimization analysis)

model performance prediction, scheduling maintenance activities is a challenging task. It requires the availability of efficient maintenance strategies in order to better quantify risk and to devise effective resilience solutions. Reliability-based optimization (RBO) offers a systematic and robust approach for making decisions under uncertainties. The RBO is a subset of classical probability theory and it can be combined with generalized probabilistic methods in order to deal with diverse representations of the uncertainties that includes variability, imprecision, incompleteness, vagueness, ambiguity, indeterminacy, dubiety, subjective experience, and expert knowledge [14, 100]. This extension allows one to obtain robust maintenance strategies since the solution can be obtained without introducing either artificial or unrealistic assumptions.

3.4.1 The Model

The design of robust maintenance strategies for metallic structures subject to cyclic loading is here analyzed. The maintenance activities are performed in order to prevent the failure of a welded connection in a simplified model of a bridge structure (Fig. 56.55). Due to cyclic loading caused by the vehicles, traffic on the bridge deck, metallic components tend to develop fatigue cracks. Fatigue is a localized damage process of a component produced by cyclic loading. As these cracks propagate,

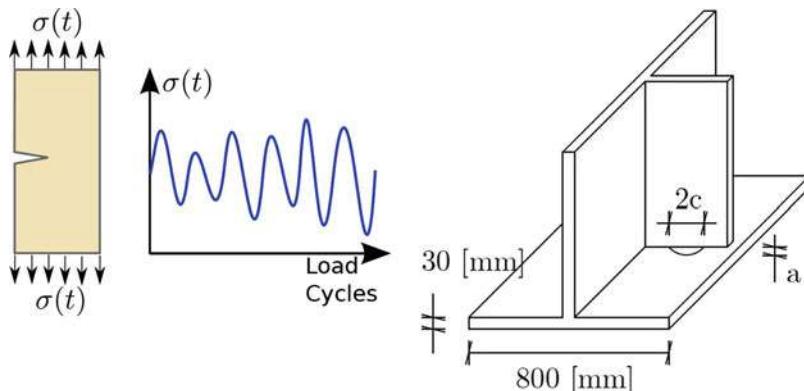

Fig. 56.55 Fatigue crack due to cyclic loading and a simplified model of welded connection of a bridge structure [22]

the structural system accumulates damage that may lead to loss of serviceability or collapse.

One of the most effective and traditional approaches to model crack propagation is the so-called S-N curves approach originally proposed by [55] that describes the relationship between stress amplitude and the number of load cycles. The crack propagation is modeled using the Paris-Erdogan law:

$$\frac{da}{dN} = C(\Delta K)^m \quad (56.12)$$

where N represents the number of load cycles, a represents the crack length, ΔK is the stress intensity factor, and C and m are two parameters that depend on the material properties. The failure condition for the welded component is given as the stress intensity factor that exceeds the material's toughness. This condition can be expressed as the crack length exceeding a critical value as shown in Eq. (56.12). Hence, Eq. (56.12) can be integrated with respect to the number of load cycles until the failure condition is reached. The Paris-Erdogan law is appropriate for characterizing crack growth under constant amplitude cyclic loading, small-scale yielding (i.e., yielding ahead of the crack tip), and long cracks. For those cases where these conditions are not met, the Paris-Erdogan law may not be appropriate and alternative models should be considered. In particular, note that the Paris-Erdogan law cannot model the crack initiation stage. Here, it is assumed that structures possess initial cracks of length. More specifically, the initial crack length, a_0 , is modeled with a log-normal distribution:

$$p(a_0) = \frac{1}{a_0 \sigma \sqrt{2\pi}} e^{-\frac{(\ln a_0 - \mu)^2}{2\sigma^2}}, \quad a_0 > 0. \quad (56.13)$$

The critical crack length is set as 15 mm. The parameters of the Paris-Erdogan law are taken as $m = 2.4$ and $C = 2 \cdot 10^{-10} \text{ mm}/\text{cycle(N/mm}^{1.5}\text{)}^{2.4}$, while the amplitude of the alternating stress applied is 30 MPa. Imprecise probability is adopted to characterize the mean value of the initial crack length μ_{a_0} and modeled as a fuzzy variable with a triangular membership function defined by the triplet {0.5, 1, 1.5} mm and a standard deviation of 0.4 mm. In this model, the maintenance activities consist of a nondestructive inspection and repair. A nondestructive inspection is a procedure that is used to detect cracks in a structure without introducing additional damage. This includes ultrasonic, magnetic-particle, liquid penetrant, radiographic, remote visual inspection. Such inspection activities are not perfect, and the outcome of the inspection (i.e., probability of detection) can be modeled as follows:

$$POD = (1 - p)(1 - e^{-\lambda a}) \quad (56.14)$$

where λ represents the quality of the inspection, a crack length at the time of the inspection and p the probability of non-detection of a very large crack that depends on the quality of the inspection. If the crack is detected, the crack will be repaired and it is assumed that the reparation will be perfect (i.e., no crack after a reparation activity).

During the target lifetime of the structure, the following events may occur: the crack length reaches a critical value and fracture occurs at a time before inspection takes place; the structure survives until a nondestructive inspection is carried out. The inspection may not detect any cracks and hence no repair is carried out. In case one or more cracks are detected, the structure is repaired.

Despite the unavoidable uncertainties, the selection of appropriate time of inspection, t_I (and eventual repair), is of fundamental importance for scheduling effective maintenance activities. A robust maintenance scheduling is defined as the maintenance strategy that minimizes the total costs for inspection, repair, and failure. These costs are affected by uncertainties. For instance, the initial crack length, a_0 , affects the probability of failure of the system, and hence the expected failure cost and the quality of inspection λ affect the cost of inspection. The maintenance problem can be generally formulated as a constrained optimization problem, where the constraint represents the limit state safety level that the system has to comply with.

Given a system that evolves in time, $S(t)$, a mission time, T_M , which is the time when the system is required to function as specified, and a number of inspections, N , performed at times, $t^{\text{insp}} \in \mathbb{R}^N$, the maintenance problem is formulated as an optimization task, where both objective and constraints require the evaluation of the reliability, $r(t)$. Three main different costs can be identified: the costs due to inspection C_I and repair C_R and the cost due to the failure (and their consequences), C_F . It is assumed that manufacturing costs are deterministic as they are linked to construction and usage of materials. Note that, as pointed out in [93], the costs of

Fig. 56.56 Example of a OPENCOSSAN script used to solve the robust optimization problem including the definition of imprecise variables (fuzzy variables)

repair and failure are obtained as expected values, $E[\cdot]$, as they are obtained from the estimation of repair and failure probability, respectively.

The cost due to inspections depends on inspection quality, λ , and on the inspection times, t_I . In this example the dependence of the time of inspection is not considered and $C_I(\lambda, t_I) \approx C_I(\lambda)$. Costs due to repair occur only if a crack is detected. Hence they depend on the probability of repair and in turn to the inspection quality and the crack length, a . The cost of failure is also function of the inspection quality as well as on the state of damage (i.e., crack length a). The total cost of maintenance is (the objective function)

$$E[C_T] = C_I(\lambda) + E[C_R(\lambda)] + E[C_F(\lambda, t)]. \quad (56.15)$$

It is important to notice that the evaluation of the objective function (Eq. (56.15)) requires solving a reliability problem which significantly increases the computational costs of the analysis. Furthermore, since some input variables are modeled with imprecise probability, the outputs are also affected by imprecision (i.e., only bounds of the expected costs can be obtained).

The maintenance problem can be solved by using advance simulation techniques available in OPENCOSSAN. An example of the script required to perform the robust optimization is shown in Fig. 56.56. The solution of this problem requires the definition of an inner loop to solve the reliability problem. In this example,

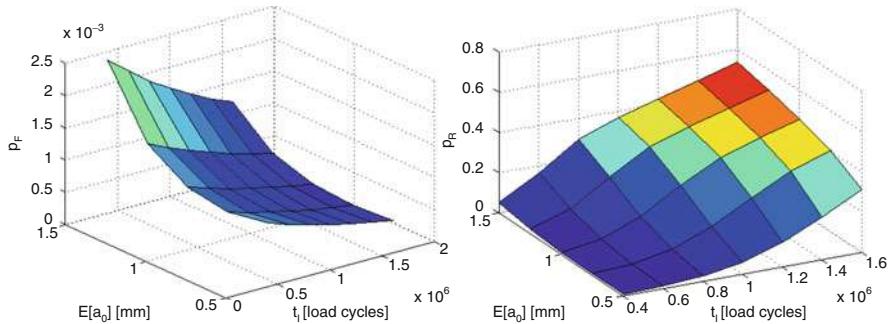

Fig. 56.57 Probability of failure (left plot) and repair (right plot) as a function of time (i.e., load cycles) and the membership function (representing the imprecision level) of the initial crack length

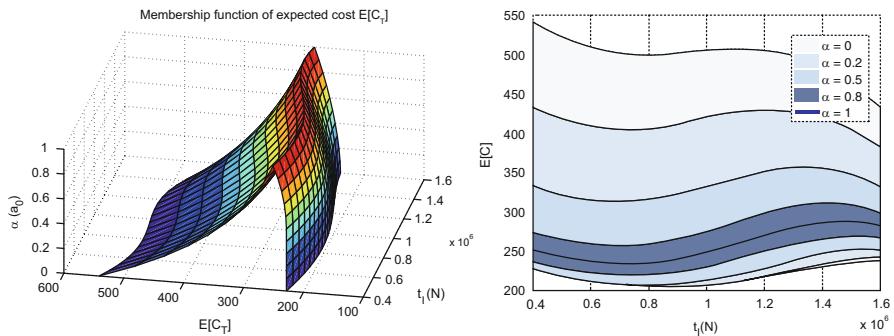

Fig. 56.58 Expected total cost as a function of the time of inspection for different values of the membership function (α) of the initial crack length

importance sampling procedure [38, 62] has been used to estimate the probability of failure of the metallic component. The gradient-free COBYLA algorithm [70] is selected to drive the optimization procedure.

3.4.2 Results

The results of the robust scheduling maintenance are shown in Figs. 56.57 and 56.58. Figure 56.57 shows the estimated probability of failure and probability of repair of the metallic structures subject to cyclic loading. It shows that when the inspection is performed too early, the cost tends to increase. This is due to the fact that by the time inspection takes place, the crack is still too small to be detected. As a consequence, there is a small probability of detecting (and repair) the crack. As time increases, the inspection becomes more effective in detecting the crack. As a consequence the probability of failure is reduced. This implies the total expected costs to become minimal. If the inspection is performed too late, the total expected costs increase again due to a nonnegligible probability of failure before the inspection. The optimal inspection time identified is equal to 0.74 million load cycles. Figure 56.58 shows

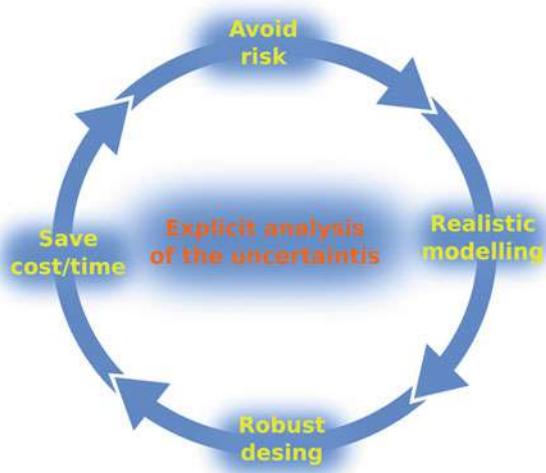

the expected total costs $E[C_T]$ as a function of the time of inspection t_I for different levels of imprecision α in the initial crack length $\mu(a_0)$. $\alpha = 1$ correspond to a traditional probabilist analysis where no imprecision in the model parameters is present.

The results obtained in this numerical example have shown the relevance of considering uncertainty in the scheduling of maintenance activities for fatigue-prone metallic components. In fact, the optimal time for performing maintenance is a compromise between repair activities and the negative consequences of failure. Considering explicitly epistemic uncertainties allows to identify the robustness of the results as a function of the imprecision of the input parameters. The numerical strategy adopted computes the upper and lower values of the expected costs for different alpha levels by means of a global optimization strategy combined with an efficient reliability approach. This allows creating models capable of more rationally processing the uncertainties that are no longer based only on traditional probabilistic approaches and providing to the final user self-contained measures of robustness.

4 Conclusions

Stochastic analysis is the basis for designing more competitive, reliable, and resilient products on different engineering fields such as automotive and nuclear industry, aerospace, mechanical and civil engineering, and more. It supports sustainable developments and economical and safety relevant decisions in our society (Fig. 56.59). To ensure a faultless life of complex technological installations, engineering systems, and products and to provide decision margins, the explicit consideration of all the uncertainties and threats needs to be considered. Uncertainty and imprecision are unavoidable since they are, e.g., inherent within manufacturing

Fig. 56.59 Advantages of the explicit consideration of the uncertainties

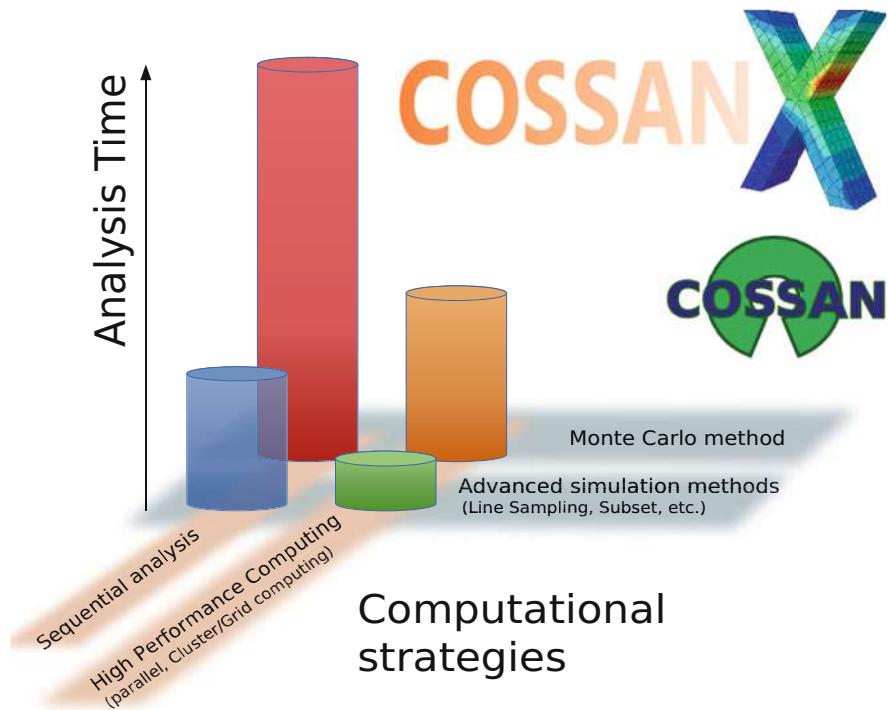

Fig. 56.60 Computational costs required by a nondeterministic analysis and advantages of using advanced simulation methods and high-performance computing implemented in the COSSAN software

process, fatigue and corrosion, human errors, and extreme load conditions (e.g., wind, wave, earthquake). In consequence, realistic consideration and treatment of uncertainties of various nature and scales is a key issue in the development of sustainable, durable, cost-effective, and feasible engineering solutions.

The merits of considering uncertainties are manifold and industry is fully aware that stochastic methods offer a much more realistic approach for analysis and design. However, the utilization of such approaches in practical applications remains quite limited. One common limitation is that the computational cost of stochastic analysis is often by orders of magnitude higher than the deterministic analysis. These computational costs can be significantly reduced combining efficient numerical strategies with high-performance computing (see Fig. 56.60). In this way nondeterministic analysis can be included as a common practice in computational models and numerical simulations allowing engineers to design products faster and cope with risk and uncertainty.

The general-purpose stand-alone application COSSAN-X is an easy-to-use yet powerful software for uncertainty quantification and risk management. Its user-friendly graphical interface allows to create a bridge between the academic research

and the industrial practice. The reason is that COSSAN-X allows nonexpert users in programming and in stochastic analysis to account for the uncertainty in their models in a straightforward manner and without an excessive learning curve. It also represents an indispensable tool for training professionals and students. This is because stochastic analysis can be taught and learned without the necessity to write ad hoc programs or scripts, and moreover, stochastic analyses are performed using the same (deterministic) models that the users are already familiar with.

The open-source model adopted for the computational engine (i.e., OPENCOSSAN) encourages the cross-discipline utilization of stochastic analysis. The open-source approach makes the software development more sustainable, continuously updated to make the cutting-edge technologies available to a large number of developers, researchers, and academics resulting in a reduction of code duplication, an increasing of the software reliability, and, finally, enable world-class research.

Stefano Tarantola and William Becker

Abstract

SIMLAB 4.0 is a comprehensive stand-alone software package for performing global sensitivity analysis. Several sampling strategies and sensitivity measures are available. SIMLAB includes the most recent variance-based formulas for first-order and total-order sensitivity indices, graphical methods, as well as more classical methods. The peculiarity of SIMLAB, in contrast to previous versions of the package, is the possibility to run sequential sensitivity analysis, which allows updating the sensitivity measures at each run, or group of runs, of the model. The techniques can be accessed through the R environment as well as through a graphical user interface. The user can also add new techniques by simply adding the corresponding R code to the core layer. SIMLAB can be downloaded for free from the Joint Research Centre's website.

1 Introduction

SIMLAB 4.0 is a newly implemented version of a software framework for uncertainty and sensitivity analysis. SIMLAB is the property of the Joint Research Centre (JRC) of the European Commission, which has financed its design and development since its first version, made available back in 1999. With this product, the JRC aims to employ up-to-date tools and practices of global sensitivity analysis in order to disseminate the culture of sensitivity analysis to an ever-increasing number of customers. In agreement with the EC dissemination policy, SIMLAB is publicly available for use by any person, company, or organization that downloads, installs, and uses the software, according to an end user software license agreement.

SIMLAB is available on the website of the *Econometrics and Applied Statistics* research group of the European Commission's Joint Research Centre [3].

SIMLAB contains a set of techniques to execute global sensitivity analysis (GSA), primarily by Monte Carlo and sampling-based methods (as opposed to emulator/metamodel-based methods). No local sensitivity analysis tools are present in the software. The conceptual framework of GSA and the techniques available to perform GSA are described in Sobol' (variance-based) sensitivity indices: theory and estimation algorithms. In summary, GSA is based on performing multiple model evaluations with a probabilistically-selected model input and then using the results of these evaluations to quantify the relative importance of the inputs in determining the uncertainty of the model output.

The tool, running in a 64-bit environment under Windows, is delivered as a self-installing setup. It provides a set of transparent, well-commented, and self-maintainable functions, coded in the R environment, that implement GSA techniques. The user can work both in the R environment by calling the R functions and, on the pre-compiled functions, through a graphical user interface (GUI), developed in C# for the .NET framework, which facilitates the use of the application and allows to visually present the results of the sensitivity analysis.

The R package acts as the core layer of the application and contains all the algorithms and methods of global sensitivity analysis, with source codes available to the user. SIMLAB can easily be extended with new GSA techniques by adding the corresponding R code to the core layer. Modifications and maintenance of the core algorithms can be carried out by the user.

The GUI is built on top of a control layer, developed in C++, which links the core layer in R with the GUI itself. The control layer is responsible for the correct

management of the calls to R, given the instructions provided by the user through the GUI. The control layer also handles warning and error messages.

The system requires the installation of R. SIMLAB uses two R packages through which R and SIMLAB communicate: *Rcpp* and *RInside*. Other R packages are used for statistical operations: *stats*, *pspearman*, *sensitivity*, *lhs*, *randtoolbox*, and *rngWELL*. Those packages are automatically downloaded from the Comprehensive R Archive Network (<https://cran.r-project.org/>) during SIMLAB installation.

SIMLAB gathers a variety of routines, written by different authors in Matlab or R, that implement various GSA techniques. These routines are heterogeneously programmed and are harmonized and integrated in SIMLAB.

SIMLAB offers a test suite of three commonly used analytical functions that the user can employ to test the methods implemented in SIMLAB. These functions are described in this chapter.

With respect to previous versions, SIMLAB 4.0 offers a new functionality that allows the user to perform sequential sensitivity analysis. The sequential process is entirely managed by the control layer. Specifically, the user can run a number of iterations of the sequence composed by sample generation, model execution, and sensitivity estimation, thus obtaining continuous updates and convergence monitoring of the sensitivity analysis results in real time. In the sequential sensitivity analysis, the iteration is repeated until the user is satisfied with the results of the sensitivity analysis. The user does not need to specify *ex ante* how many sample points to use in the analysis. A visualization tool assists the user to monitoring the convergence of the sensitivity results. This approach has the advantage of stopping the analysis when the user is satisfied with the level of precision of the GSA results, avoiding useless, and often expensive, extra model executions.

2 Installation

Requirements to install SIMLAB:

- A PC running Windows
- An internet connection
- R already installed

SIMLAB is currently only available for Windows. SIMLAB is written in C++, but uses packages from R. Therefore in order to use SIMLAB, the user must have both SIMLAB and R installed. It is recommended to install R prior to installing SIMLAB. R can be downloaded from <https://cran.r-project.org/bin/windows/base/>. Throughout the installation process, an internet connection is required.

To install SIMLAB, first unzip the Simlab_v4.rar file. In the folder SIMLAB Installation Files, run the setup.exe file. At this point, you may be asked to install Visual C++ Runtime Libraries. Since SIMLAB is dependent on these components, you must choose “Install” to continue. The SIMLAB Setup Wizard will now open automatically. Follow the instructions of the Wizard, including choosing a suitable

directory for the installation. You will also be asked to nominate a folder which will be used for automatically depositing files to exchange information with R. Next, the Wizard will download and install the required R packages onto your R installation. This can also be done manually if desired. The following R packages are required to run SIMLAB:

- stats
- pspearman
- sensitivity
- lhs
- randtoolbox
- e1071
- mc2d
- rngWELL

Additional to these packages, SIMLAB installs its own package “SimLab4R” on R.

After installing the packages, automatically or otherwise, SIMLAB is installed and ready to run on your computer.

3 Data Workflow

Figure 57.1 below shows how data are processed by SIMLAB. The files for data exchange are represented by green boxes and contain ASCII text with an easy to understand format. These files contain information on the input distributions and their correlation structure, the generated sample (sample file), and the results of the model execution (simulated output). The setup of the input variables (i.e., the choice of the probability density functions and their parameters and the correlation matrix for the statistical characterization of input uncertainty) and the computer code implementing the simulation model are provided by the user (the blue boxes). The red boxes are the tools offered by SIMLAB: the sample generation step, the

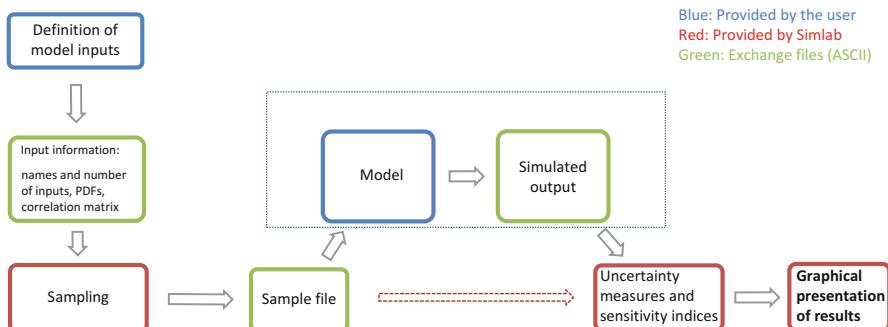

Fig. 57.1 SIMLAB data workflow (Courtesy of Federico Ferretti, Joint Research Centre, European Commission)

uncertainty analysis, and the GSA technique to compute the sensitivity indices. This latter is usually intimately related to the type of sampling used. SIMLAB also offers graphical tools to visualize the results of the GSA.

The core layer in R contains different functions that can be considered as building blocks for the GSA. Those functions allow the user to select among different types of sampling methods, to impose a desired correlation between inputs, to generate random samples from a set of assigned distributions, to evaluate the GSA measures according to the method selected, and to choose the stopping criterion for the GSA evaluation process. For example, the R command used to generate a log-uniformly distributed sample of size N with lower bound a and upper bound b is:

```
    sam <- random(N, 1)
    qloguniform(sam, a, b)
```

The GUI facilitates the interaction of the user with the core layer. The GUI allows the user to save the working configuration for subsequent analyses to avoid the need to rerun the entire process. In particular, four working configurations can be saved: the definition of the model inputs (their number, their names, their probability distributions, and their correlation), the generated sample of inputs (with information on the type of sampling strategy used), the generated model output, and the evaluated sensitivity indices. A specific GUI functionality is dedicated to monitor the convergence of the sensitivity indices through a visualization tool.

The next version of SIMLAB will foresee the possibility to pause the sequential analysis and then restart it at a later stage.

4 Overview of Using SIMLAB

The first step of a GSA is to select ranges and probability density functions for the model inputs that are the object of the analysis. This is accomplished by the “Factors definition” function of the GUI. Here all the properties of the inputs are specified. It is possible to add new inputs, modifying or removing existing ones. The configuration of the model input can be saved to file and an existing configuration can be loaded into SIMLAB. Once the inputs have been defined it is also possible to specify a correlation matrix. See the next section for a summary of the probability density functions handled by SIMLAB.

The second step of the GSA is the sample generation. Four different sampling methods can be set: simple random, quasi-random, Latin hypercube, and the Sobol’ design. This latter is required if one is interested to compute Sobol’ sensitivity indices. As the GSA is executed sequentially in blocks of samples, the user is required to insert three values: the size of the first subsample, the size of the subsequent subsamples, and the maximum allowed sample size which, when reached, would terminate the GSA if not previously terminated. The generated sample can be saved to a file in ASCII format or as a csv file. The entire configuration composed by information on the input and generated sample can also be saved. The generated sample can be visualized as multiple histograms (one

per input), cumulative histograms, 2D scatterplots (between pairs of inputs), and cobwebs (all inputs together).

In the third step “Output variables selection,” model output variable names are assigned. Multiple output variables and time-dependent variables can be handled.

Further, the user has to define a threshold value for the convergence criterion. The convergence criterion is based on the calculation of the absolute difference between each sensitivity index at step $n - 1$ and step n and on the calculation of the maximum of these absolute differences across all inputs and all outputs. The process will stop when this maximum difference gets smaller than the threshold value chosen by the user. Other convergence criteria will be added in the next release of SIMLAB.

The “model execution” step allows the user to link a model to SIMLAB. The user has to specify the name of an executable (the code of the model) that returns the model output variables with the names specified in the “output variables selection step.” SIMLAB foresees the possibility for the user to add a set of arguments needed by the model when launching the executable. The user has also to specify the name of the sample file from where the sample generated at the i th iteration will be read and the name of the output file where the results of the model output at the i th iteration will be saved. This latter specification is important in order not to lose the results of the model runs, which might be computationally intensive. The executable (the code of the model) has to foresee the reading from (writing to) the sample (output) file specified by SIMLAB. As such, SIMLAB will be able to run sequentially, generating a first subset of samples, running the model on this subset, and producing a subset of model outputs, which are saved to the output file and are used to obtain estimates of sensitivity indices of various nature.

The final two steps are “sensitivity evaluation” and “uncertainty evaluation,” the first being much more developed in SIMLAB. See the next section for an overview of the sensitivity analysis methods and the options offered by the uncertainty evaluation.

5 Available Techniques

Referring back to Fig. 57.1, the workflow of a sensitivity analysis consists of a number of steps. Fundamentally, SIMLAB performs two basic tasks of this workflow: generating the sample design that is used to specify the input values to each model run and post-processing the results of the model runs specified by the sample. For both of these operations, SIMLAB has a number of features which are outlined in this section.

5.1 Sampling

The selection of the sample design for a sensitivity analysis must be given some prior consideration, because the type of design dictates which measures of sensitivity can be estimated. The sensitivity measures that are associated with each

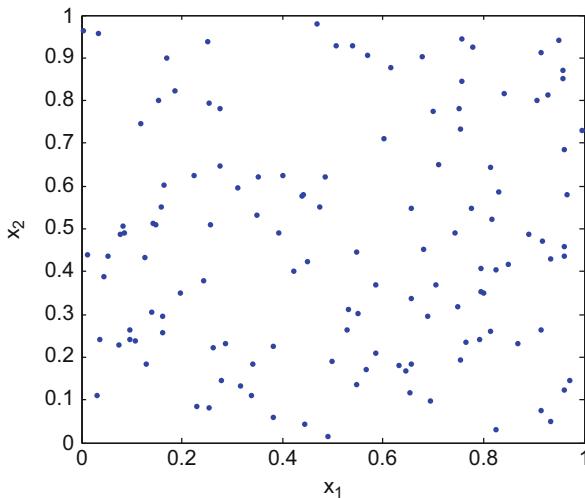

Fig. 57.2 Simple random sampling in two dimensions with 128 points

design are described in the following section. The sample designs available in SIMLAB are as follows:

Simple random: this is simply a sequence of (pseudo-)random points taken from the input space—see Fig. 57.2. Random sampling has the advantage that sample replications can be taken, in order to estimate the error due to the sample size; however, random sampling is characterized by clustering of points which can reduce the efficiency of the design in terms of convergence in Monte Carlo applications.

Latin hypercube: this is the well-known sampling design proposed by [4], which has the property that sample points are quite evenly distributed with respect to each dimension – see Fig. 57.3. For a sample of n points, the range of each variable is divided into n equally spaced intervals. A sample point is taken by randomly selecting an interval from each dimension and then taking a random sample point from within the resulting hypercube. Intervals are sampled without replacement to ensure even distribution of points with respect to each variable. A drawback of Latin hypercube sampling is that an existing design cannot be extended to higher sample sizes without repositioning all sample points.

Quasi-random: a so-called *low-discrepancy sequence* which has many of the properties of random numbers but ensures that points are well spaced in order to improve the rate of convergence of sensitivity estimates – see Fig. 57.4. Typically, quasi-random numbers will result in more accurate estimates of sensitivity at a given sample size. SIMLAB uses the Sobol' (LP- τ) sequence [9], which also has the advantage that points can be added sequentially without restructuring the whole design. Note that the LP- τ sequence has particularly low discrepancy at sample values that are positive integer powers of 2, i.e., $n = 2^i$, $i = 1, 2, \dots$

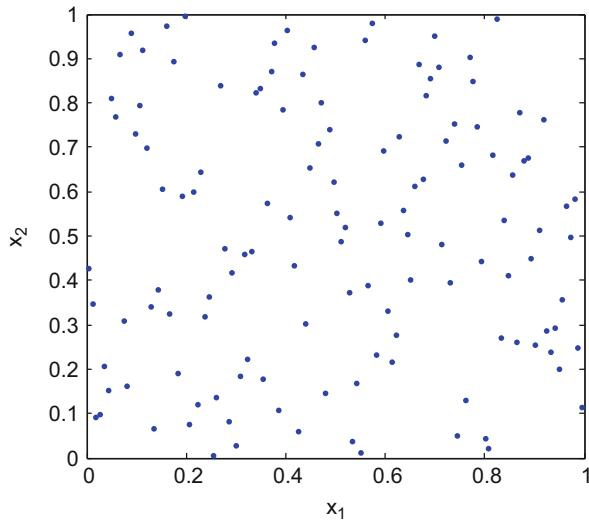

Fig. 57.3 Latin hypercube sampling in two dimensions with 128 points

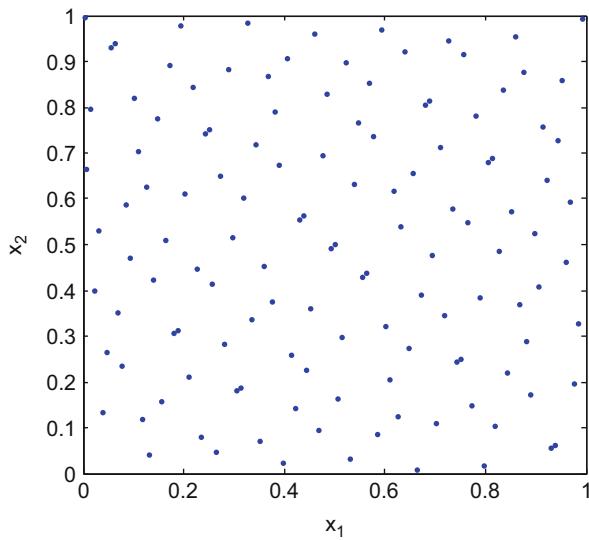

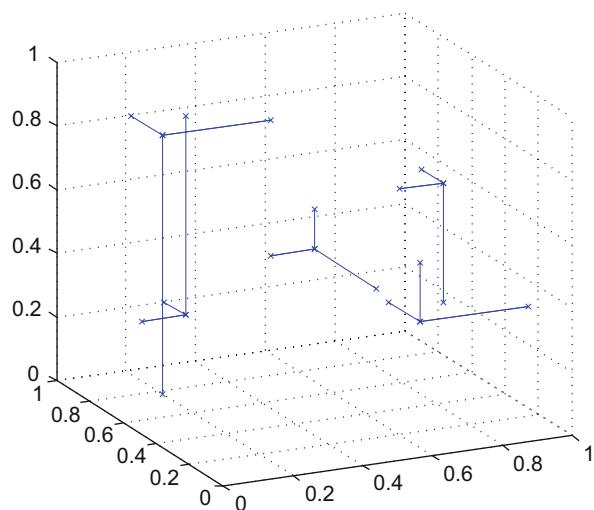

Fig. 57.4 Sobol' LP- τ sampling in two dimensions with 128 points

Sobol' design: this is a structured design based on quasi-random sampling, structured in such a way as to allow estimation of variance-based sensitivity indices (first order and total order), via Monte Carlo integration – see Chapter 5 – and [10]. It is sometimes called “radial” sampling, since the design consists of a number n_r of smaller designs that each have $k + 1$ points (where k is

Fig. 57.5 Sobol' radial design in three dimensions

the number of inputs of the model/function) that “radiate” from a single starting point – see Fig. 57.5. In fact, each of these smaller designs is equivalent to a set of k one-at-a-time designs, where each variable is perturbed individually. The total sample size (number of model runs) is therefore $n = n_r(k + 1)$.

FAST and Extended FAST design: these designs are also structured in such a way as to allow estimation of variance-based sensitivity indices: first-order indices for FAST [2], and both first-order and total-order indices for extended FAST [7]. FAST and extended FAST methods are not implemented sequentially in SIMLAB.

The sampling in all of the above designs can be performed with respect to the following distributions: discrete, uniform, piecewise uniform, log uniform, piecewise log uniform, normal, log normal, triangular, exponential, beta, gamma, and Weibull.

Before generating samples, the first step is to define the probability distributions of the input factors of the model. SIMLAB’s navigation pane is organized in steps which follow the logical workflow of a sensitivity analysis. Correspondingly, the first step is to go to the “Factors definition” pane (Fig. 57.6). This gives an overview of each input factor. To start defining the distributions of input factors, click “Add new factor” and click “Edit” on the new factor that appears in the table. This opens a window as shown in Fig. 57.7. From here, the distribution type and parameters can be set, with information on the distribution given at the bottom of the window. Click “Save params” to save the distribution parameters to SIMLAB’s database. This process can be repeated for each input factor. Notice that every time a new factor is added, it appears as a subheading in the Factors definition heading of the navigation pane, allowing it to be edited at any time. A summary of all factors can be found by returning to the “Factors definition” window – see Fig. 57.8. Here the

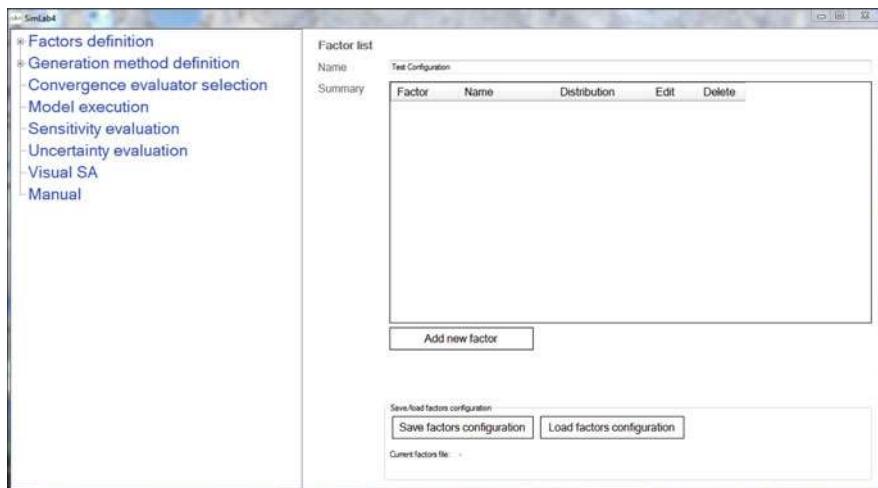

Fig. 57.6 The “Factors definition” pane

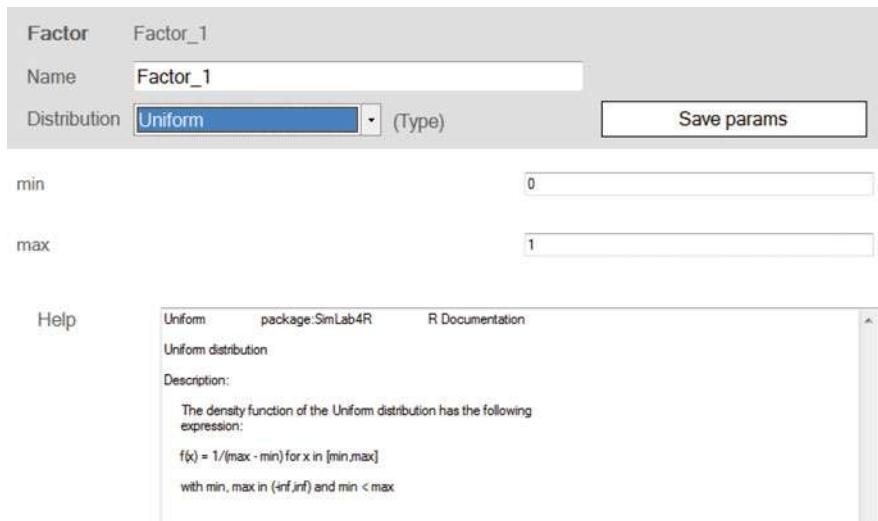

Fig. 57.7 Input distribution editing pane

configuration of all factors can also be saved for use in other sessions or projects and similarly loaded from earlier work.

To actually generate a sample, go to the “Method” subheading of the “Generation method definition” heading in the navigation pane. Here, the options for the sample generation can be set (see Fig. 57.9). The user must choose the method of sample generation using the “Method” and “Aux function” drop-down menus. Below, parameters can be set which control the sample size and optionally the step size

in the sample generation, if a sequential sampling strategy is to be used. To perform an ordinary batch-mode sensitivity analysis (as opposed to sequential), set the “first subset size” option to the same number as the “maximum sample set size,” i.e., the total number of sample points. The “next subsets size” option should be set to zero. In the case of sequential sensitivity analysis, these settings can be used to control the step sizes for each iteration of sensitivity analysis.

Returning to the “Generation method definition” page, a summary of the variables and the sampling method is now displayed – see Fig. 57.10. To generate the sample, click “Generate and save whole sample.” At this point, the sample can be viewed in a number of ways by clicking the “View generated sample” button. A window will appear which allows the selection of factor, which can be selected by moving them to the “selected factors list” using the buttons – see Fig. 57.11. Histograms, cobwebs, and scatterplots can be generated depending on the number of variables selected. For example, with two factors selected, a scatterplot can be generated (Fig. 57.12), and with two or more variables, a cobweb plot can be created (Fig. 57.13). For the latter, values can be normalized or not by checking the box in the bottom right corner.

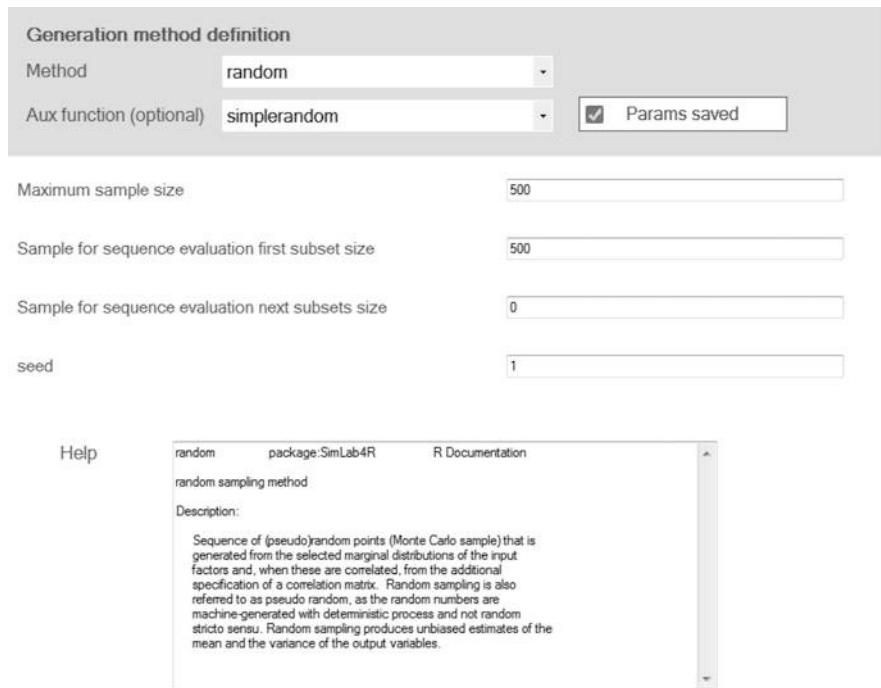

Fig. 57.9 Sample method settings

5.2 Model Execution

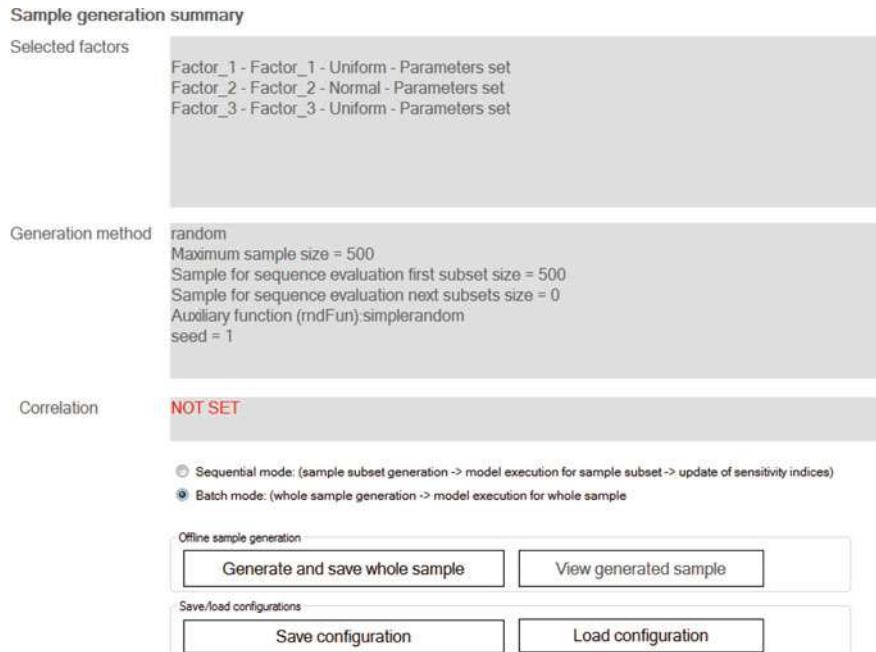

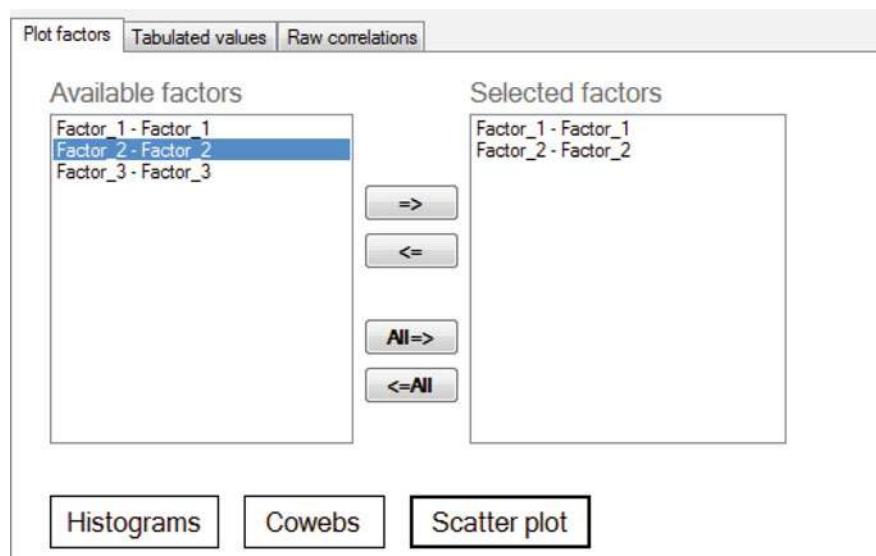

The “Model Execution” pane is presented in Fig. 57.14. SIMLAB is offered with three simple test models that can be found in the installation files. They allow the user to play and learn how to use the package. The first test model is the linear function of the form:

$$Y = \sum_{j=1}^d a_j X_j$$

The a_j coefficients are selected by the user to decide upon the relative importance of the inputs. The marginal distributions of the X_j and their correlation matrix are selected by the user.

The second test model is the so-called Sobol’ g -function, a classical test function for which an analytical expression of the Sobol’ indices is available. $Y = f_1(X_1) \times \dots \times f_k(X_k)$ with $(X_1, \dots, X_k) \sim \mathcal{U}([0, 1]^k)$ and

$$f_j(X_j) = \frac{|4X_j - 2| + a_j}{1 + a_j}, \quad a_j \geq 0, \quad j = 1, \dots, k.$$

**Fig. 57.10** Summary of sample and sample generation**Fig. 57.11** Displaying sample plots

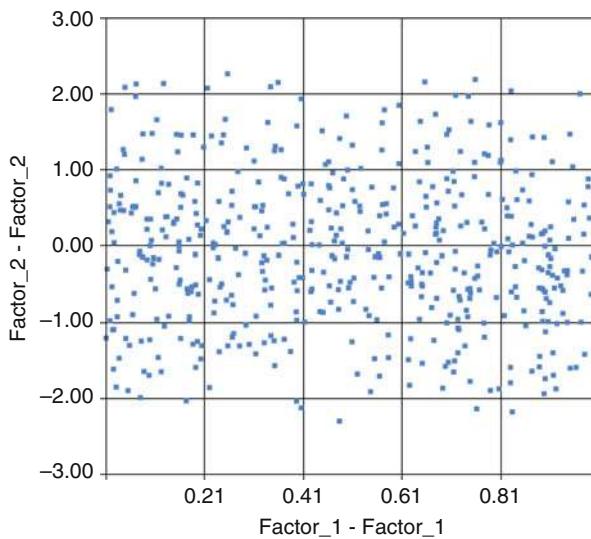

Fig. 57.12 Scatterplot of one input variable against another

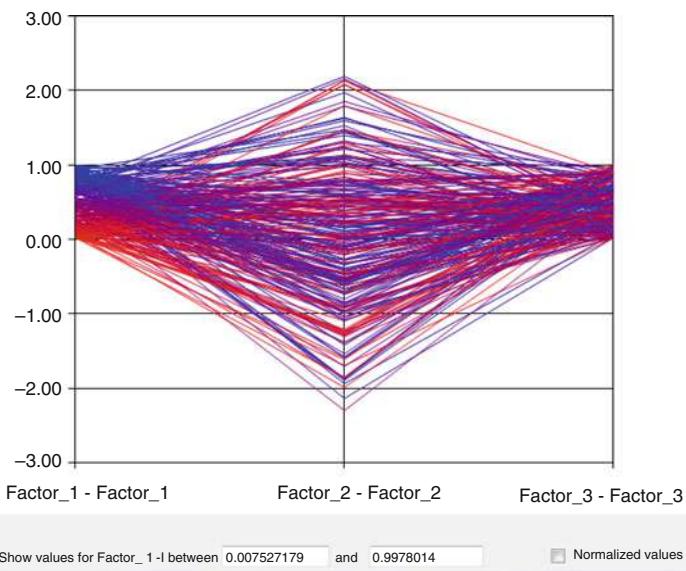

Fig. 57.13 Cobweb plot of three input variables without normalization

The a_j coefficients can be set by the user to decide upon the relative importance of the inputs. $a_j = 0$ corresponds to a very important input. As a_j increases, the relative importance of the input decreases.

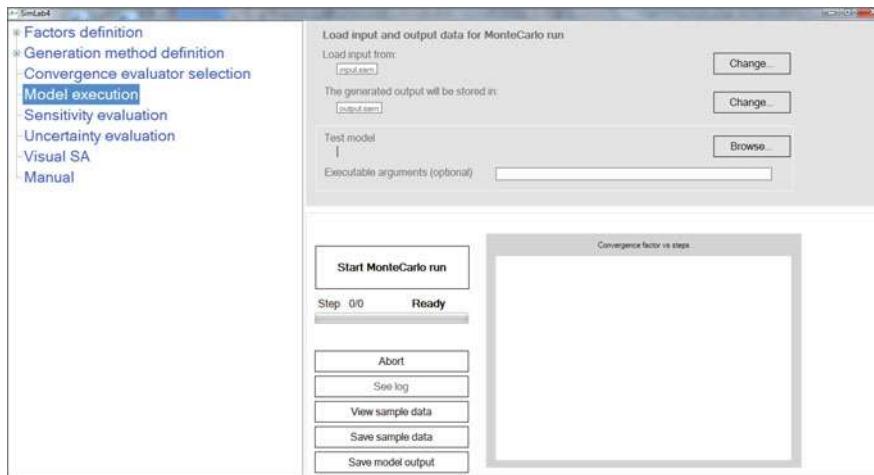

Fig. 57.14 The aspect of the “Model Execution” pane

Fig. 57.15 How to set up the “Model Execution” pane for the linear model

The third test model is the so-called Ishigami function for which analytical Sobol’ indices are also available. The Ishigami function has the form: $Y = \sin(X_1) + 7 \sin^2(X_2) + 0.1 X_3^4 \sin(X_1)$ with the three inputs uniformly distributed in the range $(-\pi, \pi)$.

In the “Model Execution” pane, the test model is selected by clicking on “Browse” and choosing the executable file that implements the model. The executable file must also contain the instructions to read from the sample file and to write to the output file. For example, the executable file “LinearModel.exe” requires some arguments to be supplied by the user. These are the name of the input file, the name of the output file, and the coefficients a_i . If the user wants to run the sensitivity analysis of the linear model with coefficients $a_1 = 2, a_2 = 7, a_3 = 5$, he has to prepare the “Model Execution” pane as depicted in Fig. 57.15.

During the execution of a sequential sensitivity analysis, the sensitivity estimates obtained at a given iteration are compared with those obtained at the previous

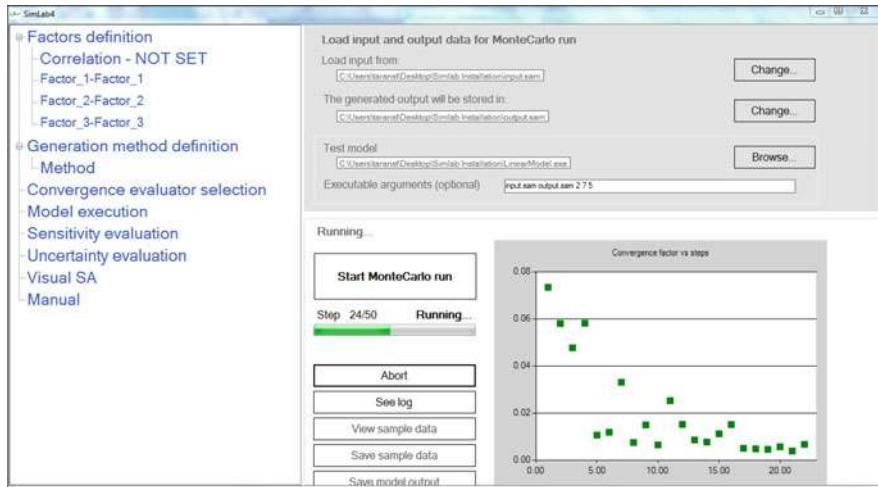

Fig. 57.16 Sensitivity analysis in progress

iteration. The convergence criterion is applied and, if convergence is not reached yet, the analysis proceeds. During this phase, the “Model Execution” pane looks as in Fig. 57.16.

5.3 Post-processing

The model must be run a number of times using one of the designs described in the previous section: this will return a vector of model output values. A number of measures of sensitivity can be estimated by SIMLAB based on the resulting model output values. Which measures can be estimated is dependent on the type of sampling design – see Fig. 57.17 for a summary.

The methods supported by SIMLAB that are compatible with simple random, Latin hypercube, and quasi-random sampling are as follows (detailed descriptions of the methods are left to the references provided):

Standardized (rank) regression coefficients: this involves fitting a simple linear regression to the sample data and then using the coefficients, standardized by their respective variances, as measures of sensitivity (Saltelli et al. 2000). This approach is appealingly simple and can work with a large number of input variables. However, when the output of the model is nonlinear with respect to its inputs, sensitivity may be misrepresented.

Kolmogorov-Smirnov test: sensitivity is measured by a statistical test which, after ordering with respect to a given variable and dividing the sample into two subsets, compares the distributions of each subset to see whether there

	Stand. Reg. Coeffs	K-S Test	Cont. to Samp. Mean	Cont. to Samp. Var.	CUSUNORO	EASI	Sens. Indices

Latin hypercube	X	X	X	X	X	X	
Quasi MC	X	X	X	X	X	X	
Sobol' structured							XC

Fig. 57.17 Compatibility of sampling methods with sensitivity measures

is a significant difference. The degree of difference is taken as a measure of sensitivity [8].

Contribution to the sample mean plot: a plot which shows how each input variable contributes to the sample mean by estimating the mean as the sample points are successively added, in order of the value of each input variable. The plots can be used as measures of sensitivity and give further information about the effects of specific quantiles of the input distributions [1].

Contribution to the sample variance plot: these plots are the same concept as the contribution to the sample mean plots, but applied to the sample variance instead of the mean [11].

CUSUNORO: a similar approach to the contribution to the sample mean, which proceeds by standardizing the ordered data to have zero mean and unit variance [6].

EASI: an algorithm that estimates first-order sensitivity indices using the fast Fourier transform [5].

The Sobol' design is more specialized than the random or quasi-random sampling and is specifically intended for use in estimating variance-based sensitivity indices, in particular first-order and total-order sensitivity indices (see Chapter 5). Note that the output from the model can be in the form of a time series or a multidimensional variable (vector of outputs). SIMLAB can provide sensitivity indices for each time point or for each element of the vector of outputs.

In order to estimate the sensitivity measures discussed in this section, model output values must be available, corresponding to the value of the model output at each of the input points in the sample matrix. If the model is available as an executable file or perhaps reachable via the command line (e.g., via Matlab), SIMLAB can run the model automatically at each of the sample points and perform a sequential sensitivity analysis by gradually increasing the sample size until convergence has been reached. Alternatively, SIMLAB can read model output values in an ASCII format – this might be easier if the model is already set up to quickly read a matrix of input values. In this case, the file containing the model

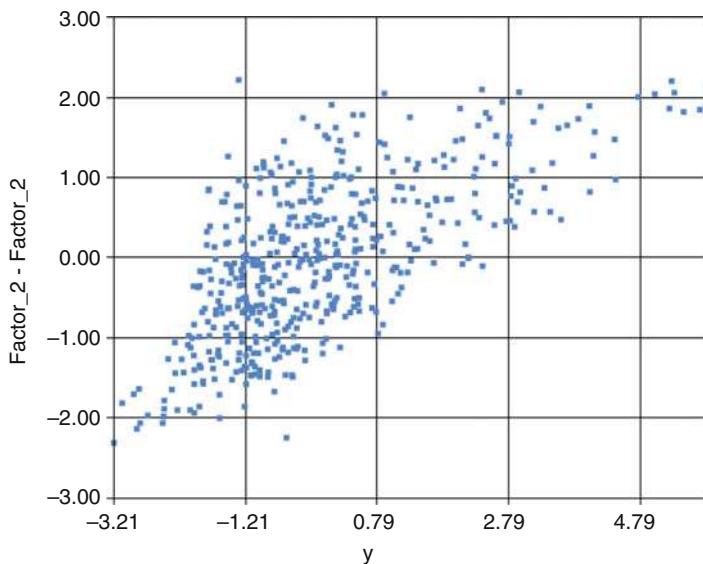

Fig. 57.18 An example of a scatterplot of the model output against one of its inputs

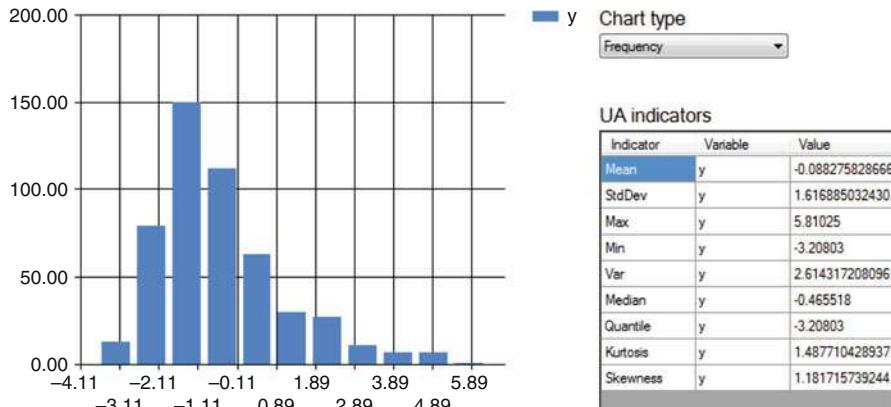

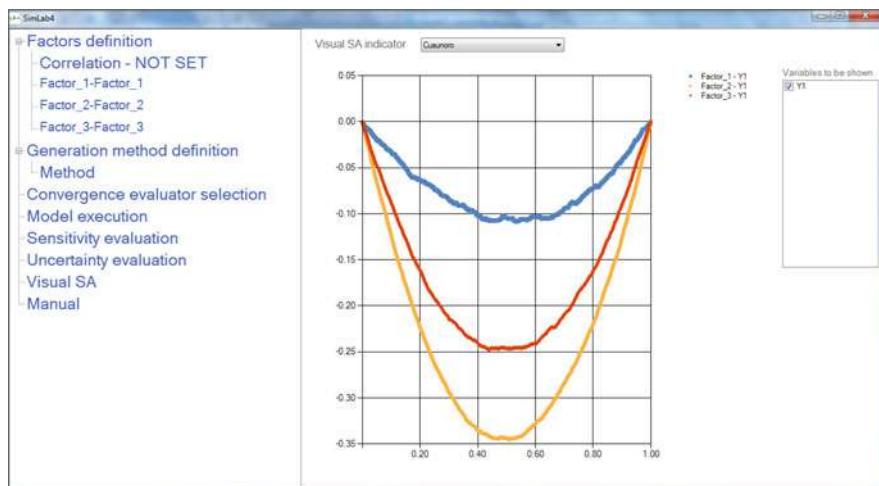

output values should be selected in the “Model execution” pane. Be sure that the file path is also specified. By clicking “Start Monte Carlo run,” SIMLAB uses the input and output samples to estimate all sensitivity measures.

To view the sensitivity measures, go to the “Sensitivity evaluation” heading in the navigation pane. The type of sensitivity measure can be selected from the drop-down menu at the top. The measures can be displayed either on a chart or in a table, although if the output is not time dependent, a table is usually more appropriate. Scatterplots can also be generated by clicking the “Visualise SA” button, for example, Fig. 57.18 shows a scatterplot of the output against one input variable.

The “Uncertainty evaluation” heading also gives information about the uncertainty in the model output, displaying a histogram, as well as giving measures of mean, variance, measures of skewness, and so on (see Fig. 57.19). Finally, by going to the “Visual SA” window, a range of visual indications of sensitivity can be plotted. Figure 57.20 shows a CUSUNORO plot for the three model inputs of the linear model shown previously. Other options that are available with a random or quasi-random sample are “contribution to sample mean” plots and “contribution to sample variance” plots.

6 Extending SIMLAB with R

SIMLAB may also be extended to use other functions and packages within R. This includes adding other types of distributions of input variables, as well as

**Fig. 57.19** Histogram and statistics of output distribution**Fig. 57.20** Contribution to sample variance plot

adding different convergence criteria, other sensitivity methods, and uncertainty indicators.

In order to make such extensions, it is necessary to edit the R project source file “SimLab4R,” which forms the technical basis of the SIMLAB installation. This must be done via RStudio. This file will be available either as part of the SIMLAB installation or separately via the website.

The process of adding extensions is best illustrated by an example. Imagine that a new type of input distribution is required – the Cauchy distribution. The package that must be edited here is “simLabDistributions.R.” In this case, the following steps must be followed:

-
1. Add the name “Cauchy” in the list of distribution names in the `getDistributions` function.
 2. Add the probability density function via the “`dcauchy`” function in the `stats` package. This is done by adding a call to “`dcauchy`” in the “`getDensityFunction`” function.
 3. Add the inverse cumulative density function in the same way, by adding a line to call the “`qcauchy`” function from the “`getInverseCDF`” function.
 4. Signal discrete and/or piecewise distribution if required, by adding lines to “`isDensityPiecewise`” and “`isDensityDiscrete`” (in this example not).
 5. Define required parameters by adding a line to “`getParameters`.”

All the steps here are explained in more detail in the manual. Further possible steps include specifying default values and validity for parameters and specifying whether distributions allow truncation.

7 Conclusions

SIMLAB is a comprehensive stand-alone program for performing global sensitivity analysis, with a number of diverse sampling strategies and sensitivity measures available for estimation, both from classical methods and more recent research. It has the capacity for sequential analysis, and its GSA techniques can be accessed through the R environment, as well as through the graphical user interface. The user can add new GSA techniques by simply adding the corresponding R code to the core layer. SIMLAB can be downloaded for free from [3].

1 Introduction

The needs to assess robust performances for complex systems and to answer tighter regulatory processes (security, safety, environmental control, health impacts, etc.) have led to the emergence of a new industrial simulation challenge: to take uncertainties into account when dealing with complex numerical simulation

frameworks. Many attempts at treating uncertainty in large industrial applications have involved domain-specific approaches or standards: metrology, reliability, differential-based approaches, variance decomposition, etc. However, facing the questioning of their certification authorities in an increasing number of different domains, these domain-specific approaches are no more appropriate. Therefore, a generic methodology has emerged from the joint effort of several industrial companies and academic institutions: [28] reviews these past developments. The specific industrial challenges attached to the recent uncertainty concerns are:

- Transparency: open consensus that can be understood by outside authorities and experts
- Genericity: multi-domain issue that involves various actors along the study
- Modularity: easy integration of innovations from the open-source community
- Multi-accessibility: different levels of use (simple computation, detailed quantitative results, and deep graphical analyses) and different types of end users (graphical interface, Python interpreter, and C++ sources)
- Industrial computing capabilities: to secure the challenging number of simulations required by uncertainty treatment

As no software was fully answering the challenges mentioned above, EDF R&D, Airbus Group, and Phimeca Engineering started a collaboration at the beginning of 2005, joined by IMACS in 2014, for the development of an open-source software platform dedicated to uncertainty propagation by probabilistic methods, named OpenTURNS for open-source treatment of uncertainty, Risk 'N Statistics [10, 29]. OpenTURNS is actively supported by its core team of four industrial partners (IMACS joined the consortium in 2014) and its industrial and academic user community that meet through the website www.openturns.org and annually during the OpenTURNS User's Day. At EDF, OpenTURNS is the repository of all scientific developments on this subject, to ensure their dissemination within the several business units of the company. The software has also been distributed for several years via the integrating platform Salome [27].

1.1 Presentation of OpenTURNS

OpenTURNS is an open-source software under the LGPL license that presents itself as a C++ library and a Python TUI and which works under Linux and Windows environment, with the following key features:

- Open-source initiative to secure the transparency of the approach and its openness to ongoing research and development (R&D) and expert challenging
- Generic to the physical or industrial domains for treating of multi-physical problems
- Structured in a *practitioner guidance* methodological approach

- With advanced industrial computing capabilities, enabling the use of massive distribution and high-performance computing, various engineering environments, large data models, etc.
- Includes the largest variety of qualified algorithms in order to manage uncertainties in several situations
- Contains complete documentation (reference guide, use cases guide, user manual, examples guide, and developers' guide)

All the methodological tools are described after this introduction in the different sections of this paper: uncertainty quantification, uncertainty propagation, sensitivity analysis, and metamodeling. Before the conclusion, a section also explains the generic wrappers' way to link OpenTURNS to any external code.

OpenTURNS can be downloaded from its dedicated website www.openturns.org which offers different pre-compiled packages specific to several Windows and Linux environments. It is also possible to download the source files from the *SourceForge* server (www.sourceforge.net) and to compile them within another environment: the OpenTURNS developer's guide provides advice to help compiling the source files. At last, OpenTURNS has been integrated for more than 5 years in the major Linux distributions (e.g., debian, ubuntu, redhat, and suze).

1.2 The Uncertainty Management Methodology

The uncertainty management generic methodology [29] is schematized in Fig. 58.1. It consists of the following steps:

- Step A: specify the random inputs X , the deterministic inputs d , the model G (analytical, complex computer code or experimental process), the variable of interest (model output) Y , and the quantity of interest on the output (central dispersion, its distribution, probability to exceed a threshold, etc.). The fundamental relation writes:

$$Y = G(X, d) = G(X), \quad (58.1)$$

with $X = (X_1, \dots, X_d)$.

- Step B: quantify the sources of uncertainty. This step consists in modeling the joint probability density function (pdf) of the random input vector by direct methods (e.g., statistical fitting, expert judgment) [15].
- Step B': quantify the sources of uncertainty by indirect methods using some real observations of the model outputs [39]. The calibration process aims to estimate the values or the pdf of the inputs, while the validation process aims to model the bias between the model and the real system.
- Step C: propagate uncertainties to estimate the quantity of interest. With respect to this quantity, the computational resources, and the CPU time cost of a single model run, various methods will be applied: analytical formula, geometrical

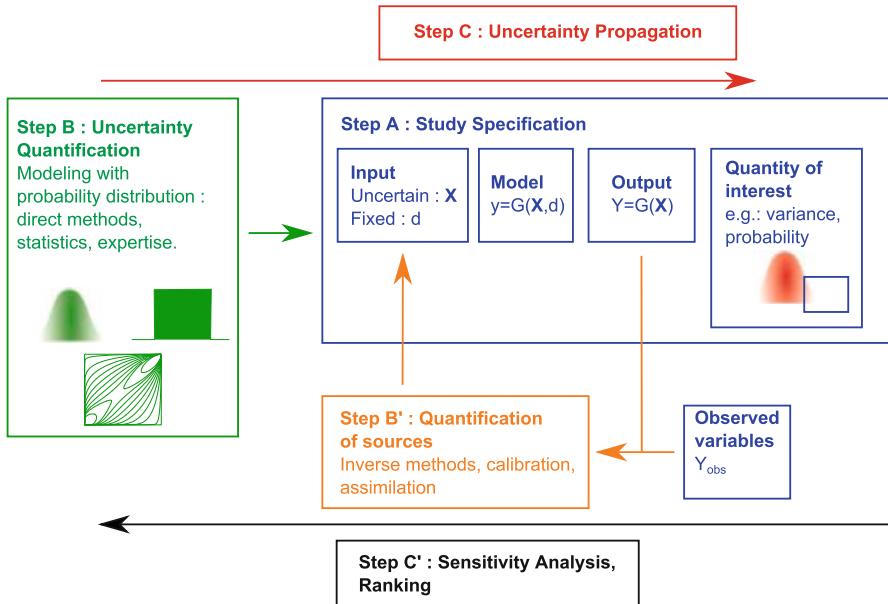

Fig. 58.1 The uncertainty management methodology

approximations, Monte Carlo sampling strategies, metamodel-based techniques, etc. [11, 21].

- Step C': analyze the sensitivity of the quantity of interest to the inputs in order to rank uncertainty sources [14, 36].

For each of these steps, OpenTURNS offers a large number of different methods whose applicability depend on the specificity of the problem (dimension of inputs, model complexity, CPU time cost for a model run, quantity of interest, etc.).

1.3 Main Originality of OpenTURNS

OpenTURNS is innovative in several aspects. Its input data model is based on the multivariate cumulative distribution function (CDF). This enables the usual sampling approach, as would be appropriate for statistical manipulation of large datasets, but also facilitates analytical approaches. Distributions are classified (continuous, discrete, elliptic, etc.) in order to take the best benefit of their properties in algorithms. If possible, the exact final cumulative density function is determined (thanks to characteristic functions implemented for each distribution, the Poisson summation formula, the Cauchy integral formula, etc.).

OpenTURNS explicitly models the dependence with copulas, using the Sklar theorem. Furthermore, different sophisticated analytical treatments may be explored:

aggregation of copulas, composition of functions from R^n into R^d , extraction of copula, and marginals from any distribution.

OpenTURNS defines a domain-specific oriented object language for probability modeling and uncertainty management. This way, the objects correspond to mathematical concepts and their interrelations map the relations between these mathematical concepts. Each object proposes sophisticated treatments in a very simple interface.

OpenTURNS implements up-to-date and efficient sampling algorithms (Mersenne-Twister algorithm, Ziggurat method, the Sequential Rejection Method, etc.). Exact Kolmogorov statistics are evaluated with the Marsaglia method and the noncentral Student and noncentral χ^2 distribution with the Benton and Krishnamoorthy method.

OpenTURNS is the repository of recent results of PhD research carried out at EDF R&D: for instance, the sparse polynomial chaos expansion method based on the LARS method [7], the adaptive directional stratification method [25] which is an accelerated Monte Carlo sampling technique, and the maximum entropy order statistics copulas [20].

1.4 The Flooding Model

Throughout this paper, the discussion is illustrated with a simple application model that simulates the height of a river and compares it to the height of a dike that protects industrial facilities as illustrated in Fig. 58.2. When the river height exceeds that of the dike, flooding occurs. This academic model is used as a pedagogical example in [14]. The model is based on a crude simplification of the 1D hydrodynamical equations of Saint-Venant under the assumptions of uniform

Fig. 58.2 The flood example: simplified model of a river

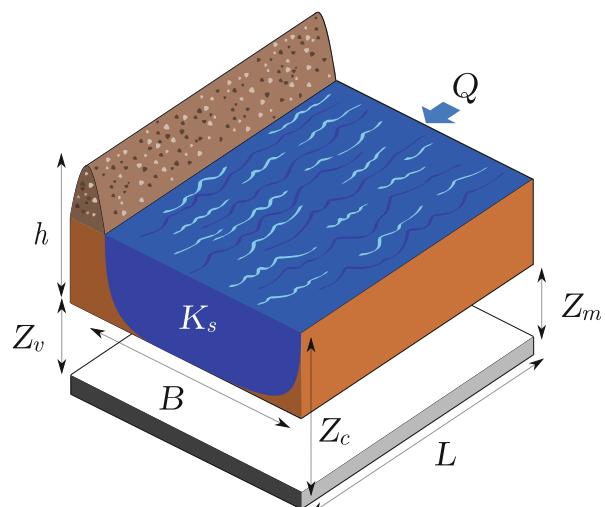

Table 58.1 Input variables of the flood model and their probability distributions

Input	Description	Unit	Probability distribution
Q	Maximal annual flow rate	m^3/s	Gumbel $\mathcal{G}(1.8e^{-3}, 1014)$
K_s	Strickler coefficient	—	Normal $\mathcal{N}(30, 7.5)$
Z_v	River downstream level	m	Triangular $\mathcal{T}(47.6, 50.5, 52.4)$
Z_m	River upstream level	m	Triangular $\mathcal{T}(52.5, 54.9, 57.7)$

and constant flow rate and large rectangular sections. It consists of an equation that involves the characteristics of the river stretch:

$$H = \left(\frac{Q}{BK_s \sqrt{\frac{Z_m - Z_v}{L}}} \right)^{0.6}, \quad (58.2)$$

where the output variable H is the maximal annual height of the river, B is the river width, and L is the length of the river stretch. The four random input variables Q , K_s , Z_v , and Z_m are defined in Table 58.1 with their probability distribution. The randomness of these variables is due to their spatiotemporal variability, our ignorance of their true value, or some inaccuracies of their estimation.

2 Uncertainty Quantification

2.1 Modeling of a Random Vector

OpenTURNS implements more than 40 parametric distributions which are continuous (more than 30 families) and discrete (more than 10 families), with several sets of parameters for each one. Some are multivariate, such as the Student distribution or the normal one.

Moreover, OpenTURNS enables the building of a wide variety of multivariate distributions, thanks to the combination of the univariate margins and a dependence structure, the copula, according to the Sklar theorem: $F(x_1, \dots, x_d) = C(F_1(x_1), \dots, F_d(x_d))$ where F_i is the CDF of the margin X_i and $C : [0, 1]^d \rightarrow [0, 1]$ the copula.

OpenTURNS proposes more than 10 parametric families of copula: Clayton, Frank, Gumbel, Farlie-Morgenstein, etc. These copula can be aggregated to build the copula of a random vector whose components are dependent by blocks. Using the inverse relation of the Sklar theorem, OpenTURNS can extract the copula of any multivariate distribution, whatever the way it has been set up: for example, from a multivariate distribution estimated from a sample with the kernel smoothing technique.

All the distributions can be truncated in their lower and/or upper area. In addition to these models, OpenTURNS proposes other specific constructions. Among them,

note the random vector which writes as a linear combination of a finite set of independent variables: $\mathbf{X} = a_0 + a_1 \mathbf{X}_1 + \dots + a_N \mathbf{X}_N$, thanks to the Python command, written for $N = 2$ with explicit notations:

```
>>>myX= RandomMixture ([ distX1 , distX2 ] , [ a1 , a2 ] , a0 )
```

In that case, the distribution of X is *exactly* determined, using the characteristic functions of the X_i distributions and the Poisson summation formula.

OpenTURNS also easily models the random vector whose probability density function (pdf) is a linear combination of a finite set of independent pdf: $f_{\mathbf{X}} = a_1 f_{\mathbf{X}_1} + \dots + a_N f_{\mathbf{X}_N}$, thanks to the Python command, with the same notations as previously (the weights are automatically normalized):

```
>>>mypdfX= Mixture ([ distX1 , distX2 ] , [ a1 , a2 ])
```

Moreover, OpenTURNS implements a random vector that writes as the random sum of univariate independent and identically distributed variables, this randomness being distributed according to a Poisson distribution: $\mathbf{X} = \sum_{i=1}^N \mathbf{X}_i$, $N \sim \mathcal{P}(\lambda)$, thanks to the Python command:

```
>>>d= CompoundDistribution (lambda , distX )
```

where all the variables X_i are identically distributed according to $distX$. In that case, the distribution of X is *exactly* determined, using the characteristic functions of the X_i distributions and the Poisson summation formula.

In the univariate case, OpenTURNS exactly determines the pushforward distribution \mathcal{D} of any distribution \mathcal{D}_0 through the function $f : \mathbb{R} \rightarrow \mathbb{R}$, thanks to the Python command (with straight notations):

```
>>>d= CompositeDistribution (f , d0 )
```

Finally, OpenTURNS enables the modeling of a random vector (X_1, \dots, X_d) which almost surely verifies the constraint $X = X_1 \leq \dots \leq X_d$, proposing a copula adapted to the ordering constraint [8]. OpenTURNS verifies the compatibility of the margins F_i with respect to the ordering constraint and then builds the associated distribution, thanks to the Python command, written in dimension 2:

```
>>>d=MaximumEntropyOrderStatisticsDistribution ([ distX1 , distX2 ])
```

Figure 58.3 illustrates the copula of such a distribution, built as the ordinal sum of some maximum entropy order statistics copulas.

The OpenTURNS Python script to model the input random vector of the tutorial presented previously is as follows:

```
#Margin distributions:
>>>dist_Q = Gumbel(1.8e-3, 1014)
>>>dist_Q = TruncatedDistribution(dist_Q,0.0, TruncatedDistribution.LOWER)
>>>dist_K = Normal(30.0, 7.5)
>>>dist_K = TruncatedDistribution(dist_K,0., TruncatedDistribution.LOWER)
>>>dist_Zv = Triangular(47.6,50.5,52.4)
>>>dist_Zm = Triangular(52.5,54.9,57.7)
# Copula in dimension 4 for (Q,K,Zv,Zm)
>>>R=CorrelationMatrix (2)
```

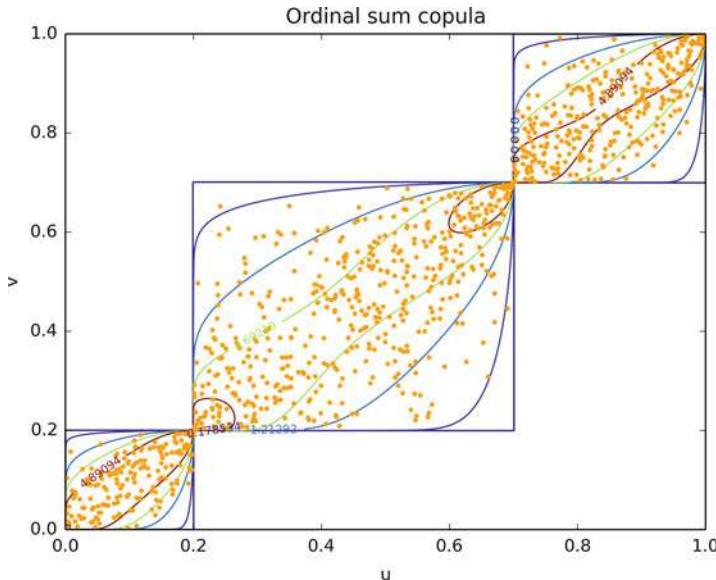

Fig. 58.3 An example of maximum entropy copula which almost surely satisfies the ordering constraint: $X_1 \leq X_2$

```
>>>R[0,1]=0.7
>>>copula = ComposedCopula([IndependentCopula(2), NormalCopula(R)])
# Final distribution for (Q,K,Zv,Zm)
>>>distInput=ComposedDistribution([loi_Q, loi_K, loi_Zv, loi_Zm], copula)
# Final random vector (Q,K,Zv,Zm)
>>>inputVector=RandomVector(distInput)
```

Note that OpenTURNS can truncate any distribution to a lower, an upper bound, or a given interval. Furthermore, a normal copula models the dependence between the variables Z_v and Z_m , with a correlation of 0.7. The variables (Q, K) are independent. Both blocks (Q, K) and (Z_v, Z_m) are independent.

2.2 Stochastic Processes

OpenTURNS implements some multivariate random fields $X : \Omega \times \mathcal{D} \rightarrow \mathbb{R}^d$ where $\mathcal{D} \in \mathbb{R}^s$ is discretized on a mesh. The user can easily build and simulate a random walk, a white noise as illustrated in Figs. 58.4 and 58.5. The Python commands write:

```
>>>myWN = WhiteNoise(myDist, myMesh)
>>>myRW = RandomWalk(myOrigin, myDist, myTimeGrid)
```

Any field can be exported into the VTK format which allows it to be visualized using, e.g., ParaView (www.paraview.org).

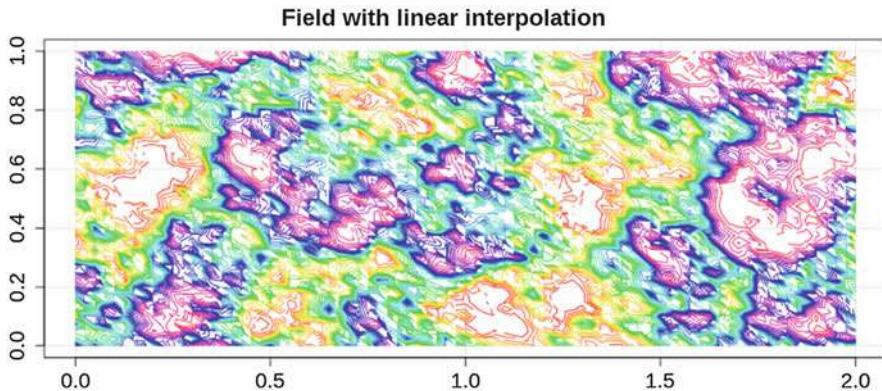

Fig. 58.4 A normal bivariate white noise

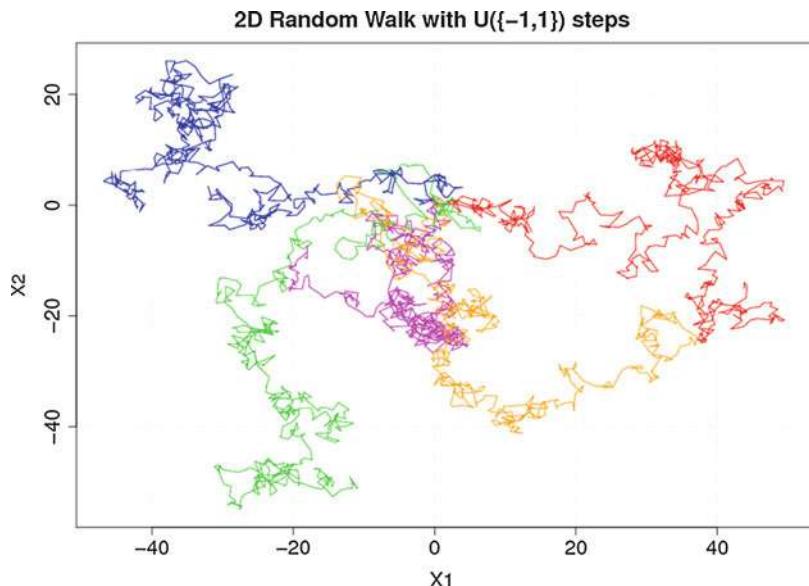

Fig. 58.5 A normal bivariate random walk

Multivariate ARMA stochastic processes $X : \Omega \times [0, T] \rightarrow \mathbb{R}^d$ are implemented in OpenTURNS which enables some manipulations on times series such as the Box Cox transformation or the addition/removal of a trend. Note that the parameters of the Box Cox transformation can be estimated from given fields of the process.

OpenTURNS models normal processes, whose covariance function is a parametric model (e.g., the multivariate exponential model) as well as defined by the user as illustrated in Fig. 58.6. Stationary processes can be defined by its spectral density function (e.g., the Cauchy model).

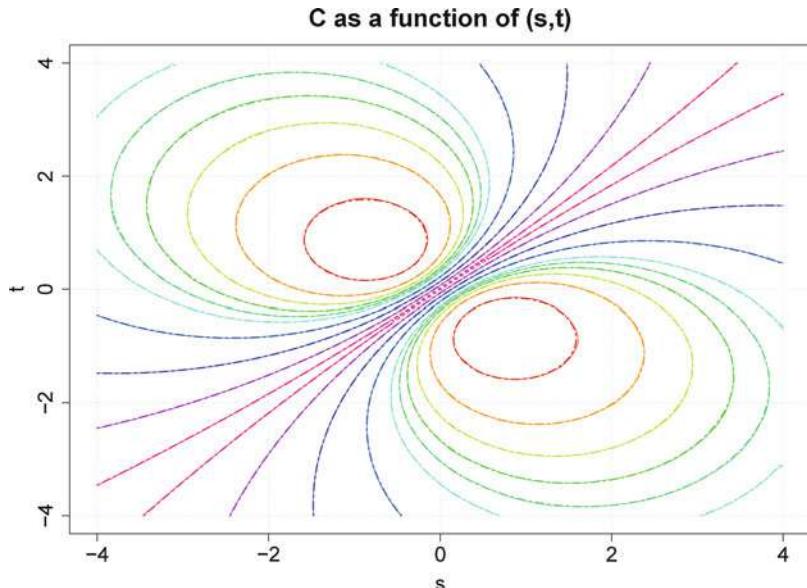

Fig. 58.6 A user-defined nonstationary covariance function and its estimation from several given fields

With explicit notations, the following Python commands create a stationary normal process defined by its covariance function, discretized on a mesh, with an additional trend:

```
>>>myNormalProcess=TemporalNormalProcess (myTrend, myCovarianceModel, myMesh)
```

Note that OpenTURNS enables the mapping of any stochastic processes X into a process Y through a function $f: Y = f(X)$ where the function f can consist, for example, of adding or removing a trend, applying a Box Cox transformation in order to stabilize the variance of X . The Python command is, with explicit notations:

```
>>>myYprocess=CompositeProcess (f, myXprocess)
```

Finally, OpenTURNS implements multivariate processes defined as a linear combination of K deterministic functions $(\phi_i)_{i=1,\dots,K}: \mathbb{R}^{d_1} \mapsto \mathbb{R}^{d_2}$:

$$X(\omega, \mathbf{x}) = \sum_{i=1}^K A_i(\omega) \phi_i(\mathbf{x})$$

where (A_1, \dots, A_K) is a random vector of dimension K . The Python command writes:

```
>>>myX = FunctionalBasisProcess (myRandomCoeff, myBasis, myMesh)
```

2.3 Statistics Estimation

OpenTURNS enables the user to estimate a model from data, in the univariate as well as in the multivariate framework, using the maximum likelihood principle or the moment-based estimation.

Some tests, such as the Kolmogorov-Smirnov test, the chi-square test, and the Anderson-Darling test (for normal distributions), are implemented and can help to select a model among others, from a sample of data. The Python command to build a model and test it writes:

```
>>> estimatedBeta = BetaFactory(sample)
>>> testResult = FittingTest.Kolmogorov(sample, estimatedBeta)
```

OpenTURNS also implements the kernel smoothing technique which is a nonparametric technique to fit a model to data: any distribution can be used as kernel. In the multivariate case, OpenTURNS uses the product kernel. It also implements an optimized strategy to select the bandwidth, depending on the number of data in the sample, which is a mix between the Silverman rule and the plugin one. Note that OpenTURNS proposes a special treatment when the data are bounded, thanks to the mirroring technique. The Python command to build the nonparametric model and to draw its pdf is as simple as the following one:

```
>>> estimatedDist = KernelSmoothing().build(sample)
>>> pdfGraph = estimatedDist.drawPDF()
```

Figure 58.7 illustrates the resulting estimated distributions from a sample of size 500 issued from a beta distribution: the kernel smoothing method takes into account

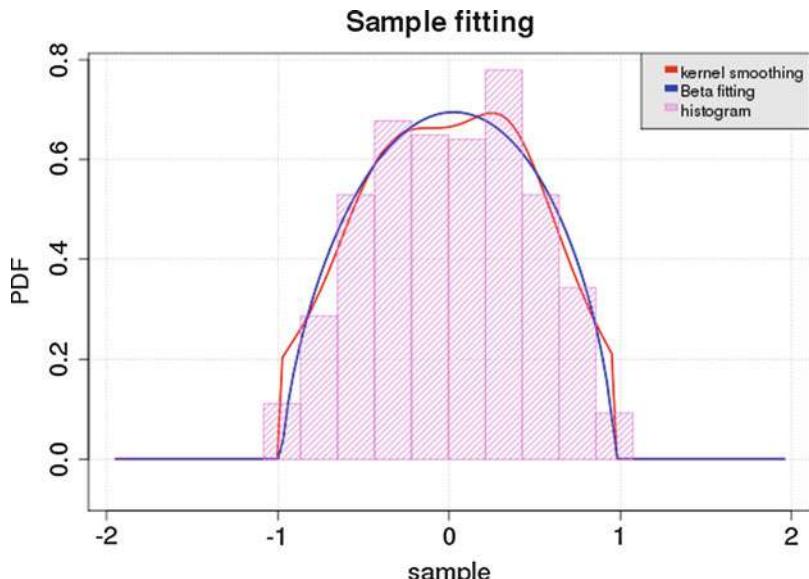

Fig. 58.7 Beta distribution estimation from a sample of size 500: parametric estimation versus kernel smoothing technique

the fact that data are bounded by 0 and 1. The histogram of the data is drawn to enable comparison.

Several visual tests are also implemented to help select models: among them, the QQ plot test and the Henry line test which writes (in the case of a beta distribution for the QQ plot test):

```
>>>graphQQplot = VisualTest.DrawQQplot(sample, Beta())
>>>graphHenryLine = VisualTest.DrawHenryLine(sample)
```

Figure 58.8 illustrates the QQ plot test on a sample of size 500 issued from a beta distribution: the adequation seems satisfying!

Stochastic processes also have estimation procedures from sample of fields or, if the ergodic hypothesis is verified, from just one field. Multivariate ARMA processes are estimated according to the BIC and AIC criteria and the Whittle estimator, which is based on the maximization of the likelihood function in the frequency domain. The Python command to estimate an $ARMA(p, q)$ process of dimension d , based on a sample of time series, writes:

```
>>>estimatedARMA = ARMALikelihood(p, q, d).build(sampleTimeSeries)
```

Moreover, OpenTURNS can estimate the covariance function and the spectral density function of normal processes from given fields. For example, the Python command to estimate a stationary covariance model from a sample of realizations of the process writes:

```
>>>myCovFunc = StationaryCovarianceModelFactory().build(sampleProcess)
```

This estimation is illustrated in Fig. 58.6.

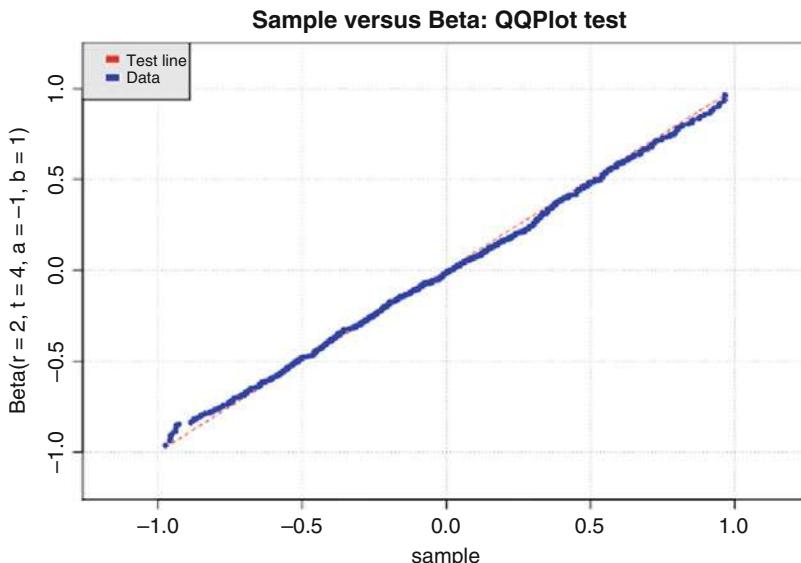

Fig. 58.8 QQ plot test: theoretical model beta versus the sample of size 500

2.4 Conditioned Distributions

OpenTURNS enables the modeling of multivariate distributions by conditioning. Several types of conditioning are implemented.

At first, OpenTURNS enables the creation of a random vector X whose distribution $\mathcal{D}_{X|\Theta}$ whose parameters Θ form a random vector distributed according to the distribution \mathcal{D}_Θ . The Python command writes:

```
>>>myXrandVect = ConditionalRandomVector(distXgivenTheta, distTheta)
```

Figure 58.9 illustrates a random variable X distributed according to a normal distribution, $\mathcal{D}_{X|\Theta=(M,\Sigma)} = \text{Normal}(M, \Sigma)$, whose parameters are defined by $M \sim \text{Uniform}([0, 1])$ and $\Sigma \sim \text{Exponential}(\lambda = 4)$. The probability density function of X has been fitted with the kernel smoothing technique from $n = 10^6$ realizations of X with the normal kernel. It also draws, for comparison needs, the probability density function of X in the case where the parameters are fixed to their mean value.

Furthermore, when the random vector Θ is defined as $\Theta = g(Y)$ where the random vector follows a known distribution \mathcal{D}_Y and g is a given function, OpenTURNS creates the distribution of X with the Python command:

```
>>>finalDist = ConditionalDistribution(distXGgivenTheta, distY, g)
```

Figure 58.10 illustrates the distribution of X that follows a $\text{Uniform}(A, B)$ distribution, with $(A, B) = g(Y)$, $g : \mathbb{R} \rightarrow \mathbb{R}^2$, $g(Y) = (Y, 1 + Y^2)$ and Y follows a $\text{Uniform}(-1, 1)$ distribution.

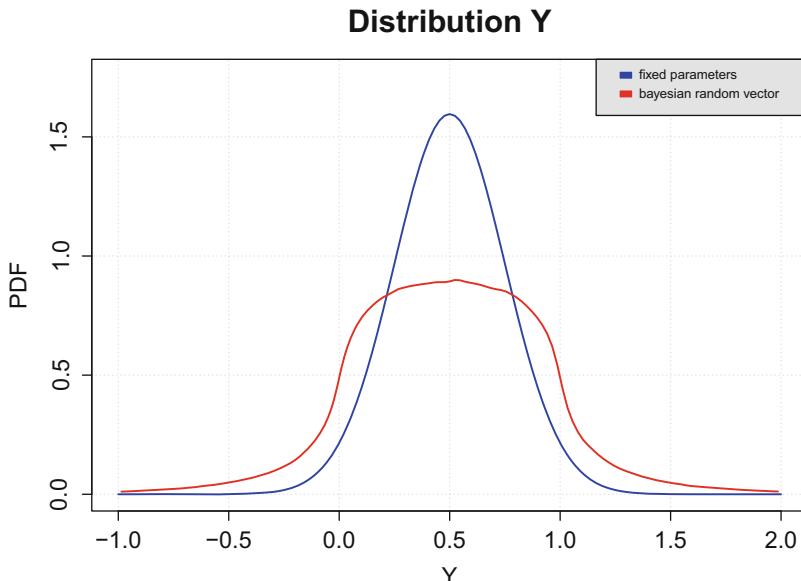

Fig. 58.9 Normal distribution with random or fixed parameters

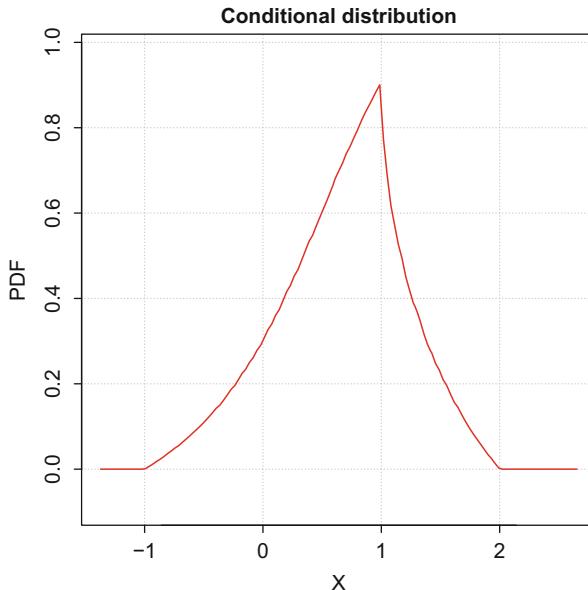

Fig. 58.10 $Uniform(Y, 1 + Y^2)$, with $Y \sim Uniform(-1, 1)$

2.5 Bayesian Calibration

Finally, OpenTURNS enables the calibration of a model (which can be a computer code), thanks to the Bayesian estimation, which is the evaluation of the model's parameters. More formally, let's consider a model G that writes: $y = G(x, \theta)$ where $x \in \mathbb{R}^{d_1}$, $y \in \mathbb{R}^{d_3}$ and $\theta \in \mathbb{R}^{d_2}$ is the vector of unknown parameters to calibrate. The Bayesian calibration consists in estimating θ , based on a certain set of n inputs (x^1, \dots, x^n) (an experimental design) and some associated observations (z^1, \dots, z^n) which are regarded as the realizations of some random vectors (Z^1, \dots, Z^n) , such that, for all i , the distribution of Z^i depends on $y^i = g(x^i, \theta)$. Typically, $Z^i = Y^i + \epsilon^i$ where ϵ^i is a random measurement error. Once the user has defined the prior distribution of θ , OpenTURNS maximizes the likelihood of the observations and determines the posterior distribution of θ , given the observations, using the Metropolis-Hastings algorithm [5, 23].

3 Uncertainty Propagation

Once the input multivariate distribution has been satisfactorily chosen, these uncertainties can be propagated through the G model to the output vector Y . Depending on the final goal of the study (min-max approach, central tendency, or reliability), several methods can be used to estimate the corresponding quantity

of interest, tending to respect the best compromise between the accuracy of the estimator and the number of calls to the numerical, and potentially costly, model.

3.1 Min-Max Approach

The aim here is to determine the extreme (minimum and maximum) values of the components of Y for the set of all possible values of X . Several techniques enable it to be done:

- Techniques based on design of experiments: the extreme values of Y are sought for only a finite set of combinations $(\mathbf{x}^1, \dots, \mathbf{x}^n)$.
- Techniques using optimization algorithms.

3.1.1 Techniques Based on Design of Experiments

In this case, the min-max approach consists of three steps:

- Choice of experiment design used to determine the combinations $(\mathbf{x}^1, \dots, \mathbf{x}^n)$ of the input random variables
- Evaluation of $\mathbf{y}^i = G(\mathbf{x}^i)$ for $i = 1, \dots, N$
- Evaluation of $\min_{1 \leq i \leq N} y_i^k$ and of $\max_{1 \leq i \leq N} y_i^k$, together with the combinations related to these extreme values: $\mathbf{x}_{k,\min} = \operatorname{argmin}_{1 \leq i \leq N} y_i^k$ and $\mathbf{x}_{k,\max} = \operatorname{argmax}_{1 \leq i \leq N} y_i^k$

The type of design of experiments impacts the quality of the metamodel and then on the evaluation of its extreme values. OpenTURNS gives access to two usual families of design of experiments for a min-max study:

- Some stratified patterns (axial, composite, factorial, or box patterns). Here are the two command lines that generate a sample from a two-level factorial pattern:

```
>>>myCenteredReducedGrid = Factorial(2, levels)
>>>mySample = myCenteredReducedGrid.generate()
```

- Some weighted patterns that include, on the one hand, random patterns (Monte Carlo, LHS) and, on the other hand, low-discrepancy sequences (Sobol, Faure, Halton, Reverse Halton, and Haselgrave, in dimension $n > 1$). The following lines illustrate the creation of a Faure sequence in dimension 2 or a Monte Carlo design experiment from a bidimensional normal (0,1) distribution:

```
# Sobol Sequence Sampling
>>>mySobolSample = FaureSequence(2).generate(1000)
# Monte Carlo Sampling
>>>myMCSSample = MonteCarloExperiment(Normal(2), 100)
```

Figures 58.11 and 58.12, respectively, illustrate a design of experiments issued from a Faure sequence and a normal distribution in dimension 2.

Fig. 58.11 The first 1000 points according to a Faure sequence of dimension 2

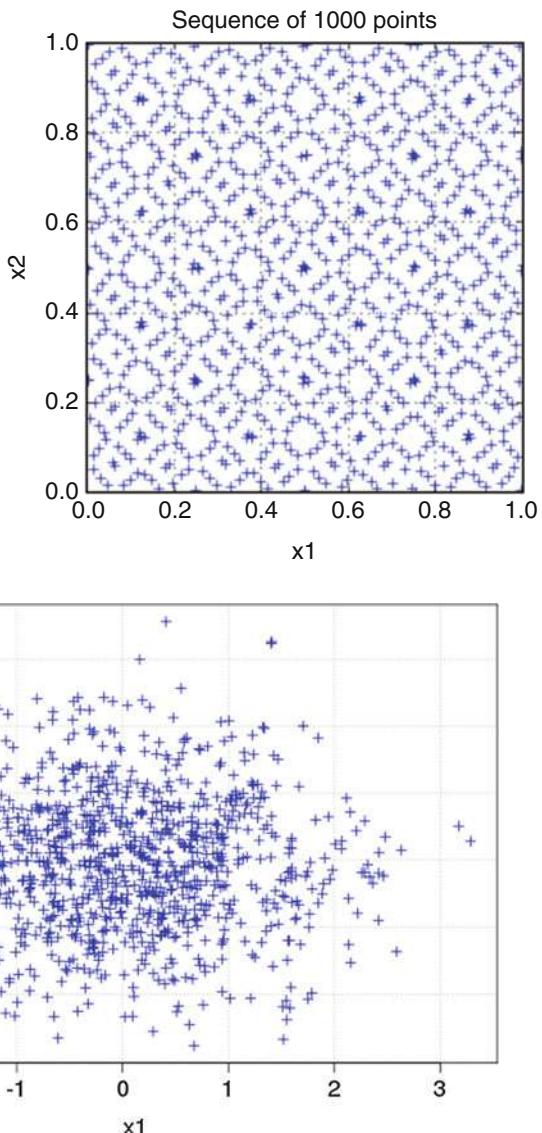

Fig. 58.12 Sample of 1000 points according to a normal $(0,1)$ distribution of dimension 2

3.1.2 Techniques Based on Optimization Algorithm

In this kind of approach, the min or max value of the output variable is sought, thanks to an optimization algorithm. OpenTURNS offers several optimization algorithms for the several steps of the global methodology. Here, the Truncated Newton Constrained (TNC) is often used, which minimizes a function with variables subject to bounds, using gradient information. More details may be found in [26].

```

# For the research of the min value
>>>myAlgoTNC = TNC(TNCSpecificParameters() , limitStateFunction ,
                     intervalOptim , startingPoint , TNC.MINIMIZATION)
# For the research of the max value
>>>myAlgoTNC = TNC(TNCSpecificParameters() , limitStateFunction ,
                     intervalOptim , startingPoint , TNC.MAXIMIZATION)
# Run the research and extract the results
>>>myAlgoTNC.run()
>>>myAlgoTNCResult = BoundConstrainedAlgorithm(myAlgoTNC).getResult()
>>>optimalValue = myAlgoTNCResult.getOptimalValue()

```

3.2 Central Tendency

A central tendency evaluation aims at evaluating a reference value for the variable of interest, here the water level, H , and an indicator of the dispersion of the variable around the reference. To address this problem, mean $\mu_Y = e(Y)$ and the standard deviation $\sigma_Y = \sqrt{V(Y)}$ of Y are here evaluated using two different methods.

First, following the usual method within the measurement science community [12], μ_Y and σ_Y have been computed under a Taylor first-order approximation of the function $Y = G(\mathbf{X})$ (notice that the explicit dependence on the deterministic variable \mathbf{d} is here omitted for simplifying notations):

$$\mu_Y \simeq G(\mathbb{E}(\mathbf{X})) \quad (58.3)$$

$$\sigma_Y \approx \sum_{i=1}^d \sum_{j=1}^d \frac{\partial G}{\partial X_i} \Big|_{e(X)} \frac{\partial G}{\partial X_j} \Big|_{e(X)} \rho_{ij} \sigma_i \sigma_j, \quad (58.4)$$

σ_i and σ_j being the standard deviation of the i th and j th components X_i and X_j of the vector \mathbf{X} and ρ_{ij} their correlation coefficient. Thanks to the formulas above, the mean and the standard deviation of H are evaluated as 52.75m and 1.15m, respectively:

```

>>>myQuadCum = QuadraticCumul(outputVariable)
# First order Mean
>>>meanFirstOrder = myQuadCum.getMeanFirstOrder()[0]
# Second order Mean
>>>meanSecondOrder = myQuadCum.getMeanSecondOrder()[0]
# First order Variance
>>>varFirstOrder = myQuadCum.getCovariance()[0,0]

```

Then, the same quantities have been evaluated by a Monte Carlo evaluation: a set of 10000 samples of the vector \mathbf{X} is generated and the function $G(\mathbf{X})$ is evaluated, thus giving a sample of H . The empirical mean and standard deviation of this sample are 52.75 and 1.42 m, respectively. Figure 58.13 shows the empirical histogram of the generated sample of H .

```

# Create a random sample of the output variable of interest of size 10000
>>>outputSample = outputVariable.getNumericalSample(10000)

```

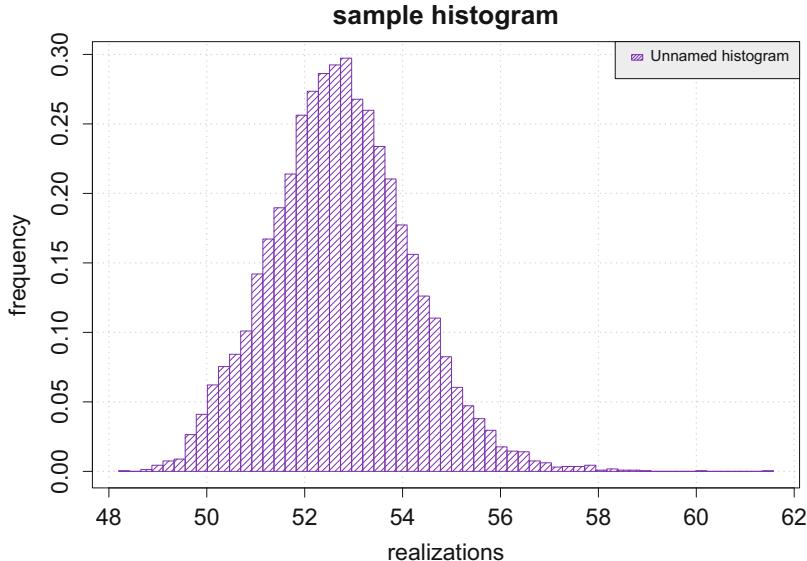

Fig. 58.13 Empirical histogram of 10000 samples of H

```
# Get the empirical mean
>>> empiricalMean = outputSample.computeMean()
# Get the empirical covariance matrix
>>> empiricalCovarianceMatrix = outputSample.computeCovariance()
```

3.3 Failure Probability Estimation

This section focuses on the estimation of the probability for the output Y to exceed a certain threshold s , noted P_f in the following. If s is the altitude of a flood protection dike, then the above excess probability, P_f , can be interpreted as the probability of an overflow of the dike, i.e., a failure probability.

Note that an equivalent way of formulating this reliability problem would be to estimate the $(1 - p)$ -th quantile of the output's distribution. This quantile can be interpreted as the flood height q_p which is attained with probability p each year. $T = 1/p$ is then seen to be a return period, i.e., a flood as high as $q_{1/T}$ occurs on average every T years.

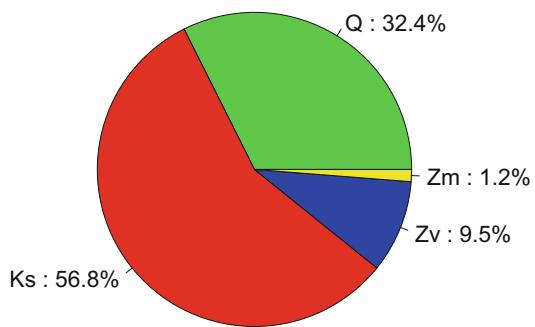

Hence, the probability of overflowing a dike with height s is less than p (where p , for instance, could be set according to safety regulations) if and only if $s \geq q_p$, i.e., if the dike's altitude is higher than the flood with return period equal to $T = 1/p$.

3.3.1 FORM

A way to evaluate such failure probabilities is through the so-called first-order reliability method (FORM) [9]. This approach allows, by using an equiprobabilistic transformation and an approximation of the limit state function, the evaluation with

Fig. 58.14 FORM importance factors

FORM Importance Factors – Event Zc > 58.0

a much reduced number of model evaluations, of some low probability as required in the reliability field. Note that OpenTURNS implements the Nataf transformation where the input vector X has a normal copula, the generalized Nataf transformation when X has an elliptical copula, and the Rosenblatt transformation for any other cases [16–19].

The probability that the yearly maximal water height H exceeds $s=58$ m is evaluated using FORM. The Hasofer-Lind reliability index was found to be equal to $\beta_{HL} = 3.04$, yielding a final estimate of:

$$\hat{P}_{f, \text{FORM}} = 1.19 \times 10^{-3}.$$

The method gives also some importance factors that measure the weight of each input variable in the probability of exceedance, as shown on Fig. 58.14.

```
>>>myFORM = FORM(Cobyla(), myEvent, meanInputVector)
>>>myFORM.run()
>>>FormResult = myFORM.getResult()
>>>pFORM = FormResult.getEventProbability()
>>>HasoferIndex = FormResult.getHasoferReliabilityIndex()
# Importance factors
>>>importanceFactorsGraph = FormResult.drawImportanceFactors()
```

3.3.2 Monte Carlo

Whereas the FORM approximation relies on strong assumptions, the Monte Carlo method is always valid, independently from the regularity of the model. It is nevertheless much more computationally intensive, covering all the input domain to evaluate the probability of exceeding a threshold. It consists in sampling many input values $(X^{(i)})_{1 \leq i \leq N}$ from the input vector joint distribution, then computing the corresponding output values $Y^{(i)} = g(X^{(i)})$. The excess probability P_f is then estimated by the proportion of sampled values $Y^{(i)}$ that exceed t :

$$\hat{P}_{f, MC} = \frac{1}{N} \sum_{i=1}^N \mathbf{1}_{\{Y^{(i)} > s\}}. \quad (58.5)$$

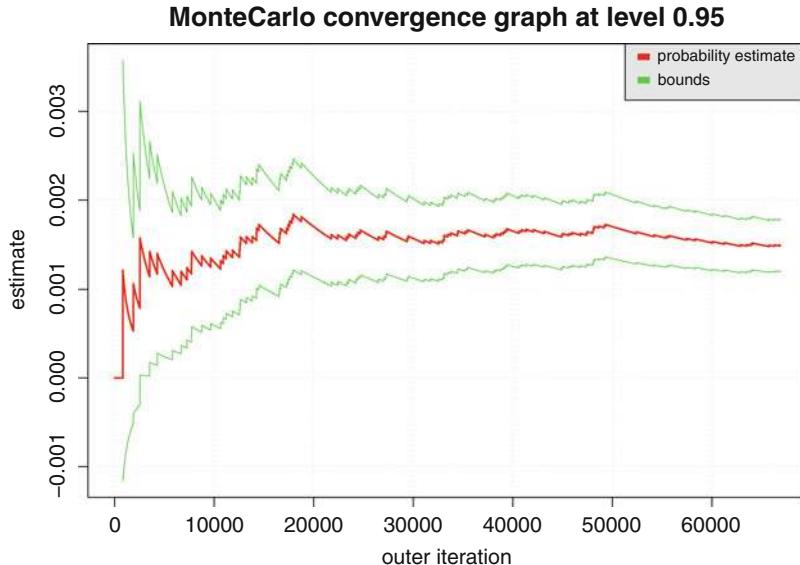

Fig. 58.15 Monte Carlo convergence graph

The sample average of the estimation error $\hat{P}_{f,MC} - P_f$ decreases as $1/\sqrt{N}$ and can be precisely quantified by a confidence interval derived from the central limit theorem. In the present case, the results are:

$$\hat{P}_{f,MC} = 1.50 \times 10^{-3},$$

with the following 95% confidence interval:

$$I_{P_f,MC} = [1.20 \times 10^{-3}, 1.79 \times 10^{-3}].$$

These results are coherent with those of the FORM approximation, confirming that the assumptions underlying the latter are correct. Figure 58.15 shows the convergence of the estimate depending on the size of the sample, obtained with OpenTURNS.

```
>>>myEvent = Event(outputVariable, Greater(), threshold)
>>>myMonteCarlo = MonteCarlo(myEvent)
# Specify the maximum number of simulations
>>>numberMaxSimulation = 100000
>>>myMonteCarlo.setMaximumOuterSampling(numberMaxSimulation)
# Perform the algorithm
>>>myMonteCarlo.run()
# Get the convergence graph
>>>convergenceGraph = myMonteCarlo.drawProbabilityConvergence()
>>>convergenceGraph.draw("MonteCarloCovergenceGraph")
```

3.3.3 Importance Sampling

An even more precise estimate can be obtained through importance sampling [31], using the Gaussian distribution with identity covariance matrix and mean equal to the design point u^* as the proposal distribution. Many values $(U^{(i)})_{1 \leq i \leq N}$ are sampled from this proposal. Because $\phi_n(u - u^*)$ is the proposal density from which the $U^{(i)}$ have been sampled, the failure probability can be estimated without bias by:

$$\hat{P}_{f,IS} = \frac{1}{N} \sum_{i=1}^N \mathbf{1}_{\{G \circ T^{-1} U^{(i)} > s\}} \frac{\phi_n(U^{(i)})}{\phi_n(U^{(i)} - u^*)} \quad (58.6)$$

The rationale of this approach is that, by sampling in the vicinity of the failure domain boundary, a larger proportion of values fall within the failure domain than by sampling around the origin, leading to a better evaluation of the failure probability and a reduction in the estimation variance. Using this approach, the results are:

$$\hat{P}_{f,IS} = 1.40 \times 10^{-3}$$

As in the simple Monte Carlo approach, a 95%-level confidence interval can be derived from the output of the importance sampling algorithm. In the present case, this is equal to:

$$I_{P_f,IS} = [1.26 \times 10^{-3}, 1.53 \times 10^{-3}],$$

and indeed provides tighter confidence bounds for P_f .

```
# Specify the starting point from FORM algorithm
>>> standardPoint = FormResult.getStandardSpaceDesignPoint()
# Define the importance distribution
>>> sigma = [1.0, 1.0, 1.0, 1.0]
>>> importanceDistrib = Normal(standardPoint, sigma, CorrelationMatrix(4))
# Define the IS algorithm : event, distribution, criteria of convergence
>>> myAlgoImportanceSampling = ImportanceSampling(
    (myStandardEvent, importanceDistrib))
>>> myAlgoImportanceSampling.setMaximumOuterSampling(maximumOuterSampling_IS)
>>> myAlgoImportanceSampling.setMaximumCoefficientOfVariation(0.05)
```

3.3.4 Directional Sampling

The directional simulation method is an accelerated sampling method that involves as a first step a preliminary iso-probabilistic transformation as in the FORM method. The basic idea is to explore the space by sampling in several directions in the standard space. The final estimate of the probability P_f after N simulations is the following:

$$\hat{P}_{f,DS} = \frac{1}{N} \sum_{i=1}^N q_i$$

where q_i is the probability obtained in each explored direction. A central limit theorem allows to access to some confidence interval on this estimate. More details on this specific method can be found in [32].

In practice in OpenTURNS, the directional sampling simulation requires the choice of several parameters in the methodology: a sampling strategy to choose the explored directions, a “root strategy” corresponding to the way to seek the limit state function (i.e., a sign change) along the explored direction, and a nonlinear solver to estimate the root. A default setting of these parameters allows the user to test the method in one command line:

```
>>>myAlgo = DirectionalSampling(myEvent)
```

3.3.5 Subset Sampling

The subset sampling is a method for estimating rare event probability, based on the idea of replacing rare failure event by a sequence of more frequent events F_i :

$$F_1 \supset F_2 \supset \cdots \supset F_m = F$$

The original probability is obtained conditionally to the more frequent events:

$$P_f = P(F_m) = P\left(\bigcap_{i=1}^m F_i\right) = P(F_1) \prod_{i=2}^m P(F_i | F_{i-1})$$

In practice, the subset simulation shows a substantial improvement ($N_T \sim \log P_f$) compared to crude Monte Carlo ($N_T \sim \frac{1}{P_f}$) sampling when estimating rare events. More details on this specific method can be found in [2].

OpenTURNS provides this method through a dedicated module. Here also, some parameters of the methods have to be chosen by the user: a few command lines allows the algorithm to be set up before its launch.

```
>>>mySSAlgo=SubsetSampling(myEvent)
# Change the target conditional probability of each subset domain
>>>mySSAlgo.setTargetProbability(0.9)
# Set the width of the MCMC random walk uniform distribution
>>>mySSAlgo.setProposalRange(1.8)
# This allows to control the number of samples per step
>>>mySSAlgo.setMaximumOuterSampling(10000)
# Run the algorithm
>>>mySSAlgo.run()
```

4 Sensitivity Analysis

The sensitivity analysis aims to investigate how a given computational model answers to variations in its inputs. Such knowledge is useful for determining the degree of resemblance of a model and a real system, distinguishing the factors that

mostly influence the output variability and those that are insignificant, revealing interactions among input parameters and correlations among output variables, etc. A detailed description of sensitivity analysis methods can be found in [36] and in the *Sensitivity analysis* chapter of the Springer Handbook. In the global sensitivity analysis strategy, the emphasis is put on apportioning the output uncertainty to the uncertainty in the input factors, given by their uncertainty ranges and probability distributions.

4.1 Graphical Tools

In sensitivity analysis, graphical techniques have to be used first. With all the scatterplots between each input variable and the model output, one can immediately detect some trends in their functional relation. The following instructions allow scatterplots of Fig. 58.16 to be obtained from a Monte Carlo sample of size $N = 1000$ of the flooding model.

```
>>> inputSample = inputRandomVector.getNumericalSample(1000)
>>> inputSample.setDescription(['Q', 'K', 'Zv', 'Zm'])
>>> outputSample = finalModelCrue(inputSample)
>>> outputSample.setDescription(['H'])
# Here, stack both samples in one
>>> inputSample.stack(outputSample)
>>> myPairs = Pairs(inputSample)
>>> myGraph = Graph()
>>> myGraph.add(myPairs)
```

In the right column of Fig. 58.16, it is clear that the strong and rather linear effects of Q and Z_v on the output variable H . In the plot of the third line and fourth column, it is also clear that the dependence between Z_v and Z_m comes from the large correlation coefficient introduced in the probabilistic model.

However scatterplots do not capture some interaction effects between the inputs. Cobweb plots are then used to visualize the simulations as a set of trajectories. The following instructions allow the cobweb plots of Fig. 58.17 to be obtained where the simulations leading to the largest values of the model output H have been colored in red.

```
>>> inputSample = inputRandomVector.getNumericalSample(1000)
>>> outputSample = finalModelCrue(inputSample)
# Graph 1 : value based scale to describe the Y range
>>> minValue = outputSample.computeQuantilePerComponent(0.05)[0]
>>> maxValue = outputSample.computeQuantilePerComponent(0.95)[0]
>>> myCobweb = VisualTest.DrawCobWeb(inputSample, outputSample,
                                         minValue, maxValue, 'red', False)
```

The cobweb plot allows us to immediately understand that these simulations correspond to large values of the flow rate Q and small values of the Strickler coefficient K_s .

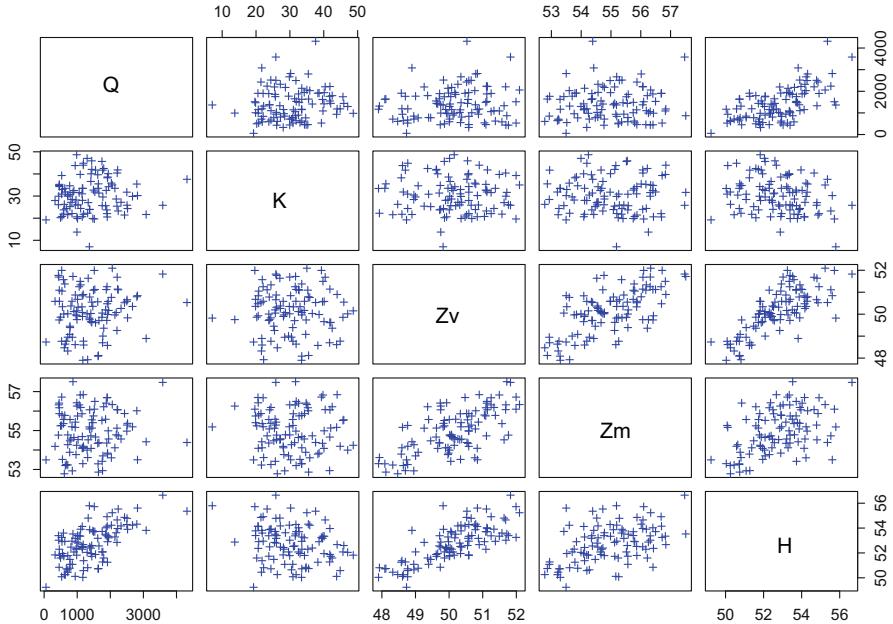

Fig. 58.16 Scatterplots between the inputs and the output of the flooding model: each combination (input i, input j) and (input i, output) is drawn, which enables to exhibit some correlation patterns

4.2 Sampling-Based Methods

In order to obtain quantitative sensitivity indices rather than qualitative information, one may use some sampling-based methods which often suppose that the input variables are independent. The section illustrates some of these methods on the flooding model with independence between its input variables.

If the behavior of the output Y compared to the input vector X is overall linear, it is possible to obtain quantitative measurements of the inputs influences from the regression coefficients α_i of the linear regression connecting Y to the $X = (X_1, \dots, X_p)$. The standard regression coefficient (SRC), defined by:

$$\text{SRC}_i = \alpha_i \frac{\sigma_i}{\sigma_Y} \quad (\text{for } i = 1 \dots p), \quad (58.7)$$

with σ_i (resp. σ_Y), the standard deviation of X_i (resp. Y), measures the variation of the response for a given variation of the parameter X_i . In practice, the coefficient R^2 (the variance percentage of the output variable Y explained by the regression model) also helps to check the linearity: if R^2 is close to one, the relation connecting Y to all the parameters X_i is almost linear and the SRC sensitivity indices make sense.

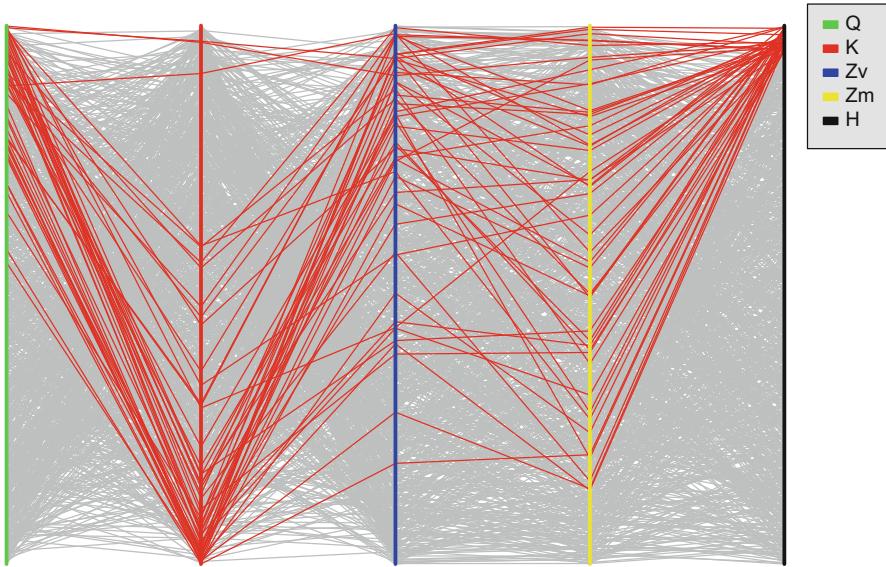

Fig. 58.17 Cobweb plot for the flooding model: each simulation is drawn. The input marginal values are linked to the output value (last column). All the simulations that led to a high quantile of the output are drawn in red: the cobweb plot enables to detect all the combinations of the inputs they come from

Table 58.2 Regression coefficients and SRC of the flood model inputs ($\alpha_0 = -0.1675$ and $R^2 = 0.97$)

	Q	K_s	Z_v	Z_m
α_i	3.2640	0.0012	-0.0556	1.1720
SRC _i	0.3462	0.0851	0.6814	0.0149

The following instructions allow the results of Table 58.2 to be obtained from a Monte Carlo sample of size $N = 1000$.

```
>>>inputSample = inputRandomVector.getNumericalSample(1000)
>>>outputSample = finalModelCrue(inputSample)
>>>SRCCoefficient = CorrelationAnalysis.SRC
        (inputSample, outputSample)
>>>linRegModel=LinearModelFactory().build
        (inputSample, outputSample, 0.90)
>>>Rsquared = LinearModelTest.LinearModelRSquared(inputSample,
        outputSample, linRegModel, 0.90)
```

The SRC values confirm our first conclusions drawn from the scatterplots visual analysis. As $R^2 = 0.97$ is very close to one, the model is quasi-linear. The SRC coefficients are sufficient to perform a global sensitivity analysis.

Several other estimation methods are available in OpenTURNS for a sensitivity analysis purpose:

- Derivatives and Pearson correlation coefficients (linearity hypothesis between output and inputs).
- Spearman correlation coefficients and standard rank regression coefficients (monotonicity hypothesis between output and inputs).
- Reliability importance factors with the FORM/SORM importance measures presented previously (Sect. 3).
- Variance-based sensitivity indices (no hypothesis on the model). These last indices, often known as Sobol indices and defined by:

$$S_i = \frac{\text{Var}[\mathbb{E}(Y|X_i)]}{\text{Var}(Y)} \text{ (first order index) and} \quad (58.8)$$

$$S_{T_i} = \sum_{i=1}^p S_i + \sum_{i < j} S_{ij} + \dots \text{ (total index),}$$

are estimated in OpenTURNS with the classic pick-freeze method based on two independent Monte Carlo samples [34]. In OpenTURNS, other ways to compute the Sobol indices are the extended FAST method [35] and the coefficients of the polynomial chaos expansion [38].

5 Metamodels

When each model evaluation is time consuming, it is usual to build a surrogate model which is a good approximation of the initial model and which can be evaluated at negligible cost. OpenTURNS proposes some usual polynomial approximations: the linear or quadratic Taylor approximations of the model at a particular point, or a linear approximation based on the least squares method. Two recent techniques implemented in OpenTURNS are detailed here: the polynomial chaos expansion and the Kriging approximation.

5.1 Polynomial Chaos Expansion

The polynomial chaos expansion enables the approximation of the output random variable of interest $Y = G(X)$ with $g : \mathbb{R}^d \rightarrow \mathbb{R}^p$ by the surrogate model:

$$\tilde{Y} = \sum_{k \in K} \alpha_k \Psi_k \circ T(X)$$

where $\alpha_k \in \mathbb{R}^p$, T is an iso-probabilistic transformation (e.g., the Rosenblatt transformation) which maps the multivariate distribution of X into the multivariate distribution $\mu = \prod_{i=1}^d \mu_i$, and $(\Psi_k)_{k \in \mathbb{N}}$ is a multivariate polynomial basis of

$\mathcal{L}_\mu^2(\mathbb{R}^d, \mathbb{R}^p)$ which is orthonormal according to the distribution μ . K is a finite subset of \mathbb{N} . \mathbf{Y} is supposed to be of finite second moment.

OpenTURNS proposes the building of the multivariate orthonormal basis $(\Psi_k(\mathbf{x}))_{k \in \mathbb{N}}$ as the Cartesian product of orthonormal univariate polynomial family $(\Psi_l^i(z_i))_{l \in \mathbb{N}}$:

$$\Psi_k(\mathbf{z}) = \Psi_{k_1}^1(z_1) * \Psi_{k_2}^2(z_2) * \cdots * \Psi_{k_d}^d(z_d)$$

The possible univariate polynomial families associated to continuous measures are:

- Hermite, which is orthonormal with respect to the *normal*(0, 1) distribution
- Jacobi($\alpha, \beta, param$), which is orthonormal with respect to the *Beta*($\beta + 1, \alpha + \beta + 2, -1, 1$) distribution if $param = 0$ (default value) or to the *Beta*($\alpha, \beta, -1, 1$) distribution if $param = 1$
- Laguerre(k), which is orthonormal with respect to the *Gamma*($k + 1, 1, 0$) distribution
- Legendre, which is orthonormal with respect to the *Uniform*(-1, 1) distribution

OpenTURNS proposes three strategies to truncate the multivariate orthonormal basis to the finite set K : these strategies select different terms from the multivariate basis, based on a convergence criterion of the surrogate model and the cleaning of the less significant coefficients.

The coefficients of the polynomial decomposition writes:

$$\boldsymbol{\alpha} = \operatorname{argmin}_{\boldsymbol{\alpha} \in \mathbb{R}^K} E_\mu \left[\left(g \circ T^{-1}(\mathbf{Z}) - \sum_{k \in K} \alpha_k \Psi_k(\mathbf{Z}) \right)^2 \right] \quad (58.9)$$

as well as:

$$\boldsymbol{\alpha} = (E_\mu [g \circ T^{-1}(\mathbf{Z}) \Psi_k(\mathbf{Z})])_k \quad (58.10)$$

where $\mathbf{Z} = T(\mathbf{X})$ is distributed according to μ .

It corresponds to two points of view implemented by OpenTURNS: the relation (58.9) means that the coefficients $(\alpha_k)_{k \in K}$ minimize the mean quadratic error between the model and the polynomial approximation; the relation (58.10) means that α_k is the scalar product of the model with the $k-th$ element of the orthonormal basis $(\Psi_k)_{k \in K}$. In both cases, the expectation E_μ is approximated by a linear quadrature formula that writes, in the general case:

$$E_\mu [f(\mathbf{Z})] \simeq \sum_{i \in I} \omega_i f(\mathcal{E}_i) \quad (58.11)$$

where f is a function $L_1(\mu)$. The set I , the points $(\mathcal{E}_i)_{i \in I}$, and the weights $(\omega_i)_{i \in I}$ are evaluated from weighted designs of experiments which can be random (Monte Carlo experiments and importance sampling experiments) or deterministic (low-discrepancy experiments, user-given experiments, and Gaussian product experiments).

At last, OpenTURNS gives access to:

- The composed model $h : \mathbf{Z} \mapsto \mathbf{Y} = G \circ T^{-1}(\mathbf{Z})$, which is the model of the reduced variables \mathbf{Z} . Then, $h = \sum_{k \in \mathbb{N}} \alpha_k \Psi_k$.
- The coefficients of the polynomial approximation: $(\alpha_k)_{k \in K}$.
- The composed metamodel: \hat{h} , which is the model of the reduced variables reduced to the truncated multivariate basis $(\Psi_k)_{k \in K}$. Then, $\hat{h} = \sum_{k \in K} \alpha_k \Psi_k$.
- The metamodel: $\hat{g} : \mathbf{X} \mapsto Y = \hat{h} \circ T(\mathbf{X})$ which is the polynomial chaos approximation as a NumericalMathFunction. Then, $\hat{g} = \sum_{k \in K} \alpha_k \Psi_k \circ T$.

When the model is very expensive to evaluate, it is necessary to optimize the number of coefficients of the polynomial chaos expansion to be calculated. Some specific strategies have been proposed by [6] for enumerating the infinite polynomial chaos series: OpenTURNS implements the hyperbolic enumeration strategy which is inspired by the so-called sparsity-of-effects principle. This strategy states that most models are principally governed by main effects and low-order interactions. This enumeration strategy selects the multi-indices related to main effects.

The following lines illustrate the case where the model $\mathcal{G} : \mathbf{x} \mapsto x \sin x$ and where the input random vector follows a uniform distribution on $[-1, 1]$:

```
# Define the model
>>> model = NumericalMathFunction(['x'], ['x*sin(y)'])
# Create the input distribution
>>> distribution = Uniform()
# Construction of the orthonormal basis
>>> polyColl = [0.]
>>> polyColl[0] = StandardDistributionPolynomialFactory
                                (distribution)
>>> enumerateFunction = LinearEnumerateFunction(1)
>>> productBasis = OrthogonalProductPolynomialFactory
                                (polyColl, enumerateFunction)
# Truncature strategy of the multivariate orthonormal basis
# Choose all the polynomials of degree <= 4
>>> degree = 4
>>> indexMax = enumerateFunction.getStrataCumulatedCardinal(degree)
# Keep all the polynomials of degree <= 4
# which corresponds to the 5 first ones
>>> adaptiveStrategy = FixedStrategy(productBasis, indexMax)
# Evaluation strategy of the approximation coefficients
>>> samplingSize = 50
>>> experiment = MonteCarloExperiment(samplingSize)
```

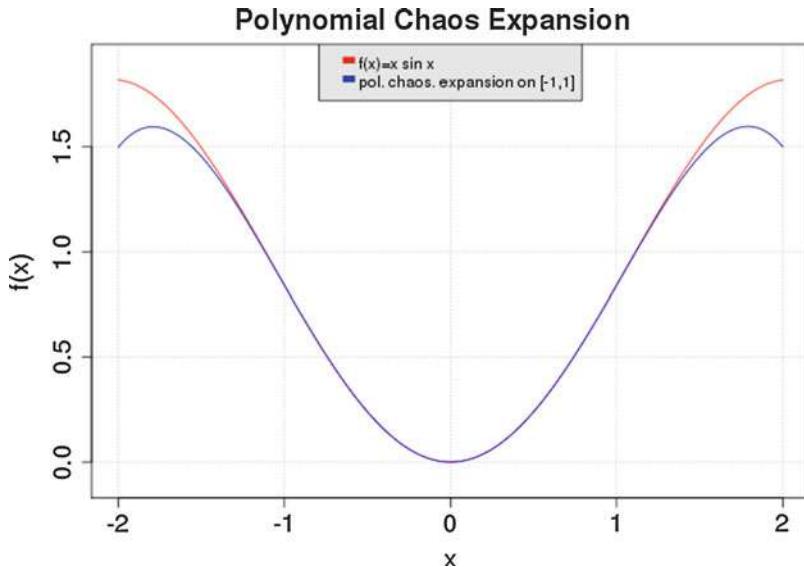

Fig. 58.18 An example of a polynomial chaos expansion: the *blue line* is the reference function $\mathcal{G} : x \mapsto x \sin x$ and the *red one* its approximation only valid on $[-1, 1]$

```
>>> projectionStrategy = LeastSquaresStrategy(experiment)
# Creation of the Functional Chaos Algorithm
>>> algo = FunctionalChaosAlgorithm(model, distribution,
                                     adaptiveStrategy, ..., projectionStrategy)
>>> algo.run()
# Get the result
>>> functionalChaosResult = algo.getResult()
>>> metamodel = functionalChaosResult.getMetaModel()
```

Figure 58.18 illustrates the result.

5.2 The Kriging Approximation

Kriging (also known as Gaussian process regression) [24, 30, 33, 37] is a Bayesian technique that aims at approximating functions (most often in order to surrogate them because they are expensive to evaluate). In the following, it is assumed that the aim is to surrogate a scalar-valued model $G : x \mapsto y$. Note the OpenTURNS implementation of Kriging can deal with vector-valued functions ($G : x \mapsto y$), with simple loops over each output. It is also assumed that the model was run over a design of experiments in order to produce a set of observations gathered in the following dataset: $((x^i, y^i), i = 1, \dots, n)$. Ultimately Kriging aims at producing a predictor (also known as a response surface or metamodel) denoted as \tilde{G} .

It is assumed that the model G is a realization of the normal process $Y : \Omega \times \mathbb{R}^d \rightarrow \mathbb{R}$ defined by:

$$Y(\omega, \mathbf{x}) = m(\mathbf{x}) + Z(\omega, \mathbf{x}) \quad (58.12)$$

where $m(\mathbf{x})$ is the trend and $Z(\mathbf{x})$ is a zero-mean Gaussian process with a covariance function $c_\theta : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}$ which depends on the vector of parameters $\boldsymbol{\theta} \in \mathbb{R}^{n_\theta}$:

$$\mathbb{E}[Z(\mathbf{x}), Z(\mathbf{y})] = c_\theta(\mathbf{x}, \mathbf{y}) \quad (58.13)$$

The trend is generally taken equal to the generalized linear model:

$$m(\mathbf{x}) = (\mathbf{f}(\mathbf{x}))^t \boldsymbol{\beta} \quad (58.14)$$

where $(\mathbf{f}(\mathbf{x}))^t = (f_1, \dots, f_p)$ and $\boldsymbol{\beta} = (\beta_1, \dots, \beta_p)$. Then, the Kriging method approximates the model f by the mean of the Y given that:

$$Y(\omega, \mathbf{x}^{(i)}) = y^{(i)} \quad \forall i = 1, \dots, n \quad (58.15)$$

The Kriging metamodel \tilde{G} of G writes:

$$\tilde{G}(\mathbf{x}) = \mathbb{E}[Y(\omega, \mathbf{x}) | Y(\omega, \mathbf{x}^{(i)}) = y^{(i)}, \forall i = 1, \dots, n] \quad (58.16)$$

The metamodel is then defined by:

$$\tilde{G}(\mathbf{x}) = (\mathbf{f}(\mathbf{x}))^t \tilde{\boldsymbol{\beta}} + (\mathbf{c}_\theta(\mathbf{x}))^t C_\theta^{-1} (\mathbf{y} - F \tilde{\boldsymbol{\beta}}) \quad (58.17)$$

where $\tilde{\boldsymbol{\beta}}$ is the least squares estimator for $\boldsymbol{\beta}$ defined by:

$$\tilde{\boldsymbol{\beta}} = (F^t C_\theta^{-1} F)^{-1} F^t C_\theta^{-1} \mathbf{y} \quad (58.18)$$

and $C_\theta = [c_\theta(x_i, x_j)]_{i,j=1\dots n}$, $F = [f(x_i)^t]_{i=1\dots n}$ and $\mathbf{c}_\theta^t(\mathbf{x}) = [c_\theta(x, x_i)]_{i=1\dots n}$. The line command writes:

```
>>> algo = KrigingAlgorithm(inputSample, outputSample, basis,
                           covarianceModel)
>>> algo.run()
>>> result = algo.getResult()
>>> metamodel = result.getMetaModel()
>>> graph = metamodel.draw()
```

Figure 58.19 approximates the previously defined model $\mathcal{G} : \mathbf{x} \mapsto x \sin x$ with a realization of a Gaussian process based on six observations.

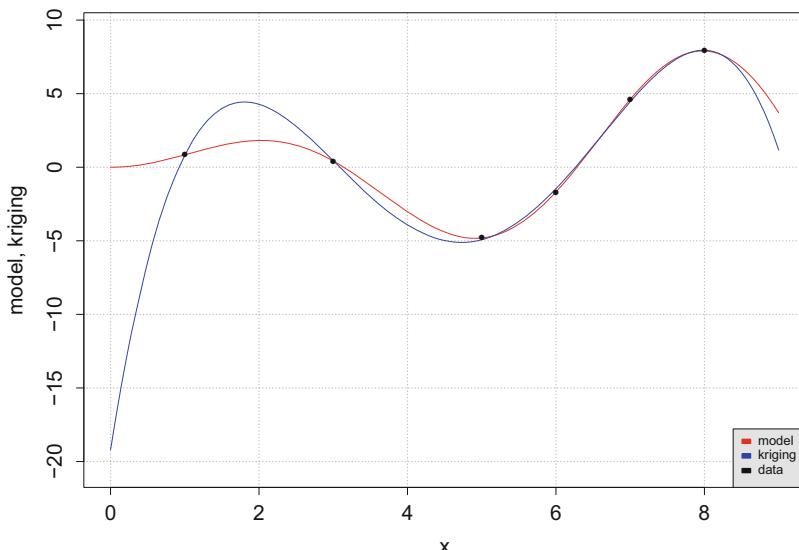

Fig. 58.19 An example of Kriging approximation based on six observations: the *blue line* is the reference function $G : x \mapsto x \sin x$ and the *red one* its approximation by a realization of a Gaussian process

6 The External Simulator

6.1 Fast Evaluations of G

On the practical side, the OpenTURNS software provides features which make the connection to the simulator G easy and make its evaluation generally fast. Within the OpenTURNS framework, the method to connect to G is called “wrapping.”

In the simplest situations, the function G is analytical and the formulas can be provided to OpenTURNS with a character string. Here, the Muparser C++ library [4] is used to evaluate the value of the mathematical function. In this case, the evaluation of G by OpenTURNS is quite fast.

In the following Python script, consider the function $G : \mathbb{R}^3 \rightarrow \mathbb{R}^2$, where $G_1(\mathbf{x}) = x_1 + x_2 + x_3$ and $G_2(\mathbf{x}) = x_1 - x_2 x_3$, for any real numbers x_1 , x_2 , and x_3 . The input argument of the NumericalMathFunction class is a Python tuple, where the first item describes the three input variables, the second item describes the two output variables, and the last item describes the two functions G_1 and G_2 .

```
>>>G = NumericalMathFunction(
    ("x0", "x1", "x2"),
    ("y0", "y1"),
    ("x0+x1+x2", "x0-x1*x2"))
```

Once created, the function G can be used as a regular Python function or can be passed as an input argument of other OpenTURNS classes.

In most cases, the function G is provided as a Python function, which can be connected to OpenTURNS with the `PythonFunction` class. This task is easy (for those who are familiar with this language) and allows the scientific packages already available in Python to be combined. For example, if the computational code uses XML files on input or output, it is easy to make use of the XML features of Python (e.g., the `minidom` package). Moreover, if the function evaluation can be vectorized (e.g., with the `numpy` package), then the `func_sample` option of the `PythonFunction` class can improve the performance a lot.

The following Python script creates the function G associated with the flooding model. The `flood` function is first defined with the `def` Python statement. This function takes the variable X as input argument, which is an array with four components, Q , K_s , Z_v , and Z_m , which correspond to the input random variables in the model. The body of the `flood` function is a regular Python script, so that all Python functions can be used at this point (e.g., the `numpy` or `scipy` functions). The last statement of the function returns the overflow S . Then the `PythonFunction` class is used in order to convert this Python function into an object that OpenTURNS can use. This class takes as input arguments the number of input variables (in this case, 4), the number of outputs (in this case, 1), and the function and returns the object G .

```
>>>from openturns import PythonFunction
>>>def flood(X) :
    L = 5.0e3;          B = 300.0
    Q, K_s, Z_v, Z_m = X
    alpha = (Z_m - Z_v)/L
    H = (Q/(K_s*B*sqrt(alpha)))**0.6
    return H
>>>G = PythonFunction(4, 1, flood)
```

If, as many of the computational codes commonly used, the data exchange is based on text files, OpenTURNS provides a component (`coupling_tools`) which is able to read and write structured text files based, for example, on line indices and perhaps containing tables (using line and column indices). Moreover, OpenTURNS provides a component which can evaluate such a Python function using the multi-thread capabilities that most computers have.

Finally, when the computational code G is provided as a C or Fortran library, OpenTURNS provides a generic component to exchange data by memory, which is much faster than with files. In this case, the evaluation of G is automatically multi-thread. This component can be configured by Python, based on a XML file. If this method is not flexible enough, then the connection can be done with the C++ library.

The previous techniques are documented in the OpenTURNS developer's guide [1].

Figure 58.20 compares the performance of three methods to connect to the function G : the `PythonFunction` class, the `PythonFunction` class with

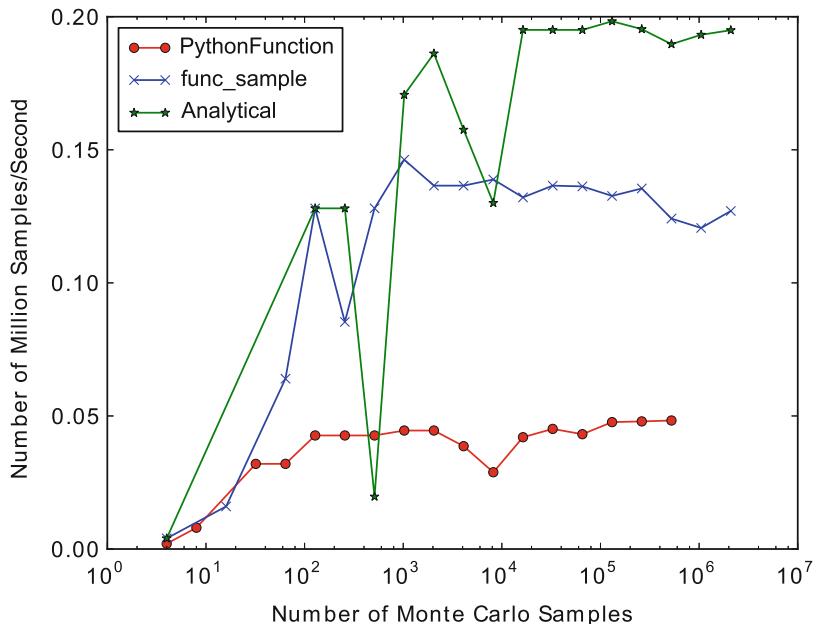

Fig. 58.20 Performance of various connection methods in OpenTURNS

the `func_sample` option, and the analytical function. This test was performed with a basic MS Windows laptop computer. Obviously, the fastest method is the analytical function, which can provide as many as 0.2 million samples per second, a performance which is four times the performance of the `PythonFunction` class.

6.2 Evaluation of the Derivatives

When the algorithm involves an optimization step (e.g., in the FORM-SORM method) or a local approximation of G (e.g., in the Taylor development used to approximate the expectation and variance), the derivatives of G are required.

When the computer code can compute the gradient and Hessian matrix of G , this information can be used by OpenTURNS. This happens sometimes, for example, when the computer code has been differentiated with automatic differentiation methods, such as forward or adjoint techniques.

In the case where the function is analytical and is provided as a character string, OpenTURNS is able to compute the exact derivatives of G . In order to do this, the software uses the Ev3 C++ library [22] to perform the symbolic computation of the derivatives and MuParser [4] to evaluate it.

In most common situations, however, the code does not compute its derivatives. In this case, OpenTURNS provides a method to compute the derivatives based on

finite difference formulas. By default, a centered finite difference formula for the gradient and a centered formula for the Hessian matrix are used.

6.3 High-Performance Computing

For most common engineering practices, OpenTURNS can evaluate G with the multi-thread capabilities of most laptop and scientific workstations. However, when the evaluation of G is more CPU consuming or when the number of evaluations required is larger, these features are not sufficient by themselves, and it is necessary to use a high-performance computer such as the Zumbrota, Athos, or Ivanhoe supercomputers available at EDF R&D which have from 16,000 to 65,000 cores [40].

In this case, two solutions are commonly used. The first one is to use a feature which can execute a Python function on remote processors, connected on the network with ssh. Here, the data flow is based on files, located in automatically generated directories, which prevents the loss of intermediate data. This feature (`DistributedPythonFunction`) allows each remote processor to use its multi-thread capabilities, providing two different levels of parallel computing.

The second solution is to use the OpenTURNS component integrated in the Salome platform. This component, along with a graphical user interface, called “Eficas,” makes use of a software, called “YACS,” which can call a Python script. The YACS module allows calculation schemes in Salome to be built, edited, and executed. It provides both a graphical user interface to chain the computations by linking the inputs and outputs of computer codes and then to execute these computations on remote machines.

Several studies have been conducted at EDF based on the OpenTURNS component of Salome. For example, an uncertainty propagation study (the thermal evaluation of the storage of high-level nuclear waste) was making use of a computer code where one single run required approximately 10 min on the 8 cores of a workstation (with shared memory). Within Salome, the OpenTURNS simulation involving 6000 unitary evaluations of the function G required 8000 CPU hours on 32 nodes [3].

7 Conclusions

This educational example has shown a number of questions and problems that can be addressed by UQ methods, uncertainty quantification, central tendency evaluation, excess probability assessment, and sensitivity analysis, that can require the use of a metamodel.

Different numerical methods have been used for solving these three classes of problems, leading substantially to the same (or very similar) results. In the industrial practice of UQ, the main issue (which actually motivates the choice of one mathematical method instead of another) is the computational budget, which is actually given by the number of allowed runs of the deterministic model G .

When the computer code implementing G is computationally expensive, one needs specifically designed mathematical and software tools.

OpenTURNS is specially intended to meet these issues: (i) it includes a set of efficient mathematical methods for UQ and (ii) it can be easily connected to any external black box model G . Thanks to these two main features, OpenTURNS is a software that can address many different physics problems and thus help to solve industrial problems. From this perspective, the partnership around OpenTURNS focuses efforts on the integration of the most efficient and innovative methods required by the industrial applications that takes into account both the need of genericity and of ease to communicate. The main projects for 2015 concern the improvement of the Kriging implementation to integrate some very smart methods of optimization. Around this theme, some other classical optimization methods will also be generalized or newly implemented.

A growing need for model exploration and analysis of uncertainty problem in industrial applications is to better visualize the information provided by such a volume of data. In this area, specific visualization software, such as ParaView, can provide very efficient and interactive features. Taking the advantage of the integration of OpenTURNS in the Salome platform, EDF is working on a better link between the ParaView module in Salome (called ParaVIS) and the uncertainty analysis with OpenTURNS: in 2012, functional boxplot [13] has been implemented. Some recent work around in situ visualization for uncertainty analysis should also be developed and implemented and so benefit very computationally expensive model physics that generate an extremely high volume of data.

Part of this work has been backed by French National Research Agency (ANR) through the Chorus project (no. ANR-13-MONU-0005-08). We are grateful to the OpenTURNS Consortium members. We also thank Regis Lebrun, Mathieu Couplet, and Merlin Keller for their help.
